One main advantage of a sunspace is that it provides occupants with extra living space. However, it also has some shortcomings. Firstly, a sunspace might lead to extreme overheating in summertime, especially in a hot climate of Vietnam. The glazed parts need to be openable and be protected by shading devices. In that case, a sunspace works as a terraced area or a veranda. Moreover, sunspace is usually considered less efficient as it saves less energy in comparison with its cost. In refurbishment of a tube house, an additional sunspace is not always available if the house uses all the space of its plot.

Thermal mass
In climates that are constantly hot or cold, the thermal mass effect can actually be detrimental. All surfaces of the mass will tend towards the average daily temperature; if this temperature is above or below the comfortable range, it will result in even more occupant discomfort due to unwanted radiant gains or losses. Therefore, in warm tropical and equatorial climates buildings tend to be very open and lightweight.

Heat Protection

Thermal Insulation
In the Vietnam summer time, it is essential to protect the building from heat gains. High sun angles make the roof to be the most important element to be protected from radiative heat gains. Insulation on the roof is usually done with a layer of low emissivity material and a ventilated cavity. A bright colour paint can help the walls to reduce heat gains from radiation. However, because of the high humidity, natural ventilation is encouraged and windows are usually open. The small difference in temperature between the outdoor and indoor space makes the resistance to heat conduction less significant.

Air-tightness
The winter of Vietnam is not so harsh compared to countries in a temperate climate. However, existing housing is facing problems of air leakage or infiltration. Together with a poor insulated opaque envelope, it makes the heating demand becomes much higher.

Active design strategy

Renewable energy sources
Utilising renewable energy sources is an important step in both the Trias Energetica and C2C-inspired approach. Such power sources come from the sun (photovoltaic, solar collector), the wind (wind turbine), the earth (geothermal energy) or biomass.

Photovoltaic (PV) energy
Vietnam has a constant solar energy source. In the North, solar radiation intensity ranges from 2.4 to 5.6 kWh/m2/day while in the Central and the South, energy from solar irradiance varies is distributed uniformly from 4 to 5.9 kWh/m2/day (N. T. Nguyen & Ha-Duong, 2009). However, efficiency of PV systems in the tropical climates is not necessarily better than that in the temperate climate. This is mainly due to the fact that PV cells efficiency largely depends on the cell surface temperature. The higher the temperature, the lower the efficiency (Bahaidarah et al, 2013). The main solution to this problem is to cool the cells by using water or air on top or under the cells surface.

Solar thermal systems
Solar thermal systems are quite popular in Vietnam because of its easy installation, low cost and availability of solar radiation. Installation of solar collectors and water tanks is easy. However, in refurbishment projects, it is often required to also replace the plumbing system because traditional ones were not designed for hot water and such replacement is usually more complex. It could be a good solution when the owner wants to replace the service system in the house after a long time use.

Biomass
Biomass systems often require a specific area to burn the fuel to generate heat. Therefore, this energy source is more popular in rural areas than in high density urban area of Vietnam.

Active cooling/heating

Air source heat pump
Contemporary Vietnamese houses often do not employ enough natural ventilation due to the limited design parameters. Furthermore, the outdoor temperature is not always healthy. Therefore, air-conditioning systems are widely used in Vietnam to introduce fresh air with an appropriate temperature, ensuring indoor air quality. However, they often consume too much energy and thus increase the environmental impact of the buildings.

Ground source heat pump (GSHP)
In climates with high average air temperature levels and little temperature fluctuations, the application of geothermal energy is very limited (Eicker, 2014). Furthermore, geothermal heat pumps are usually incorporated into new buildings projects and are not suitable for refurbishment project because their installation involves digging into the ground and the cost is usually quite high. Therefore, GSHP is not applicable in housing refurbishment in Vietnam.

Efficient use of non-renewable sources

Heating and cooling
In Vietnam, where both heating and cooling are required, air-conditioner often carries both duties in one single system. Efficiency of the air-conditioning system can be improved by increasing insulation for the pipes system. It is also important to keep indoor air temperature cool as long as possible. Therefore, reducing heat transfer through building envelope also help reduce energy consumption of the air-conditioner (Konstantinou, 2014). The Vietnamese National Building Code of Energy Efficiency Buildings set out certain requirements for air-conditioning system (MOC, 2013).

Lighting and appliances
In Vietnam, electrical appliances and lighting accounted for 11% and 8% energy use in residential building respectively (MOC, 2013). Improving energy efficiency of such equipment during refurbishment can contribute to the total energy saving of the houses. To reduce the energy consumption of this part, low energy efficient products should be replaced. Furthermore, the government also issues a regulation framework for the energy labelling program and directives for implementation (DECISION, 2011). Energy efficiency of appliances can also be improved by using smart control system with human sensors and automatic programming function.

CONCLUSION

In Vietnam, popular passive design strategies include solar control, natural ventilation and evaporative cooling. However, tube houses constraints limit the effectiveness of passive design measures. For example, orientation is generally not changeable. Small land plots and high demands of living spaces do not allow many options for massing and courtyard although a courtyard is a very important feature of a traditional tube house. Thermal insulation layers are mostly found on the roof. Air-tightness can efficiently prevent the houses from losing heat in winter. Passive solar gain might work for the cold winter of Vietnam directly or indirectly (sun space). Geothermal cooling and thermal mass are not recommended for renovating houses in Vietnam.

Active design strategies are generally not popular in Vietnam yet. Although the country has a high annual solar radiation, solar energy is mostly captured by solar collectors that provide hot domestic water. This system is easy to install and has high efficiency. Solar photovoltaics have not been applied widely because they are often – wrongly, considering the recent price of PV - considered not cost effective compared to the traditional fossil sources and they are mostly used for off-grid areas. Biomass is another clean energy source that can be used for homes. But it is not suitable for urban housing since it takes up spaces for burning and might harm air quality and human health. Using highly efficient equipment and lighting appliances can potentially reduce energy consumption in housing. To promote using energy-efficient equipment, it requires the commitment of the government, manufacturer and potential users.

The Influence of Courtyards' Microclimate Condition on The Users' Spatial Behaviour: A Case Study in A University Campus in Hot Dry Regions

Bushra Obeidat[1], Mohammed Alshayeb[1], and Afnan Barri[1]

[1] Department of Architecture, School of Architecture, design and Planning, The University of Kansas, Lawrence, Kansas, USA.

Abstract: Courtyards are essential architectural elements that form places for gatherings and are designed based on climatic considerations. This study aims to investigate the impacts of three simulated thermal variables on students' spatial distribution in university courtyard sittings. Spatial distribution, in our case, is understood as the location of different users in the courtyard space in consideration to their static activities; sitting and standing. Field observations and three computer simulation studies were used to investigate these effects in two similar courtyards. Simulation studies include (1) a microclimate air temperature analysis, (2) an intensity of direct solar radiation analysis, and (3) a shadow analysis of the number of sunlight hours received in the courtyard. Statistical correlation analysis demonstrates that climatic and thermal variables can impact the spatial distribution of students within the courtyards. This research provides a basis for research-based design of outdoor shared spaces; Its methodology extends the use of simulations software beyond research about microclimate data, connecting it to the study of human behaviour. Architects and designer can benefit from this research to define design variants that influences environmental and behavioural performances of courtyards in hot dry regions.

Keywords: Courtyard design, Students' distribution, Simulation, Microclimate, Grasshopper

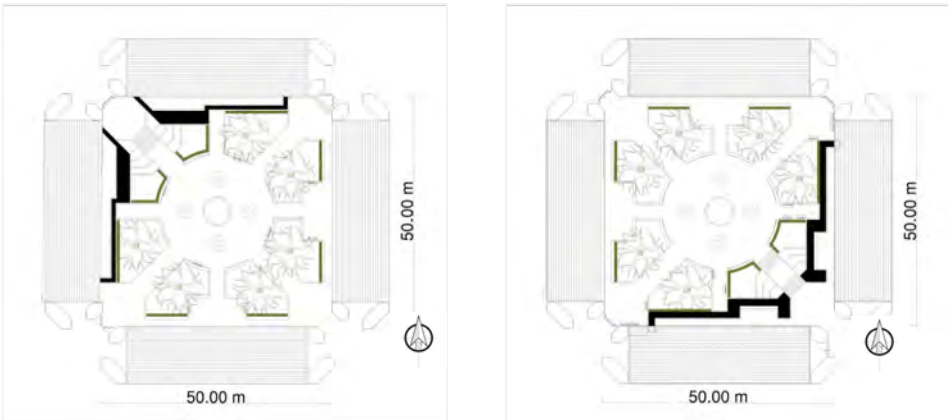
Background Information

Previous environmental-behaviour studies reported the impact of spaces' physical and spatial features on students' behaviours in campus outdoor spaces, such as location, accessibility, seating spaces, and visual qualities (Abu-Ghazzeh, 1999, Aydin and Ter, 2008). Additionally, natural elements, such as trees and plants were discussed as factors that can influence behavioural patterns in outdoor settings (Salama, 2008, Ünlü et al., 2009). However, in designing outdoor environments, literature indicated the significance of understanding the microclimate conditions of a certain environment in determining the design of outdoor spaces (Almhafdy et al., 2013, Nikolopoulou et al., 2001). Therefore, the focus of this study is to investigate the effect of microclimates on students' spatial behaviour and distribution. Two methods of data collection were used for this investigation: behavioural mapping and thermal simulation.

Behavioural mapping is a technique that was developed by Ittelson (1970) to identify patterns and frequencies of human behaviour in a space and map these data on that space layout. The methodology involves dividing the map of the environment into zones and then recording patterns of behaviour across each zone. Whyte (1980) and Marcus and Francis (1998)applied this method to investigate the impact of physical characteristics of places in relation to the users' sitting behaviour. Similarly, Gehl (2011) used behaviour mapping to address the impact of spatial definition elements, such as walls to attract people into a space.

Thermal simulations are a set of computer programs developed to simulate the thermal performance of places depending on their climatic information. Based on these simulation, many variables can be derived and can be used as a predictive tool for optimizing space layout and its proper dimensions to improve thermal comfort of occupants. Rhinoceros with its graphical algorithm editor Grasshopper was used to conduct dynamic simulations and evaluate individual metrics of environmental information, such as solar intensity, air-temperature, wind speed, and other climatic data.

This study was carried out using these two techniques, behavioural mapping and thermal simulation, to investigate students' patterns of behaviour in two identical courtyards at the Jordan University of Science and Technology. The courtyards (A) and (B) have a rectangular open form with an area of 2500 m2. As Figure (1) illustrates, the courtyard space consists of grass surfaces, trees, seating spaces, and a centralized fountain. The university buildings surround the courtyards from their four sides. The two courtyards (A) and (B) differ in their orientation, where the elements of the courtyard (A) are at opposite locations of the other courtyard (B).



A. Courtyard B. Courtyard

Figure 1: Courtyards Under Investigation

Methodology

The research methodology includes simulations of climatic qualities of the courtyards, onsite observation study, and statistical analysis. During the on-site observation, the researcher collected both students' situations and basic climatic information, which was then used to develop the baseline model for the computer simulation work. The dependent variables of the model are the number of students who are occupying the spaces and their static spatial behaviours. The independent variables are microclimate temperatures measured in Celsius degrees, solar radiation measured in kWh/m2, and sunlight hours measured in hours. The steps of the research are described in Figure (2) below.

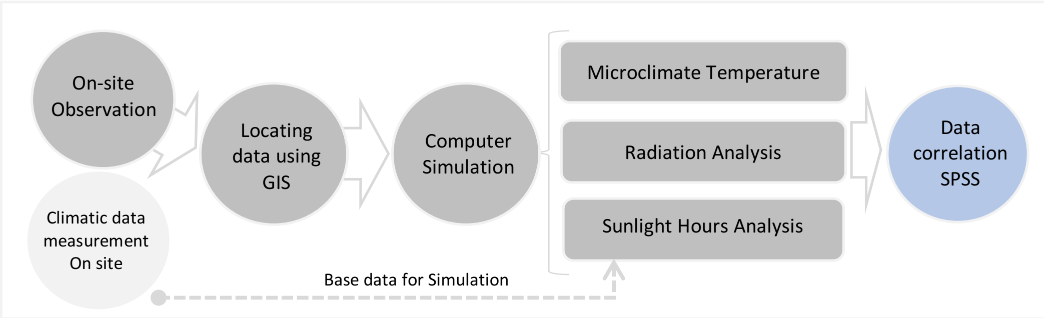


Figure 2: Research Process

On-site Observation

In Jordan, June is recognized as a month with high air temperature values and solar intensity. Hence, the site observations were conducted during five days in summer solstice of June 20th to June 25th. 2015. During each day, observations were carried out from 8:00am to 2:00pm within a regular interval of 30 minutes. Students' locations and their sitting and standing situations were recorded on the plan of each courtyard (Figure.3). The collected data was compiled using GIS for further analysis. Overall, 12 rounds of observations were completed in each courtyard, and 3867 of students' conditions and locations were identified during the observation period. Among them, 1489 students were male students, and 2378 were female students. The courtyards were divided into four parts in order to record patterns of behaviour across each zone in detail.

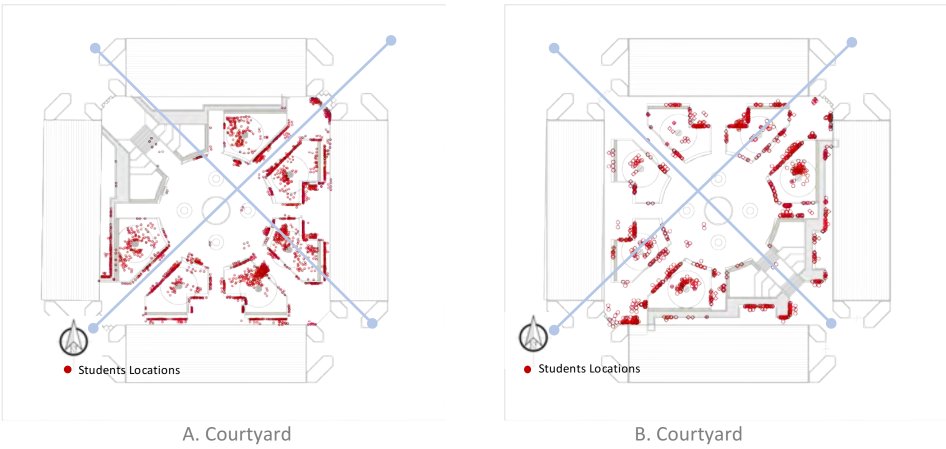

Figure 3: Recording Students' Behaviour and Position during Observations

Computer Simulation

Site observation was the first process of developing the baseline model for the computational experiment. In order to investigate students' situations based on the thermal conditions of the case study courtyards, a model was built using Grasshopper software. Grasshopper in Rhinoceros is a complete environmental analysis tool that covers the broad range of simulation and analysis functions (Rutten, 2012). In this research three types of simulations were conducted: microclimatic map analysis, radiation analysis, and sunlight hours' analysis as shown in Figure (4) below.

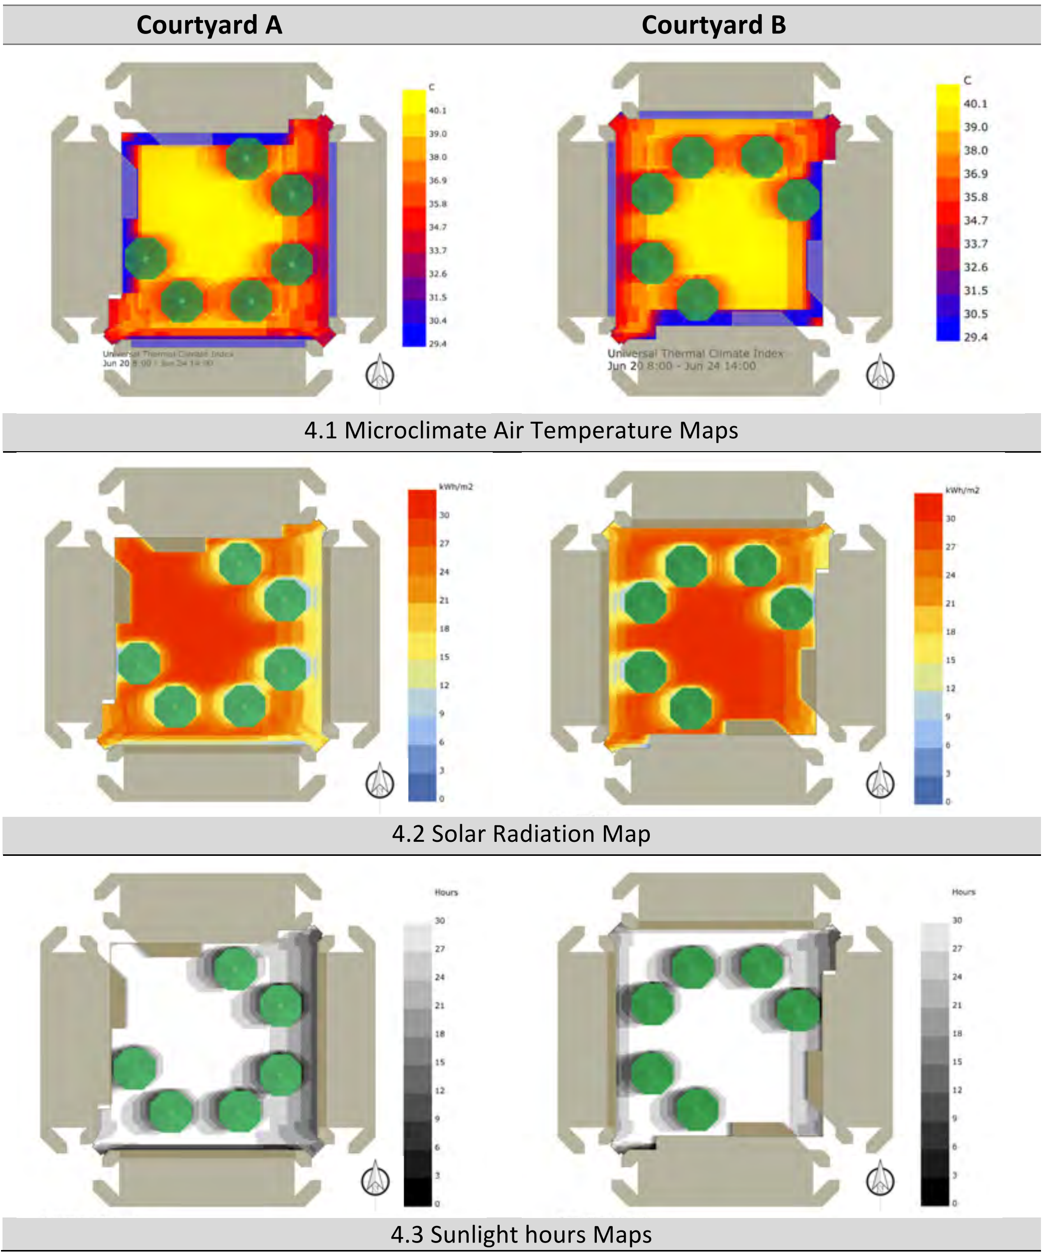

Figure 4: Three Thermal Studies using Grasshopper in Rhinoceros

Statistical Analysis

Using IBM SPSS 22 (SPSS, 2013), correlation analyses were performed to describe relationships between different climatic and thermal variables and students' numbers and their static behaviours. Statistical study tested the following two hypotheses with *gender* as a moderating variable:

- Hypothesis-1: Different thermal variables of campus courtyards would show different but consistent relationships with students' aggregate numbers.
- Hypothesis-2: Different thermal variables of campus courtyards would show different but consistent relationships with students' static activity positions (sittings, and standings).

The Aggregate Number of Students

The correlation coefficients in Table (1) illustrate a strong negative correlation between the number of students existing in the courtyard and the thermal variables; average air temperature, solar radiation, and sunlight hours recorded in the courtyards (Pearson r = -0.787, -0.726, and -0.739 respectively). Any increase in air temperature, solar radiation, and the number of sunlight hours in the courtyards will decrease the number of students' occupying the courtyards. The analysis showed strong negative correlations between the total number of male students in the courtyard and average air temperature and sunlight hours (Pearson r = - 0.814, and -0.712 respectively). The correlation coefficients show strong negative correlations between the courtyard average air temperature, solar radiation, and average sunlight hours and the number of female students who use the courtyards. The statistical analysis noticeably showed an increase in courtyards' temperature would negatively impact the number of female students using the courtyard.

Supporting Hypothesis-1, different courtyards' microclimate and thermal features show different relationships with the number of male and female students who are using the courtyards. Microclimate air temperature variable show stronger effects on students' numbers comparing with other two variables; solar radiation and sunlight hours.

Table 1: Correlation between the numbers of students and thermal variables

	Microclimate Temperature	Solar Radiation	Sunlight Hours
Students' Total	-0.787*	-0.726*	-0.739*
Male Students	-0.814*	-0.674	-0.712*
Female Students	-0.739*	-0.720*	-0.721*

*. Correlation is significant at the 0.05 level (2-tailed).
**. Correlation is significant at the 0.01 level (2-tailed).

Static Activities (sittings, and standings)

The correlation coefficients in Table (2) show a strong negative correlation between the average microclimate temperature, sunlight hours recorded in the courtyard, and the total number of students' who are in sitting positions in the courtyards (Pearson r = -0.768 and -0.721). The number of female students who are In sitting positions in the courtyards is more influenced more by courtyards' microclimate and thermal status than the number of male students. Similarly, the number of female students who are in standing positions in the courtyards is more correlated with the thermal variables than the number of male students who are in standing positions. These results indicated that thermal variables show stronger effects on female students' than male students' static behaviours.

Partially supporting Hypothesis-2, different courtyards' microclimate and thermal features show different relationships with the number of male and female students who are in sitting and standing positions in the courtyards, with microclimate temperature values having the strongest relationships.

Table 2: Correlations between the numbers of students in static positions and thermal variables

		Microclimate Temperature	Solar Radiation	Sunlight Hours
Sitting	_ Students total	-0.769*	-0.700	-0.721*
	_ Male	-0.725*	-0.577	-0.637
	_ Female	-0.743*	-.717*	-0.718*
Standing	_ Students total	-0.277	-0.139	-0.264
	_ Male	0.010	0.155	0.037
	_ Female	-0.697	-0.736*	-0.734*

*. Correlation is significant at the 0.05 level (2-tailed).
**. Correlation is significant at the 0.01 level (2-tailed).

Mapping students' locations on microclimate air temperature maps

Statistical correlation analysis showed that the number of students occupying the courtyards are influenced by the average microclimate air temperature recorded in the courtyards. Mapping students' locations on microclimate air temperature map show that students mostly sit and stand in spaces with lower temperature. These spaces as shown in Figure (5) are either spaces close to the surrounding buildings of the courtyards or spaces close to grass surfaces and trees. The surrounding buildings provided shaded spaces that have lower temperature and cooling the ground surfaces. Similarly, the presence of grass surfaces contributes to the reduction of microclimate temperature of the courtyards. Therefore, more number of students are attracted and use these green spaces.

Figure 5: Mapping Students' locations on microclimate air temperature maps.

Discussion and Conclusions

Studies have identified some critical design elements that affect the way that people use public spaces. There are several physical, climatic, and cultural factors impacting the usage of the outdoor spaces. The design of outdoor social spaces literature identifies the importance of understanding the space microclimate performance and designing around it. This research is a first step toward answering that call. This research used field observation and computer simulations to investigate the relationship between the space usage and its microclimate. Statistical analysis results verified that the courtyard microclimate performance impacts the number and distribution of students who occupied the courtyard spaces. The study indicated that air temperature values are more correlated with the number of students than other values; and that male and female students are affected differently by different climatic and thermal features. Female sitting and standing positions in the courtyard were influenced by thermal climatic and thermal features more than male students. In order to design courtyard's spaces in hot arid regions like Jordan, it is important to provide more shaded and green spaces. These two strategies will lower the microclimate air temperature in outdoor spaces.

The study concludes that despite the differences in the courtyards orientations, there is no significant difference in students' behaviours in response to courtyards' climatic features. Generating Air temperature, radiation, and sunlight hours' maps using Grasshopper can help campus designers to understand the environmental performance of their outdoor spaces designs and make design decisions regarding users' distribution at early stages of the design process. The findings of this research contribute to the design of campuses outdoor spaces in hot dry regions.

Architectural Passive Solar Design for Three Buildings in Kenya: Observations Made in Lowering Energy Use in Non-domestic Buildings

David Mwale Ogoli

Judson University, Department of Architecture & Interior Design
1151 North State Street IL 60123 (USA)

Abstract: This paper discusses design, construction & operation of sustainable buildings in the climate of Nairobi, Kenya. Local conditions were given in monthly psychrometrics. Firstly, Nairobi is about 1798 m (5900 feet) in altitude. The local climate has 215 heating degree days base 65° F (18.3° C), and 480 cooling degree days base 65° F (18.3° C), a ratio of approximately 1:2. Secondly, three buildings were compared for green building design. They were constructed with materials indigenous to equatorial highlands of Kenya. Thirdly, the paper provided some drawings to illustrate passive solar design strategies for architectural composition: form, shape, geometry, and building spatial proportions. Comfort in buildings is dependent on the adaptive strategies, behavioural actions and clothing levels of occupants of a building in a given climatic environment. Some adaptive strategies for thermal comfort (changing clothing levels, activity, posture, location within a space, opening a window, complaining and/or leaving a space) have profound architectural implications. The American Society of Heating Refrigerating and Air-conditioning Engineers *ASHRAE Green Guide* was referenced for design techniques. It is this bringing together of physical factors of the environment and adaptive factors (clothing, activity, posture) that allows participants to truly experience comfort in architecture in Kenya.

Keywords: Climate, comfort, thermal mass and energy

Introduction

Kenya has a wide range of climatic conditions that have uniquely differing characteristics. The equator bisects the country at almost its mid-point and there is a predominant need for cooling which puts a major requirement on building characteristics, i. e. materials, form, siting and planning, to assist in achieving this objective of cooling by natural means. Problems of design are generally associated with outdoor air temperature, solar radiation and, air infiltration of warm outside air into the building. A thorough knowledge and understanding of the climate of Kenya has been made before analysing the role of thermal mass.

Passive and Low Energy is a topic that has received theoretical and practical attention during the past several years and there now exists ample research information in temperate climates. Urban areas in Kenya are rapidly growing in population and size with non-domestic buildings coming up in different sizes and shapes. Many of them are conceived are designed with air conditioning as part of the "design brief". The large amounts of energy needed by such buildings has prompted many designers to seriously re-think the passive cooling option. In Kenya, electricity is a very expensive commodity and conserving it is advisable. By passive cooling design attention is drawn to those attempts of using the building's fabric to control external solar gains and provide the much needed time-lag in high daytime temperatures so that they appear much later after office hours or at night. The presumption is that night-time ventilation will provide adequate cooling to the thermal mass.

ASHRAE Design techniques

Sustainability has been a matter of concern locally and globally for both public and private sectors. The American Society of Heating Refrigerating and Air-conditioning Engineers (ASHRAE) has *ASHRAE Green Guide* aimed at improving the impact of buildings on the environment. It defines sustainability as "providing for the needs of the present without detracting from the ability to fulfil the needs of the future" (ASHRAE, 2017:35.1). ASHRAE differentiates sustainable design from green design by stating that although these two are similar green design focuses on the near-term impacts of indoor air quality, operation and maintenance. Sustainable design on the other hand addresses the future long-term global impact caused by buildings. It therefore goes beyond just keeping data on "energy usage, carbon emissions, pollution, waste disposal, or population growth" (ASHRAE, 2017:35.1). It is the full stock of buildings and other elements in the society that will comprehensively develop a good sustainable design. The observance of these three buildings in diverse climatic conditions may provide insight for other similar regions in Africa, and probably elsewhere also.

The *ASHRAE Green Guide* suggests that the building energy use elements for effective impact in sustainable design are (1) envelope, (2) lighting and (3) other loads) ASHRAE 2017:35.10-11). Use of night-cooled thermal mass, insulation, operable windows, control of solar gains, natural daylighting, and overall heating, ventilating and air conditioning (HVAC) systems were considered and adapted in the following experimental house types in Kenya.

Experimental Method

Three similar buildings were simulated in three climatic equatorial zones of Kenya: highland (Eldoret), mid-highland (Nairobi) and lowland (Mombasa). These three regions represent conditions that vary from cool temperate-like areas to hot humid conditions at sea level. This paper gives a brief introduction to the problem, describes the climatic conditions in the different zones and their impact on building design. It provides architectural strategies of prevention and modulation of thermal gains by controlling solar gains and external gains, with a specific look at those climatic zones, with specific reference to the role of thermal mass in achieving passive cooling. Thermal simulations were conducted using Autodesk REVIT.

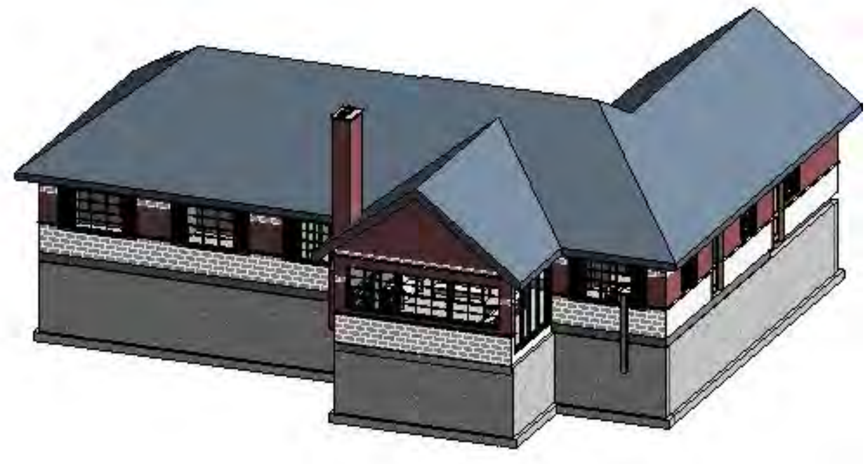

Figure 1. Test building with high thermal mass used in the simulations

The test building measured 20.0 x12.0 metres. See figure 1. Other design considerations:

1. One wall was north facing, insulated externally, and has variable thermal mass. Values ranging from light-weight to heavy-weight that were tested were:- 12mm, 25mm, 50mm, 100mm, 200mm, 300mm and 400mm.
2. Two walls were east-west facing, insulated externally, and have variable thermal mass. Values to be tested were:- 12mm, 25mm, 50mm, 100mm, 200mm, 300mm and 400mm.
3. One wall was an internal partition with variable thermal mass. Its value was kept constant when that of the external walls is being varied, and vice versa it was varied when that of external walls was kept constant. Values to be tested were:- 12mm, 25mm, 50mm, 100mm, 200mm, 300mm and 400mm. Finally from the results, an ordinary acoustic partition was used as described in Fig. 18
4. One wall, corridor, floor and ceiling were assumed to be having no heat gains/losses i.e. the temperature difference between the adjacent spaces and the room being examined will be same.
5. All other factors, such as volume-to-surface ratio, etc., etc., were kept constant.

NOTE: walls measuring 12mm, 25mm and 50mm, had not been simulated initially until after the results of the larger masses. These are taken as being equivalent to less dense materials. Lord Kelvin (1824-1907) said: “When you can measure what you are speaking about, and express it in numbers, you know something about it; but when you cannot express it in numbers, your knowledge is of a meagre and unsatisfactory kind; it may be the beginning of knowledge, but you have scarcely, in your thoughts, advanced to the stage of science, whatever the matter may be”. This paper is a discussion of practical observable occurrences of three similar house design in three equatorial areas in Kenya.

Observations

Climate of Kenya

In Kenya, lowland areas are very hot and tend to have poor rainfall and a dry atmosphere with low humidity. The main exemption is the coastal strip and the area along the shores of Lake Victoria which are hot with high rainfall and high humidity. Snow is found daily on the peak of Mount Kenya all year round and conditions at such altitudes are typical of cool temperate winters (Figure 2).

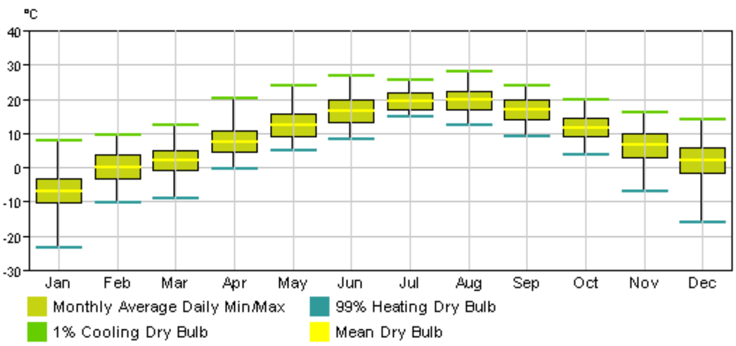

Figure 2. Monthly dry-bulb temperatures

At lower altitudes, high temperatures exists. Temperature falls as altitude rises using the following relationship between altitude (A) above sea level and mean air temperature (T_{Mean}) (Ogoli, 2000:827-828):

$$T_{Mean}) \text{ (°C)} = 28.7 - 0.00590A_{metres} \text{ (SI system)}$$

T_{Mean}) (°F) = 83.7 – 0.00324A_{feet} (IP system)

Annually, Nairobi requires cooling 6% of the year, heating 60% of the year and it is within the comfort zone 34% of the year. An equatorial region has high solar radiation yet, as a recent study shows, air temperature drops with altitude at a rate of approximately 5.9ºC every 1000-metre rise (approximately 3.24ºF every 1000-foot rise). Table 2 shows observed outdoor weather data.

Table 1. Observed outdoor weather data

	Heating Dry-bulb temperature (°C)		Cooling Dry-bulb (DB) temperature and mean coincident wet-bulb (MCWB) temperature (°F)						Heating degree days	Cooling degree days

Topography

A typical section showing the topography of Kenya is summarized in Figure 2. Mombasa is at sea level. The highest point is Mt Kenya at an altitude of 5199m (17058 feet) above sea level. The rift valley is a major feature occurring in the central highlands. The ensuing climatic zones are affected by this topographical layout. Kenya experiences strong seasonal winds that are responsible for the rainy seasons. Most people live at altitudes between 1000 and 2500m (3048 and 8202 feet) above sea level.

Analysis and Discussion

Impact of climate on design

Air temperature

For much of the day and year outdoor air temperatures in the different climatic zones of Kenya are well outside the comfort limits. A major function of non-domestic buildings is therefore to modify and regulate outdoor air temperatures so that the temperatures indoors may be within comfort limits. The structure of the building itself offers an important means of thermal control. Choosing wall and roof materials that have a high thermal capacity and/or high thermal insulation value can give the required modification. Local materials with a high insulation value such as Makuti[1] and expanded polystyrene have a low rate of conductivity while elements made of high capacity materials such as locally available stone are able to store up large amounts of heat without greatly raising the temperatures of their internal surfaces. The peak temperature delay they create, termed time-lag, is essential in the balancing of time. Heavy structures of high thermal capacities have a dampening effect on the daily temperatures and hence balance-off the "time".

Floor temperatures remained consistently within the comfort zone except for a few times when there was an overheated point late in the afternoon hours. The observable point in the graphs is that the higher the thermal mass, the more the moderating effect on indoor maximum temperatures. As expected, temperatures were stratified in the room; cooler at the lower levels and hotter at higher levels. The low mass buildings closely followed outdoor conditions and did not offer much thermal storage. In one case when maximum outdoor temperature was over 33ºC (91ºF), the indoor maximum temperature in high mass building was 25.4ºC (77.7ºF), which is within the comfort zone. The humidity levels appear to be similar throughout the test period. The highest humidity is at dawn when air temperature is least; humidity is least in the early afternoon when air temperature is highest (Figure 4).

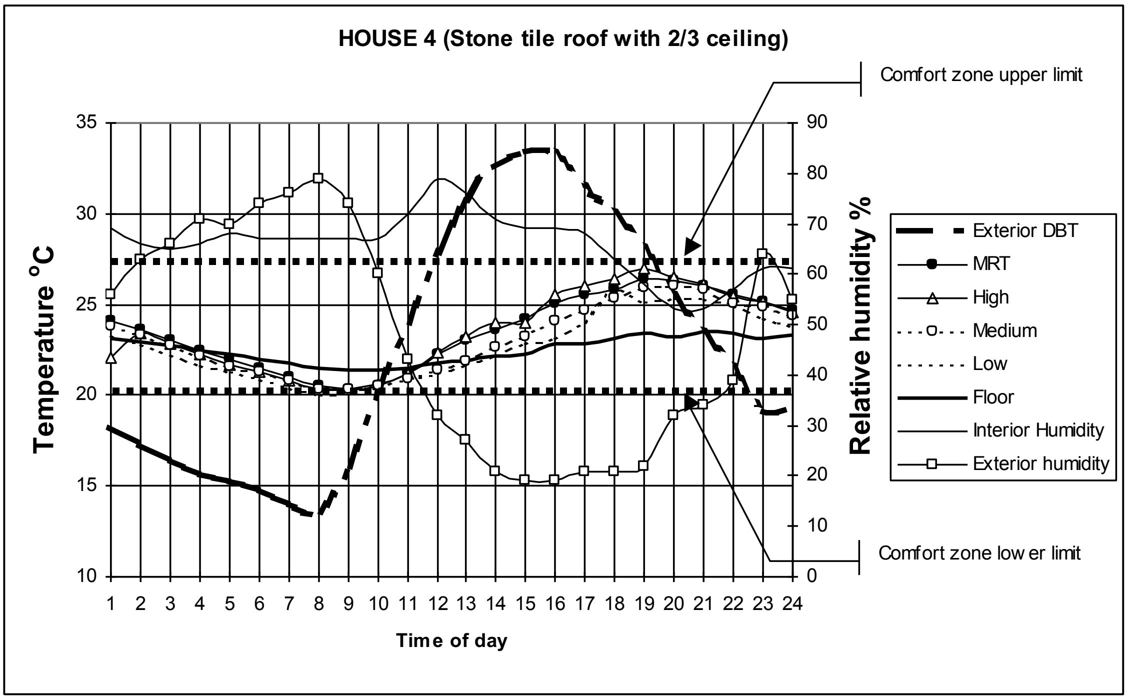

Figure 4. Observations in House 4 with high thermal mass

Sunshine and radiation

Radiation on external surfaces of walls and roofs can raise temperatures well above that of the ambient air; dark coloured surfaces absorb more heat than light coloured surfaces. When dark elements are used in direct contact with solar radiation the heat they absorb is conducted to the inner faces of walls and roofs which then become heat radiators. This raises indoor temperatures. Glazed elements are largely transparent to solar radiation. When heat is re-emitted by internal surfaces where direct sunlight is incident, it is long wave radiation

[1] Makuti is the local Swahili name for coconut palm tree leaves. It is used as a roofing material.

[low temperature]. It cannot escape to the outside since this type of radiation is blocked by glazing as glass is opaque to energy emitted from low temperature sources, and hence a green-house effect. Horizontal roof surfaces receive the greatest quantities of radiation followed by east and west walls. North and south walls receive the least intensities. Greater solar heat gains are experienced on west walls than east walls as there is more cloud cover in the morning than in the afternoon, and on south more than north walls as there is greater cloudiness during the months when the sun is north of equator [April to September] than during the months when the sun is south of the equator. Careful orientation of windows can be freed from direct sunlight.

From the foregoing, building forms that minimise the areas of roofs and east and west walls are advantageous in limiting solar gains. Multi-storey non-domestic buildings, except their top floors, have the considerable advantage of receiving no direct solar heating from above. Similarly, if single-storey buildings are elongated along the east-west axis so that the proportion of east/west walls to north/south walls is reduced, then good solar advantages will be experienced. Roof overhangs are more effective on north/south walls than east/west walls. Roof overhangs once heated are free to lose their heat to the ambient environment.

Table 2. Typical house design considerations in the three regions of Kenya

	Mombasa	**Nairobi**	**Eldoret**
Altitude	Mombasa is at 50m (164 feet) above sea level.	Nairobi is at 1790m (5900 feet) above sea level. Some areas are hilly areas open to strong prevailing winds.	Eldoret is at 2500m (8400 feet) above sea level.
Dry-bulb temperature	Annual mean max.: 29.0 - 30.5^{o}C Annual mean min.: 22.5 - 24.5^{o}C Diurnal range: 5.0 - 8.0^{o}C	Annual mean max.: 23.0 - 26.0^{o}C Annual mean min.: 8.0 - 14.0^{o}C Diurnal range: 10.5 - 17.5^{o}C	Annual mean max.: 18.0 - 25.0^{o}C Annual mean min.: 8.0 - 13.0^{o}C Diurnal range: 10.0 - 14.0^{o}C
Rainfall (mainly from April to June)	Annual mean 750 - 1500mm	Annual mean 700 - 1500mm	Annual mean 950 - 1250mm Max. at approx. 2500m
Humidity (3PM)	65 - 75%	46 - 53%	47 - 56%
Thermal comfort	Discomfort occurs mainly due to high humidity and high temperature. Air movement is necessary to reduce the effect of high humidity.	Climate mostly within thermal comfort ranges. Air change is more important than air movement.	Climate mostly within thermal comfort ranges. Air change is more important than air movement
Floor layout	House forms and plans provide cross-ventilation with the main orientation being along north/south axis.	House forms and plans tend to be compact. Orientation mainly faces north/south. Deep overhangs help to provide shaded and semi-enclosed outdoor space and/or courtyards.	Forms and plans very compact. Orientation is general. Cross-ventilation not required. Deep overhangs help to provide shaded area for livestock. Fireplaces are very common.
Windows & doors	Generally have large shaded openings, facing north and south for natural ventilation and natural daylight. Mechanical systems and artificial light sources are not seen as sustainable.	Windows comprising about 1/3 of north and south walls need to be operable. Mechanical systems and artificial light sources are not seen as sustainable.	Windows comprising about 1/3 of north and south walls need to be operable. Mechanical systems and artificial light sources are not seen as sustainable.
Building Materials	Low thermal mass walls and roofs with night-time cooling are recommendable	High thermal mass walls with night-time cooling not being recommendable	High thermal mass walls with night-time cooling not being recommendable

The energy consumption, monthly heating and cooling energy are shown in Figures 5-7.

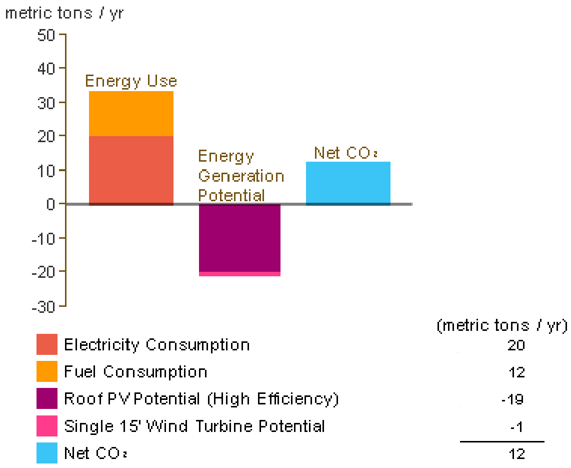

Figure 5. Simulated energy consumption in Nairobi house

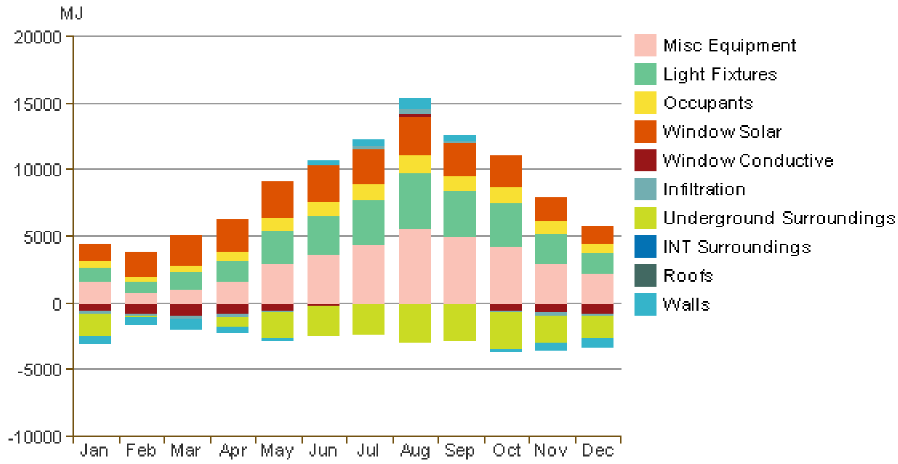

Figure 7. Simulated monthly cooling energy in Nairobi house

Observations from other studies

Balcomb said that dense building materials with the right mix of thermal conductivity and heat capacity, such as brick, concrete and concrete block, store and release considerable amounts of energy when they rise and fall in temperature. … Thermal mass is particularly effective in regions where the outdoor air temperature fluctuates daily above and below the building balance point (the exterior temperature at which a building is in equilibrium with heat gains equalling heat losses) (Balcomb, 1997:105-110).

Ogoli (2002) observed in Nairobi that Thermal mass affects the indoor temperatures in buildings. Na dpoposed a formula to predict indoor maximum temperatures for closed high mass buildings at equatorial high altitudes as follows:

$$T_{max}\text{-in} = T_{max\text{-}out} - 0.488(T_{max\text{-}out} - T_{min\text{-}out}) + 2.44$$

Where $T_{max\text{-}in}$ is the indoor maximum temperature; $T_{max\text{-}out}$ the outdoor maximum temperature; and $T_{min\text{-}out}$ is the outdoor minimum temperature.

Materials with high thermal mass have long time lag and moderating effects to temperature swings. An analysis of the mean radiant temperatures (MRT) measured in low mass buildings was plotted with exterior air temperature with the regression best fit is as follows:

$$MRT = 0.8372(\text{exterior air temperature}) + 5.3648$$

Indoor conditions are predicable.

Conclusions and lessons learnt

Dense building materials with the right mix of thermal conductivity and heat capacity, such as brick, concrete and concrete block, store and release considerable amounts of energy when they rise and fall in temperature. Thermal mass is particularly effective in regions where the outdoor air temperature fluctuates daily above and below the building balance point (the exterior temperature at which a building is in equilibrium with heat gains equalling heat losses).

Abstract: The poultry sector has high thermal requirements for an efficient development of the egg production process, which in a region of warm climate like the Colombian Caribbean, results in a high energy dependence in order to power air conditioning systems. The power outage periods, which are common in the region, interrupt the operation of these systems, resulting in a considerable risk of laying hens mortality, negatively affecting one of the products projected to be part of the national food security plan. This situation highlights the need to find alternatives that reduce energy dependence and increase the efficiency of this process. The purpose of the present investigation is to design an egg production shed under bioclimatic principles, that responds to the thermal requirements of the process, making use of passive strategies that diminish the environmental and economic impacts in this productive sector. Using solar analysis tools and analytical ventilation calculations, a design that responded to the environmental requirements of this productive process was developed. Once the shed was built, its environmental performance was evaluated, using on-site temperature measurements. The application of passive strategies resulted in energy savings of approximately 30% during the building operation, when compare to the traditional design, and in large periods of energy independence, as well.

Keywords: Bioclimatic design, energy efficiency, egg production.

Introduction

Colombia is highly vulnerable to climate change in many aspects, situation that has become more evident in the past 5 years. In the energy sector, for example, hydroelectric plants generate about 70% of the country's energy, which makes it greatly dependent on its water sources for its energy production. A decrease in the water level in its surface water sources and in precipitation, considerably reduces its capacity of generation energy, increasing the risk of using strategies such as rationing or the need to generate energy using fossil fuels, with high environmental and economic impacts, which have already been experienced in the past during lengthy periods of drought, caused by climatic phenomena such as "El Niño"(Blanco 2013).

The Caribbean region, located north-west of the country, is particularly vulnerable to this situation. It presents some of the most arid climatic characteristics of the national territory, in addition to a growing financial crisis of the public services company of the area which has compromise its ability to guarantee a proper, stable energy supply (Superintendencia de Servicios Públicos Domiciliarios 2016a; Superintendencia de Servicios Públicos Domiciliarios 2016b; Superintendencia de Servicios Públicos Domiciliarios 2017).

Numerous industries, whose production plants are located in this region, present a high dependence of electrical energy due to the specific requirements that each of the production process demand. The energy dependence of the poultry sector and egg production, for example, originates from the need to maintain strict hygrothermal conditions, necessary for the birds to maintain their level of productivity and to avoid the death of individuals.

At low temperatures, the food demand of the birds increases in order for them to maintain their energy level, and it decreases proportionally with the rise of the space temperature, in a range between 15.5ºC and 26.6ºC. This condition is maintained until an air temperature of 28.3ºC, therefore, the goal for poultry farmers is to keep this condition between 27.7ºC and 28.3ºC, in order to achieve the best production, with the smallest feeding amount, without compromising the integrity of the production birds. That is why, the Colombian Caribbean becomes a strategic location for this type of industries.

Like humans, birds are homeostatic organisms. When heat production is greater than the bird can dissipate through the usual processes of elimination (conduction, convection and radiation), their body uses a mechanism of latent heat loss, panting, which starts when the outside temperature exceeds 29.4°C. When the bird can no longer thermo-regulate itself, and its body reaches a temperature around 47ºC, called "mortal elevated temperature", it dies of "Caloric Prostration".

Similar to what happens to the human body and sweating, with the presence of a high percentage of humidity in the air, this condition inhibits the bird's ability to give it to the environment, and therefore to eliminate excess heat by means of panting. Thus, when the sum of the value of temperature and relative humidity exceeds 105, the birds will be in Caloric Stress (AgroParlamento n.d.).

The climatic conditions of the site, the poor material definition of the shed and the considerable internal gains generated by a concentration of more than 41,000 individuals, result in the need to use mechanical conditioning systems to maintain a thermal environment acceptable to birds, that for its operation requires a great amount of electrical power. In the event of a power outage, with the cessation of operation of mechanical environmental control systems, poultry farmers risk losing entire lots of productive birds, compromising the sustainability of the industry and at a large-scale, food security of the regions they provide for.

The purpose of the present investigation was to design a shed under bioclimatic principles, which responds to the thermal requirements of the industry, using passive strategies that reduce the environmental and economic impact of this productive sector, and that decreases its energy dependence, in order to maintain the welfare of productive birds.

Characterization of the site location

The weather condition of the municipality of Montería, where the project is located, is classified as a very dry-warm climate. The average outdoor temperature is 27.8ºC, reaching values between 32 and 34ºC throughout the day. At dawn, the period in which the lowest temperatures are recorded, this varies between 22 and 23ºC. The relative humidity of the air, on the other hand, oscillates during the year between 76 and 82%, being greater in the months of October and November (IDEAM 2014).

Considering the strict hygrothemic requirements necessary for the birds to be productive without presenting signs of stress, the climatic characteristics of the site, constitute a major challenge for a design under bioclimatic parameters.

Poultry production shed design background

The challenge of designing efficient sheds has resulted in multiple architectural typologies, according to the breeding parameters established by each production farm. In the present investigation the design team worked closely with the company Santa Rio Shed, AVES EMAUS LTDA, and the parameters adopted by this company. This farm already had a traditional shed in the same site where the object of the present study was built.

Both sheds have the same dimensions in their floor plan (104.86 m long and 15 m wide) with the longest façades oriented toward north and south, and with an equal bird occupation (41,000 birds), criteria that allowed the team to make a quantitative comparison with the new shed after the last was built.

The traditional shed operates under the "controlled environment" model and requires for its operation 18 air master fans, of 1.5 HP, 3f, 60hz v130-3, and two water panels located in the central part of the long facades, turned on 100% of the time. This means a permanent, 24 hours a day, energy consumption, for the operation of the turbines, as well as a high water resource requirement for the operation of the panels.

The temperatures resulting from this air conditioning system, range between 24.3°C and 33.1°C, while relative humidity remains between 62.5% and 97.5%.

Taking as reference the amount of Kwh registered in the utility bills of the 6 months prior to the start of the consultancy, it was determined that the monthly consumption of the traditional shed is, on average, 20,020 kwh. Each kilowatt costs COP$ 440 (0.15 USD), which equals a total monthly payment of COP$ 8,808,800 (USD$ 2,995).

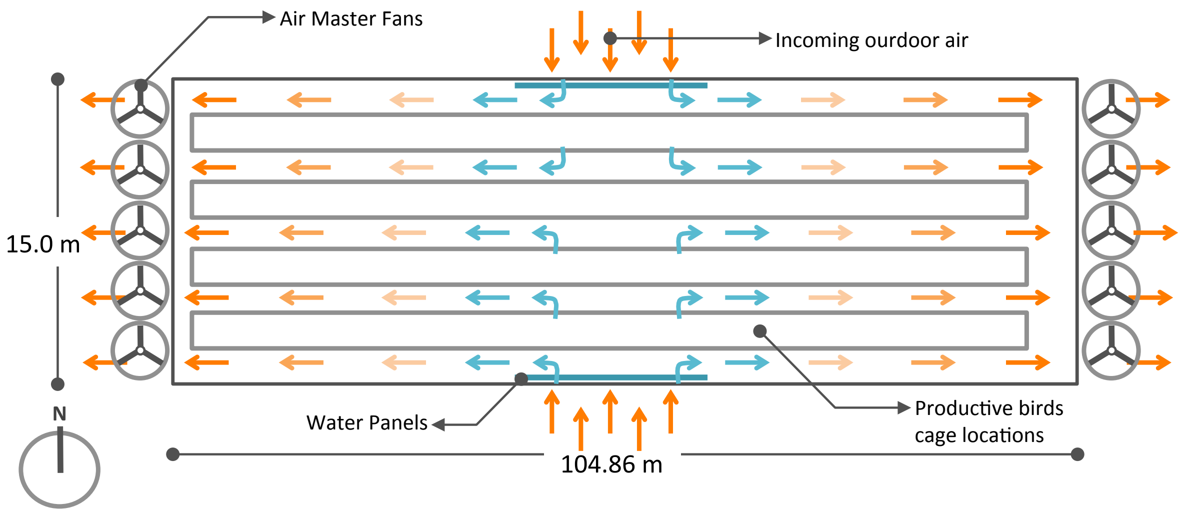

Figure 1. Scheme of distribution of the existing shed.

Methodology

As a starting point for the design of the shed, the basic spatial and environmental requirements necessary for an egg production process were considered as design guidelines, which were defined based on the standards adopted by the contracting company.

Spatial Requirements

The space was composed of a metal structure of rectangular plant, raised on concrete columns up to 3 meters off the ground; with a gable metal roof, with a slope of 19º, which had to respect, for the entire inner area, a minimum clearance height of 3.5m. The floor, for operational reasons, was defined as a metallic mesh. The four façades of the space are open, protected from direct solar radiation by a woven mesh composed of fibres of high resistance polyethylene.

Thermal requirements

Considering that the productive birds should not receive direct solar radiation at any time, the dates and times in which each façade presents the most unfavourable condition of solar incursion, that is to say, the periods of time during the day and the year, in which each orientation receives the solar beam with the greatest inclination, were determine, making use of the solar shade diagram designed for the latitude 8.62ºN, corresponding to the city of Montería (Melguizo Bermudez & Uribe Toro 1987), in order to define the extent and the slope of attachment of the lateral sun protection elements.

On the other hand, the constant circulation of the air volume of the space is an effective tool to help maintain the indoor temperature and control the humidity of the environment, especially in this case, where the birds also contribute with a considerable additional heat and moisture load, to the already high values of both variables in the pre-existing climatic conditions. Each bird requires approximately 14.4 m3/h of air, and considering that the shed should house about 41,000 individuals, it was estimated that the air volume should be renewed 62 times per hour.

Considering the irregularity of the natural air currents and the calm period, which for this region is almost 40% of the time, it was decided to design a natural ventilation system based on the air convection physical principle, taking as inlets the mesh of the floor and the open façades, and locating the outlet in a central opening on the main roof, protected from the sun and rain by a secondary cover. To estimate the size of area of openings, the ASHRAE method for “when the airflow is mainly due to the temperature difference” was used (see equation E1) ((ASHRAE, 2001 as citated by Yarke, 2005).

$$A = \frac{Q}{116\sqrt{h(T_i-T_o)}} \qquad \text{E1}$$

Where A is the opening area (m^2), Q is the design air flow rate (l/s), h is the height between the inlet window and the outlet window (m) and Ti and To are the average indoor and outdoor temperatures, respectively.

Results

The space resulting from the spatial and environmental premises is shown in Figure 2.

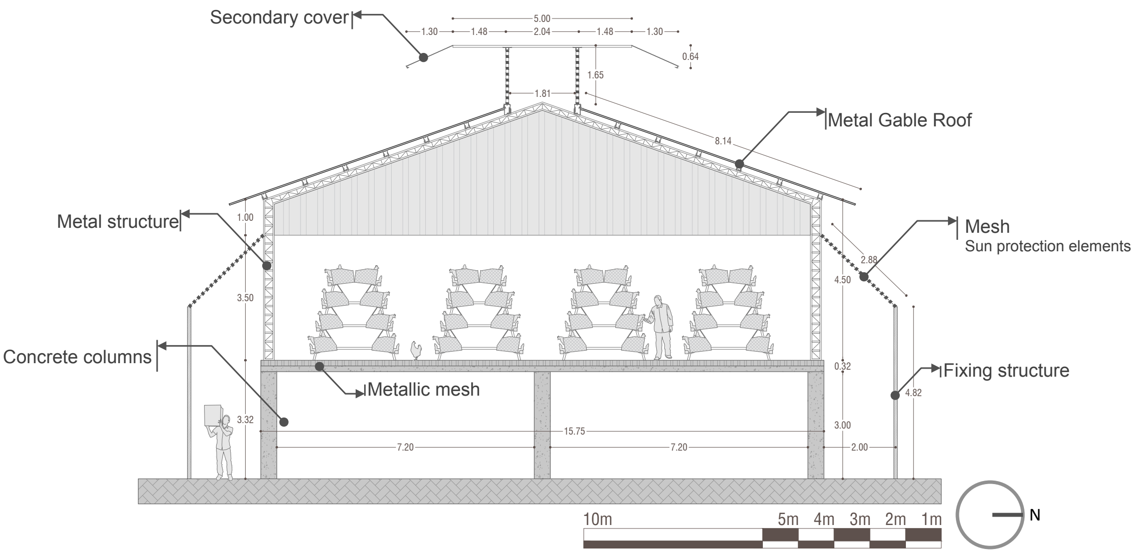

Figure 2. Schematic section of the new shed.

As it was stated that laying birds should not receive direct solar radiation, it was defined that the protection elements should guarantee full control of this condition during an hourly range between 7:00 am and 5:00 p.m., in both, open façades and roof. Using the shade diagram of the city of Montería, it was identified that for the limits of the hourly range of protection, June 21st and December 21 st presented the most inclined solar incursion in the north and south façades, respectively, and based on this information, the dimensions and inclination of fixing of the sun protection elements was determine as shown in Figure 3.

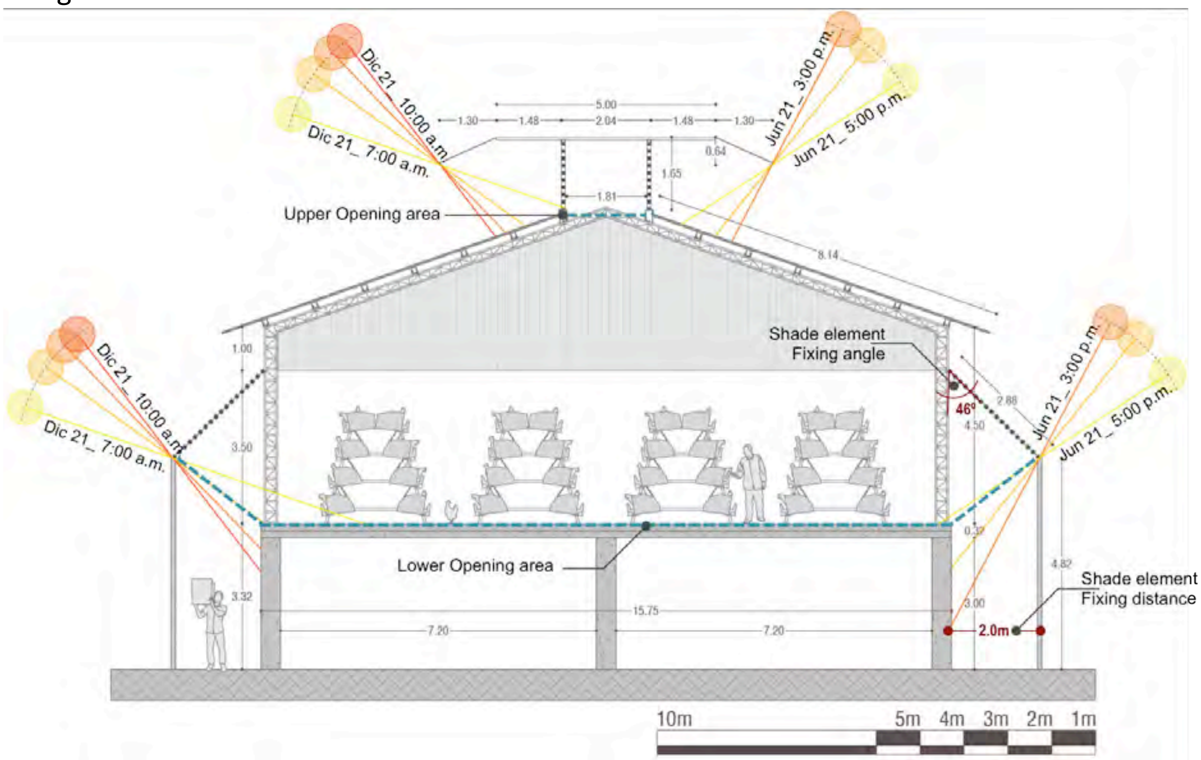

Figure 3. Solar incursion verification and openings location

In order to reach the 62 air changes per hour necessary to obtain an adequate ventilation of the shed, the openings were dimensioned considering a thermal delta of 1.5ºC and a difference of heights, between openings, of 8.25 m.

Since the availability of surfaces for the location of openings was considerably smaller for the upper vent, an adjustment was made to the area according to the "increase in flow due to a difference of size between the openings" figure presented by the ASHRAE method (ASHRAE, 2001 as citated by Yarke, 2005). As a result, the equation determined that the space required a lower opening area of 1005.29 m2 and an upper opening area equal to 168.59 m2, located as shown by Figure 3.

Information Comparison and analysis

Once the shed was built and put into operation, the internal temperature and relative humidity were monitored every half hour for two weeks in order to evaluate its environmental performance. A total of 648 measurements were obtained for each variable. During this period the outside temperature values moved in a range from 25°C to 30°C, with the relative humidity ranging between 76 and 82%; usual weather conditions for that time of the year.

According to the data, 51% of the time, the indoor temperature was below the desired upper limit (28.3°C). On the other hand, when adding the values of both variables, temperature and relative humidity, to determine the thermal stress indicator, it was obtained that 67% of the time evaluated, this indicator exceeded the reference value (105). What makes this last value, the most accurate tool to determine the energy autonomy of the new shed.

Based on the evaluated period of time and the totality of the recorded data, it can be concluded that 33% of the time the shed can operate autonomously, without mechanical assistance; 18% of the time, it would require such assistance to reduce the humidity of the environment by dehumidifying or by increasing air circulation, and 49% of the time, it will require it to achieve the desired air temperature values.

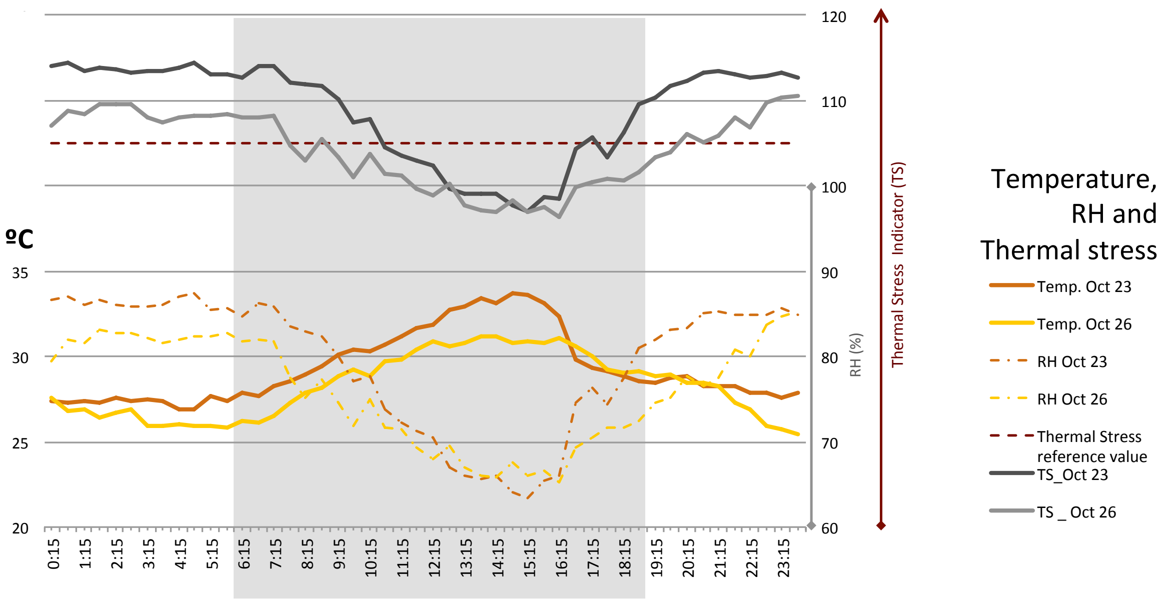

Figure 4. Temperature, Relative Humidity and Thermal Stress Indicator (TS) for the 23rd and 26th of October, 2016

Figure 4, shows the values of indoor temperature, relative humidity and thermal stress indicator, obtained for two of the evaluated days, October 23 and 26, in which respectively, the highest and lowest temperature values were recorded, thus containing the total range of temperatures documented inside the space.

On the day with the highest recorded temperatures, the shed presents conditions that allow it to operate autonomously 29% of the time, while during the day with the lowest recorded temperatures, it reached an autonomy of 50%, presenting a difference between the two cases, of approximately 5 hours.

It could be speculated that periods of thermal stress would occur more frequently during the day due to the increase in the outside temperature, which in the afternoon usually exceeds the desired range of values. However, as the figure illustrates, the values of the thermal stress indicator that exceed the reference value are recorded mostly during the night and dawn. During the day, solar radiation favours the exchange of heat with the outside, increasing the capacity of the natural ventilation system, which is based on the convection principle, to renew the volume of the air.

During the night, on the other hand, although the temperature drops considerably, the ventilation system loses efficiency and the space stores more humidity, inhibiting the mechanism of latent heat loss of the birds, and therefore requiring the support of the mechanical ventilation system.

Conclusions

The application of bioclimatic principles and passive solar design to the design of the new shed allowed obtaining energy autonomy of approximately 30% of its operating time. Considering that according to climate statistics (IDEAM 2014), the most adverse conditions in terms of humidity are in October and November, this percentage is expected to increase.

The consumption records registered in the last 6 months, show that, on average, the shed designed under passive design criteria consumes 14,813 kwh monthly, that is 5,207 kwh month less than the traditional shed; this is equivalent to an economical saving Of COP$ 2,290,933 (USD$ 800).

Although the initial concern expressed by the contracting company was the high internal temperatures, the design actions taken managed to maintain that condition within the desired limits 51% of the time. However, the measurements showed that the presence of high humidity in the environment, recorded during the night and dawn hours, is the climatic factor that limited the most the possibility of operating without mechanical assistance throughout the day.

Despite this condition, according to the production company, when the mechanical ventilation support system ceases to function due to irregularity in the public energy service, the mortality of birds during periods when there is high humidity in the environment, and even at times when the temperature of the interior air of the new shed is higher than 28.4°C, is considerably smaller than that presented in the traditional sheds when for this same reason, its air conditioning system is suspended; going from a risk of losing almost 100% of a batch of productive birds, to less than 5%.

Based on what was concluded with the analysis of the data presented here, it is proposed, as an additional measurement, to lift the sun protection mesh during the night time, between 19:00 and 7:00 h, in order to potentiate cross ventilation throughout the period of solar radiation absence. The impact of this measure will be verified in subsequent environmental monitoring. An additional measure could be to reduce the number of birds present in the shed, in order to lower the heat and humidity loads in the environment. However, this would mean that the company would require a larger infrastructure to house the same amount of birds, which could prove to be economically unfeasible.

Acknowledgments

We would like to thank Juan Manuel and Juan Esteban Mejía and his team at AVES EMAUS LTDA, for all their help and support during this process.

Brazilian Modernist Envelopment Elements Reinterpreted through Precision: a Case Study on Energy Efficiency and Environmental Comfort in an Experimental Building

Aderson Passos[1], Karoline Cordeiro[1], Nayana Castro[1], Bruno Raviolo[1], Natasha Catunda[1] and Daniel Cardoso[1]

[1] Departamento de Arquitetura e Urbanismo da UFC, Universidade Federal do Ceará - UFC, Fortaleza, Ceará, Brazil, Av. da Universidade, 2890 - sala 11 - Benfica

Abstract: In some latin-based languages, the word *precision* means both accuracy and necessity. Through history, architects have thrived creating solutions both fit for their contemporary methods of fabrication and with a certain level of performance towards our needs, such as environmental comfort. Perforated elements in facades and roofings in brazilian modernist buildings are examples. Although, while necessity has usually been addressed, accuracy is commonly neglected when further customization is needed for optimal improvement in thermal and lighting comfort, both often needing accurate analyses of nature's behavior. This is usually due to the unavailability of fabrication logistics proper for mass customizing buildings elements. This paper studies how these architectural elements can evolve, starting from old inaccurate designs, then presenting a case study of an experimental building in Brazil built for a research on energy efficiency according to specific bioclimatic necessities that adapted, combined and optimized the original concepts of these elements using computational simulations, parametric modeling and genetic algorithms. Local technological conditions were respected, dealing with the low amount of customization allowed by accessible solutions and still delivering a reinterpretation of modernist architecture that, for the accurate adaptation of the envelopment to local climate, local language can understand by true, latin-based *precision*.

Keywords: Modernist Architecture, Environment, Parametricism, Computational Simulation, Solar Control.

Introduction

The construction of buildings is an activity ten thousand years old. Only about 130 years ago these buildings started using electricity, and 115 years ago they began with the possibility of using air conditioning systems in their interiors. Thus, it can be concluded that in most of their history, buildings had to be adapted to the climate in order to provide adequate environmental comfort conditions for their users (Romero, 2012).

Architecture underwent significant changes in the years following the incorporation of artificial conditioning systems. The so-called International Style, in turn, as a consequence of its indiscriminate use, brought the creation of an architecture alien to its climatic context, one in which what was to be specific for a given reality became a general rule. As a result, the aspects of environmental comfort were left out of this style's design premises (Lamberts et al, 2014). Thus, inadequate architecture generated a demand for active systems to guarantee environmental comfort, consequently increasing energy costs.

Soon after, the modernist movement in Brazil comes to confront this strand by creating its own architectural features, mainly taking into account its cultural and regional aspects. Brazil's great contribution to modernist architecture was the implementation of creative solutions to prevent the entry of heat and direct light through glass surfaces with the aid of articulated sunshades. These innovations were previously recommended by Le Corbusier, however it was in Brazil that they found a favorable scenario to be incorporated into modernist architecture and adapt this language to a tropical reality (Goodwin, 2012).

The use of these elements in brazilian architecture brought advantages for the buildings that incorporated such solutions and, nowadays, their optimization during the design process can be facilitated by the use of computational simulations. The adoption of these simulations as evaluation tools for a building’s performance is very important for the reduction of energy demand if carried out in early stages of design (Gonçalves et al, 2015).

The materialization of performance-oriented projects often involves concepts such as complex geometries and mass customization. For both industrial production and assembly on a construction site, Computer Aided Manufacturing (CAM) technologies, such as CNC or robotized machines, may be required (Dunn, 2012). The conflict lies in the high costs involved, as these technologies are often confined to rapid prototyping even in high technology environments. Thus, it is necessary an approximation between the design and the techniques to be used in its execution, seeking suitable middle grounds, feasible for the capacity of local industries but that do not compromise the performance of the project, reducing the costs of production and installation to facilitate the process of implementation.

Considering the presented context, this work aims to present a case study where computer simulation and parameterization tools were used to optimize the dimensions and spacing of solar protection elements commonly used in brazilian modernist architecture in order to maximize indirect natural illumination inside a building which will function as the administrative headquarters of a company, in order to achieve energy efficiency. This Experimental Building is located in a brazilian coastal city in the state of Ceará, characterized by a hot and humid climate, with intense solar radiation throughout the year. In addition, it also has the objective to combine the solutions found in this process with the local technology, in order to make them feasible, since the building would, in fact, be built.

Historical Evolution of Solar Protection Elements

Permissive elements of solar protection for natural lighting and ventilation were already being applied to buildings in different places and times in architectural history (Bittencourt, 1995). Zenithal openings in renaissance domes, brises-soleil at early european modernist production and arabic muxarabis[1], inspiring the brazilian cobogós[2] as cultural heritage of the country, were examples of the different versions of these elements, as found outside Brazil.

On the international scene, Frank Lloyd Wright made use of prefabricated blocks of concrete, called “textile blocks”[3], which relate to the cobogó but present a more solely aesthetic aspect, emphasizing the monumental and plastic character of buildings (Figure 1).

---

[1] Light framework constructed with wooden lines, used to partially close internal environments.

[2] Brazilian perforated blocks, usually made of cement or ceramic, used to complete walls allowing greater ventilation and luminosity in interiors. The name is an acronym from the names of Coimbra, Boeckmann and Góis, the architects and engineers who invented it in the beginning of the 20th century (Sunguroglu, 2008).

[3] Construction system perfected by Wright in the Californian period (1914-25). It is a construction system based on the use of concrete blocks, decorated and prefabricated with the aid of wooden mats used as formwork in the concrete walls molded in loco (Folha de S. Paulo, 2001).

Another example is the Institute of Zoology of Nancy in France (1932-1933), which brings a reinterpretation of Wright's blocks (Figure 1). The cement blocks applied in this building additionally confer an unquestionable aesthetic effect, evidencing the constructive demand, because the designs made in the blocks made them lighter, facilitating handling and transportation (Bauer et al, 2011).

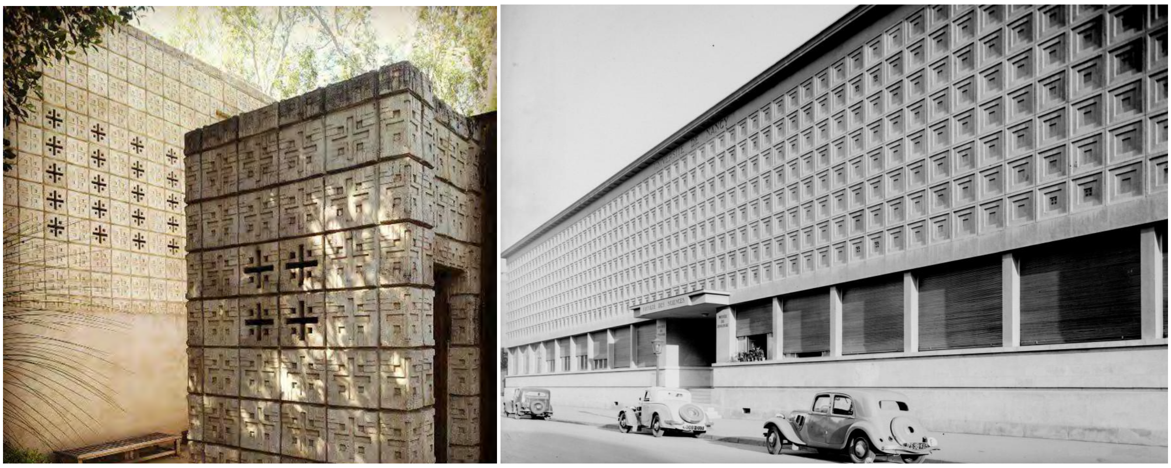

Figure 1. Frank Lloyd Wright, La Miniatura/Millard House, 1923 (left). Zoology Institute of Nancy (right).

Contemporary to the Zoology Institute of Nancy (France) and already within the brazilian national context is the modernist building of Olinda's Water Tower, from 1936, where the cobogó was used in large scale for the first time in Brazil. The use of the cobogó in this building, besides having the functional characteristic of providing constant aeration and structural lightness, presents a symbolic sense of dialogue between tradition and modernity, thus constituting a symbol of modernism (Marques et al, 2011).

The brises-soleil were also elements used in some modernist works. However, due to its high cost, the use of cobogós was more prevalent in brazilian architecture. Besides these, other solutions for solar protection elements permissive to natural lighting and ventilation were employed in modern Brazilian architecture, such as, for example, concrete flaps surrounding external frames, ventilated parapets, among others.

In Brazil, the design of these elements is still restricted to conventional shapes due mainly to production costs. During design, these elements are often given dimensions through the use of conventional techniques, using solar charts and simple geometric calculations, or even by solely aesthetic criteria. There is, therefore, space for improvements in the performance of these elements with the use of digital tools.

Modified Elements

The following are the modifications of the previously presented elements, developed in this work from adaptations through computational analyses of solar incidence in the facades and roofing of the Experimental Building in question.

The building has an elliptical shape, the result of form finding simulations, whose objective was to maximize natural ventilation and illumination captation, in order to guarantee the users' environmental comfort through passive strategies and thus reduce the energy consumption of the building.

Brises-soleil were used in the southeast facade, since it receives more ventilation and due to the fact these elements do not disturb the wind passage. Cobogós were used in the northwest facade, which needs better solar protection since it receives more thermal load.

Conceptual Modifications

Cobogós

Based on more conventional and structurally viable designs, square modules made of concrete blocks with a 20 cm inside to outside thickness were proposed with minimum structural inner thicknesses of about 3 cm for the greater use of natural ventilation and the smallest frontal dimensions possible for the elements to still block direct radiation incident on the entire curvilinear facade of the building.

Due to the fact that the solar incidence occurs differently along the curvilinear facade, three different sizes of cobogós were dimensioned, basically one for each orientation: north, northwest and west (Figure 2). The dimensioning of the pieces was defined by simulations with software Weather Tool, whose objective was to prevent direct solar radiation from entering the building until the closing time of activities, at 4:00 p.m. (Figure 3). According to Figure 2, the square openings have, respectively, from left to right, sides of 6, 8 and 16 cm, ranging from westmost to northmost blocks of cobogós.

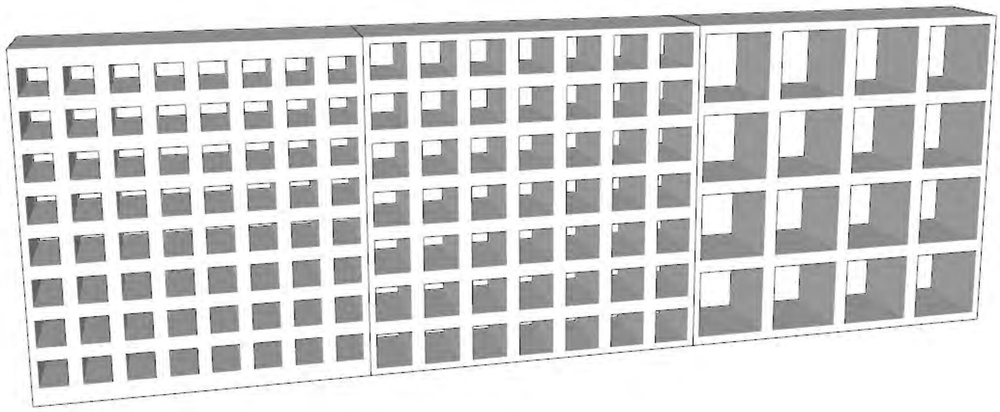

Figure 2. Variations of cobogós optimized for one of the curvilinear facades of the building (author).

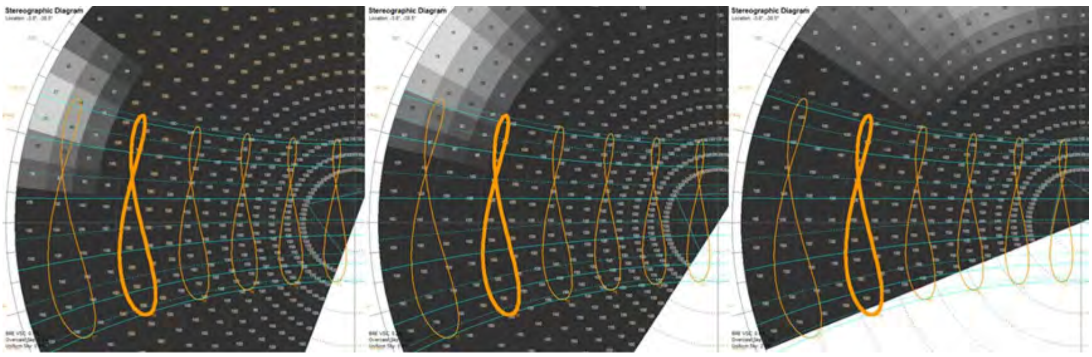

Figure 3. Solar charts for the three simulated orientations, showing dark spots of 100% shading for all solar positions until the analemma of 4:00 p.m., highlighted in bold orange (author).

Brises-soleil

In order to allow the passage of wind, protecting the interior of the building from direct solar radiation and taking advantage of external natural light, brises-soleil were used in an analogous way to the cobogós, on the opposite facade of the building, varying its geometrical properties along a curvilinear path of varying solar incidence (Figure 4).

Figure 4. Possible parametric variations of the brises-soleil adapting to the solar incidence along the curvilinear facade of the Experimental Building (author).

The Rhinoceros 3D modeling tool, along with the Grasshopper parametric plug-in, was used in conjunction with the Geco and Ecotect solar simulation components to adapt the geometric parameters of the brises-soleil, where their gradual increase of inclination, depth or quantity follows the orientation of the facade from south to east.

The variation of the brises-soleil's inclination generates continuous pieces with the entire interval between the points of largest incidence angle of the sun and the points where the sun hits the facade more perpendicularly being protected by a sequence of cross sections of the brise-soleil with inclination angles progressively larger and interpolated throughout the piece. For its execution, no easy access and implementation solution was found in terms of materials and techniques that enabled this design. Similarly, the depth parameter of the brises-soleil could be varied throughout the piece, which would be possible to execute, but not convenient given it would use a lot of horizontal space. In addition, due to the size of the facade of more than 80 meters in length, this solution would need to be made with several smaller pieces. The option of varying the amount and spacing of brises-soleil along the facade, as in the last image of Figure 4, has thus become the most feasible. It was implemented through the use of light and reflective aluminium composite panels, doubled, structured in metallic frames and stacked in the horizontal position. Each horizontal piece of the brises-soleil had approximately 3 cm of height and 40 cm of depth, and were stacked with different vertical distances from each other of 44, 36, 30, 28, 26 and 25 cm, respectively, from southmost to eastmost sections of the southeast facade.

Skylight and light shelves

Combining the concepts of light shelf and skylights, a system hereby called reflective shields was used for the solar protection of the zenithal openings applied on the roof. These openings were made from the removal of the tops from the ribbed slab, which functions as a second level of roofing for the indoor air conditioned ambients. These shields were positioned beneath the zenithal openings and were specified with a reflective material on their upper surfaces to reflect the zenithal light directly incident on it, thus allowing the diffuse entry of natural light into the building (Figure 5).

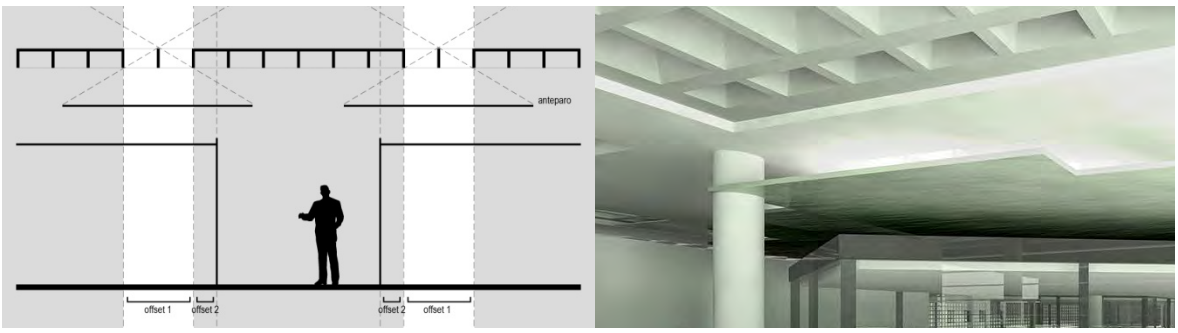

Figure 5. Schematic section of the reflective shields (left) and digital perspective (right) (author).

Further arrangements were made for the manner in which the openings were chosen on the slab and how to protect them with the reflective shields. Parametric modeling was used to link the calculation of the dimensions of the shields to the slab thickness and the possible angles of incidence of the sun. For this, the spacing between reflective shields and slab was optimized through genetic algorithms, in order to allow the reflection of a greater amount of light to the interior of the building. Adaptations were made throughout the work so that the execution of the shields was compatible with the modulation of sheets of reflective materials available in the local market. The final proposed design made use of doubled aluminium composite panels, with an inner layer of heat absorbing foams.

Optimizations and Results

Simulations

Simulations with the Diva software were made to investigate the contribution of the cobogós to the internal illumination of the building, without any other openings in the envelope being modeled (Figure 6). This gives a graph of daylight factor, which indicates the percentage of illuminance incident relative to the external incidence of the building, i.e. how much of the external illuminance is admitted into the building (Mardaljevic, 2009). In the result, a greater diffuse illumination is observed in the northernmost segment of the curvilinear facade, due to the larger sizes of the cobogós. At no point in the facade was allowed the incidence of direct sunlight inside the building within its operating hours, from 7:00 a.m. to 4:00 p.m. Cobogós and all other elements in the scene were modeled in Diva with a reflectance value of 70%, corresponding to a generic rough painting in the white color, and all other attributes remaining at their default values.

Similar to the cobogós, simulations were made with the brises whose pieces increase in quantity as they approach the segment of the facade that receives solar incidences of more perpendicular angles. Likewise, in no point was the entrance of direct radiation admitted, with diffuse levels of light being observed in the south of the building in the case of brises-soleil (Figure 6) reaching maximum values much higher than with the cobogos, in up to 6% of daylight factor. Brises were modeled in Diva with a reflectance value of 80%, corresponding to a polished white metallic surface, and all other attributes remaining at their default values. Other elements in the scene were modeled with the same material properties as the cobogós in their simulations.

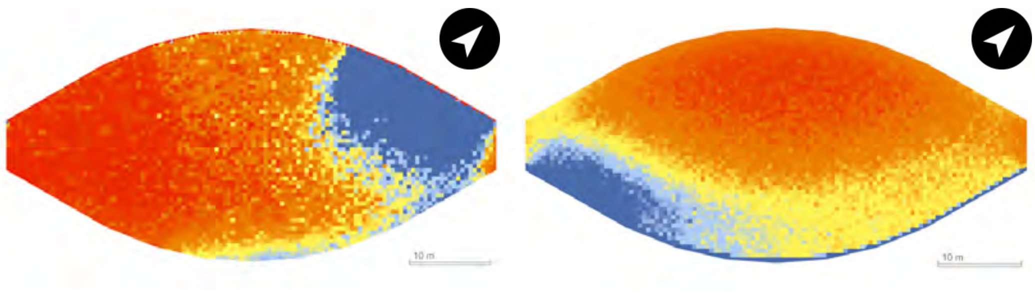

Figure 6. Daylight factor simulations. On the left, the isolated application of cobogós and their contribution to the natural lighting of the building, in a gradient of 0% to 0.5% of the external illuminance value (blue are the highest values). On the right, the isolated application of brises, in a gradient of 0% to 6% DLF (author).

Parametric Modeling and genetic algorithms

With reflective shields, computational optimization techniques were used, coupled with the versatility of parametric modeling to obtain maximum levels of illuminance within the building. Mathematical relationships were established between dimensions of the ribbed slab on the roof of the building and the reflective shields positioned just below (Figure 7). The relationships were implemented in the Grasshopper parametric modeler (Figure 7) so that whenever the shields were repositioned to a new distance from the slab, they were automatically resized in a way that at any given time of the day there is no possibility of direct sunlight entering through the roof's zenithal openings.

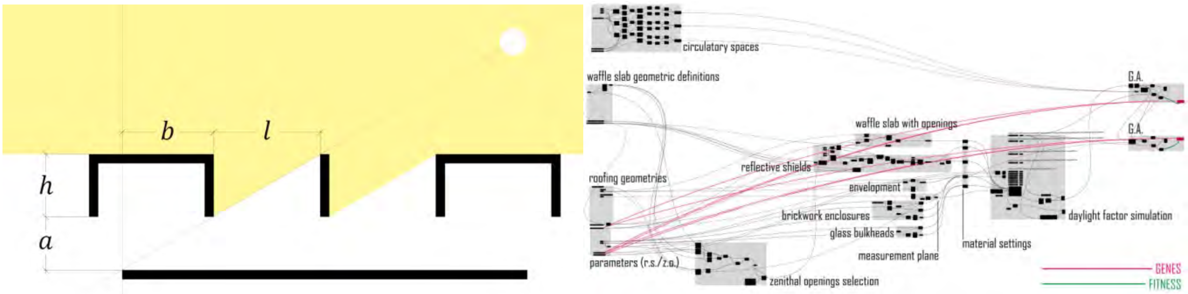

Figure 7. Reflective shields and optimized variables (left) and the algorithmic definition for the optimization of reflective shields with the use of genetic algorithms (right) (author).

By maintaining relations between variables, the modeler then investigates new combinations of openings and spacings. The Galapagos component of Grasshopper is responsible for the implementation of genetic algorithms that, in a single procedure, both use results from Diva's daylight simulations to define the performances of each tested combination of openings and spacings, as well as guides the selection of new combinations to be tested, with the tendency for each new generation of found combinations to have even greater performance values. The algorithmic technique consists of an analogy to darwinian mechanisms of natural evolution, where the environment promotes a selection of pairs compatible with a greater chance of generating an offspring of greater fitness. This optimization in the search for better combinations of parameters avoids the need for an extensive combinatorial analysis of all possibilities (Besserud et al, 2008). Finally, the best combination of the last generations is selected to be implemented in the construction of the building (Figure 8). The simulations carried by the optimization procedure introduced the reflective shields as surfaces modeled with material properties of reflectance of 90%, corresponding to polished metal with a mirrored finish, in order to maximize lighting gains, and all other properties remaining at their default configurations. These simulations isolated the reflective shields as a light gathering solution, ignoring light coming from the facades, for faster calculations due to a lesser amount of geometries, with no cobogós or brises.

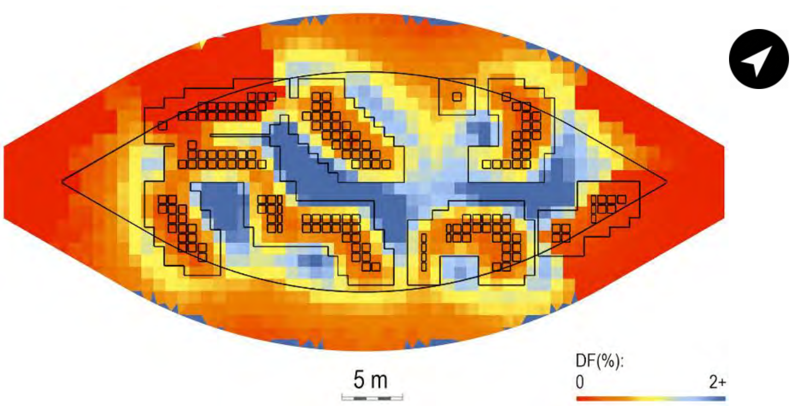

Figure 8. Final shapes of the reflective shields (pixelated outlines) and openings selected by the computational optimization procedures (squares) (author).

Conclusions

The process of optimization of solar protection elements through the use of daylight simulation and parameterization software made it possible to increase the use of indirect sunlight in the interior of the building, making clear the contribution of the customization of geometric parameters and their adaptation along the facades. The Experimental Building ended up assimilating the reinterpretations of modernist elements in a new language that, by implementing familiar materials and constructive techniques, nevertheless managed, in a subtle way, to stand out by the presence of variation and personalization of its geometrical characteristics, always according to functional aspects, in a precise - or *preciso* - way.

Abstract: Buildings in the equatorial tropics face a unique set of challenges to achieve energy efficiency and sustainability targets. The biggest consumer of electricity in these buildings are the ACMV systems. Solar heat gains through building envelopes contribute about 50% towards cooling loads in the tropics. Passive methods to reduce these solar gains from the envelope's surfaces could result in significant cooling energy savings. This paper focuses on the thermal performance evaluation of a new generation lightweight cement based material applied with a thickness of 5 cm on the walls and 20 cm on the roof. The experiment is carried out in a real- time on real building in Singapore. It was observed that the indoor ambient air temperature was reduced by up to 4.6°C and an annual heat gain reduction of up to 60% could be achieved for a residential building in the tropics.

Keywords: Tropics, Thermal Heat Flux, Passive Technology, Insulation, Sustainable Buildings

Introduction

It is well established that building sector is a major contributor towards global CO_2 emissions. In Singapore, the construction industry has been recognised as the third largest contributor of its overall emissions which was accounted for about 16% in 2005 (NEA, 2008). To provide a long-term sustainability solution to mitigate emissions from the building sector, Singapore's Building Construction Authority (BCA) launched its Green Mark Certification Scheme in 2005 under its first Green Building Master Plan. Since its launch, the scheme has seen a 16% decrease in the Energy Utilization Index (EUI) of office buildings in Singapore in 2013 (BCA, 2014). However, the most effective decrease in energy consumption is possible when the building's passive design strategies can efficiently decrease its cooling demands.

Buildings in the equatorial tropics face a unique set of climatic challenges. The climatic conditions here are classified as hot and humid throughout the year with high sun angles. Studies conducted in the tropical climate of Singapore to quantify the electricity consumption of Air Conditioning Mechanical Ventilation (ACMV) systems have concluded that 57% of the total energy consumption (Zingre et al, 2016). Another study quantifies that 30% of this cooling energy demand is due to the solar heat gain from the thermal heat flux through the opaque surfaces of the envelopes (roof and walls) of tropical buildings (Zingre et al, 2015). This evidently highlights the need of special attention while considering construction material as a passive strategy to curb the heat flux through the envelopes in hot and humid climate.

In the past, increased thermal resistance for envelopes by adding insulation material in tropical buildings was considered as an unsuitable passive strategy. However, with new studies on vertical greenery, green roofs and double skin facades have lent a different perspective to increased thermal resistance and its benefits for tropical buildings along with its application for various building typologies. This paper focuses on the study of new generation cement based insulation material on a naturally ventilated space to quantify its impact on various surface and indoor air temperatures of the test building as well extrapolate potential energy savings through computer simulations. Furthermore, impact of this study could allow building construction industry of hot and humid climates to revise its perspective on the use of external insulation on energy efficiency.

Methodology

The study was carried out in two stages. A "side by side" testing methodology was implemented to map the performance of the material. Details of the methodology are explained in section "experimental set-up". Data collected from the testing was used to calibrate a simulation model to validate the test results as well as to calculate the possible energy savings. The site selected was naturally ventilated with a mechanical fan to enhance thermal comfort by increased air velocity.

The Site

The test site was located on Nanyang Technological University Campus (NTU), Singapore. The experimental study was undertaken as part of the university's Eco-Campus initiative according to which the university is committed to reducing 35% of its energy, waste and water intensity by 2020 (baseline 2011) (NTU, 2012). For the investigation, a student's dormitory building – Hall of Residence 4 was carefully selected from other hall of residences (which are naturally ventilated) after evaluation of its orientation, massing, shading and ventilation.

Experimental Set-Up

Two identical blocks (26 and 27) at the hall of residence 4 on NTU campus were selected for comparative "side by side" study. Each block was a single storey building (10m x 4m) with a solid flat roof of 150 mm thick concrete and 12 mm plaster with a total of 40m^2 roof area as seen in figure 1. The blocks have a north-south orientation and have four identical dormitory rooms (2.5m x 4m) that are naturally ventilated with one window (0.8m x 1.6m) facing the south as seen in Fig 1 . Block 26 is considered as the "Original" cell and was not retrofitted with the insulation material. It was left as is to get benchmark case for a comparative study. Block 27 was retrofitted with 50 mm of insulation material on the walls and 200 mm on the roof (external application) and finished with the original paint colour. This was the "Test" cell used to gather data for performance evaluation from January to July 2016. Both cells were fitted with Resistance Temperature Detectors (RTD) on the inside and outside of each Test cell as seen in Figure 1 as well as indoor air and humidity sensors. Block 27 was also fitted with a pyrometer, pryheliometer and a solar tracker. Portable solar spectrum reflectometer and portable emissometer were used to measure solar reflectance and thermal emittance as seen in Figure 1. For the Test Cell, sensors were fitted on the roof, ceiling, east and south wall as north wall faced the corridor and there was no west wall available for evaluation for this cell due to the architectural design of the building as seen in Fig 2.

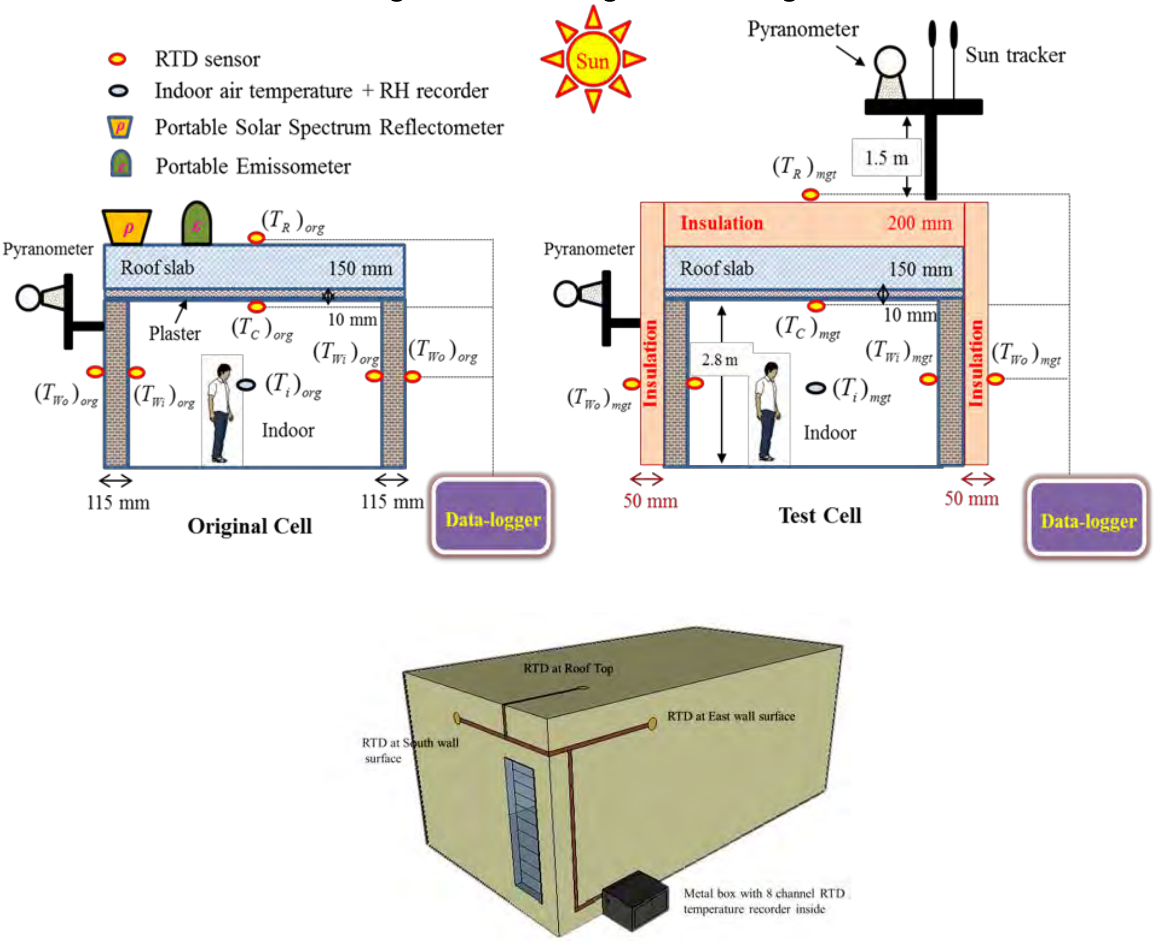

Figure 1: Experimental setup and exterior sensor placements for the Test cell

Modelling and Simulation

Google Sketch-Up Pro and Open Studio Plugin was used to develop a 3D model of the Hall of Residence – 4 as seen in Figure 2 to run simulations using Energy Plus. The physical attributes and material assumptions for the models of both cells are described in Table 1, 2 and 3.

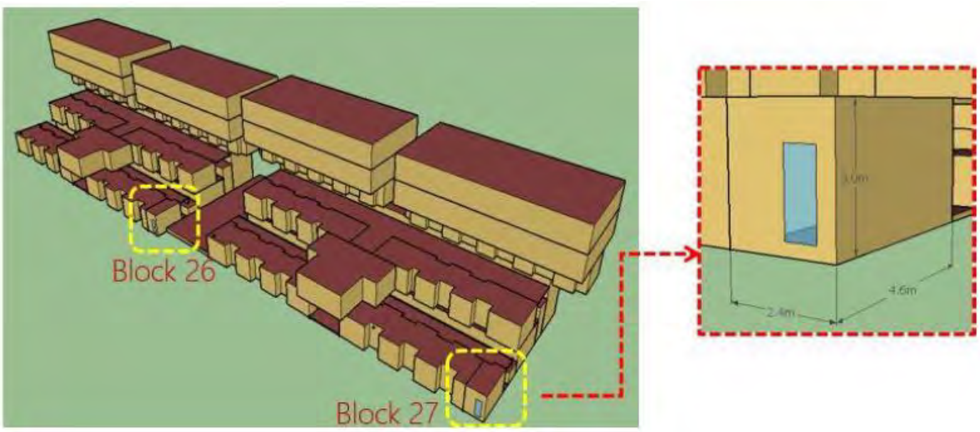

Figure 2: Energy Plus model developed in Google Sketch Up with Open Studio Plug-in

Table 1: Input Assumptions for Energy Plus Model

Inputs for Energy Plus Model	
Location	Singapore
Latitude and longitude	1.39°N and 103.9°E
Elevation	35 m
South and East facing wall area	7.2 m^2
North and West facing wall area	13.8 m^2
Roof surface area	11 m^2
Terrain	Urban
Air-conditioning system	Unitary System (Single coil) On/Off
Indoor set temperature	24°C
Cooling capacity	2.5 kW
COP	3.5
Power consumption	0.75 kW
Occupancy	1

Table 2: Input for building materials for Energy Simulation

Building Materials

Parameters	Block 26- “Original” cell*	Block 27- “Test” cell	Conduction Resistance (m^2K)/W
Walls	Concrete block (150 mm) + Gypsum Plaster layer (12 mm)	External Insulation (50 mm)+ Concrete block (150 mm) + Gypsum Plaster layer (12 mm)	0.40*/1.43
Roof	Concrete slab (150 mm) + Plaster (12 mm)	External Insulation (200 mm) + Concrete block (150 mm) + Gypsum Plaster layer (12 mm)	0.46*/ 4.55
Windows	Double Glazed units (3mm +13mm air+ 3mm)	Double Glazed units (3mm +13mm air+ 3mm)	1
Floor	Concrete Block (300 mm) + Acoustic Tiles (20 mm)	Concrete Block (300 mm) + Acoustic Tiles (20 mm)	0.85
Doors	Wood (30 mm)	Wood (30 mm)	1.5

Table 3: Input for Building Material Properties

Material Properties	Original Cell	Test Cell
Thickness (m)	0.15	0.05
Conductivity (W/m.K)	0.49	0.03
Density (kg/m^3)	512	43
Specific Heat (J/kg.K)	880	1210
Thermal Absorptance	0.9	0.9
Solar Absorptance	0.7	0.6

Calibration

The computational models developed for energy simulations were calibrated using the data opbtained from the site. This was done to predict the impact of insulation on the cooling energy demand and associated energy consumption. Temperature and weather data collected from the live test site was compared to the data set obtained from National Environmental Agency’s (NEA) Climate Research Centre in Singapore. To ensure accuracy, two parameters were compared, namely outdoor air temperature and total solar radiation. This process helped to narrow down days with similar weather profiles to precede the calibration of the model by comparing roof and ceiling surface temperatures of in the measured and computationally simulated data sets. The deviation between the two data sets was found to be between ±5% as seen in Figure 3. Since the infiltration rate of the test site was unknown, after a few simulation permutations, it was found that an infiltration rate of 0.90 air changes per hour (ACH) was the best match between the two data sets with errors within 5%. The calibrated model was used to quantify the annual heat gain, annual heat loss, net heat gain reduction and to subsequently quantify the energy saving potential.

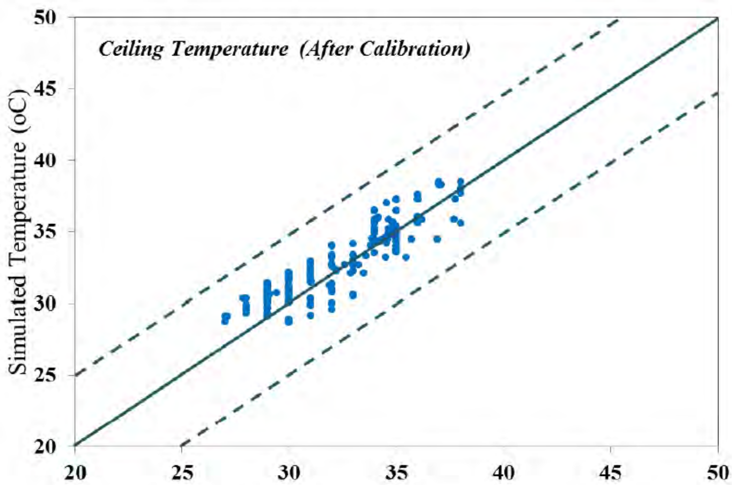

Figure 3: Comparison of computationally simulated temperatures (after calibration) against measured temperatures for ceiling (Zingre, 2016)

Results and Discussions

Table 4 shows the comparative results collected on site for the two test cells as well as the differences in the indoor air temperature. Figure 4 shows the results of indoor air temperatures from the measurements collected from the site and Figure 5 shows the rests of annual heat gain, loss and net heat transfer from the computational simulation.

External Surfaces

It was observed that the external surface temperature profiles for both units are quite repetitive with higher fluctuations for the surfaces of the Test cell with insulation. This has occurred due to an enhanced thermal resistance of the surfaces with the addition of insulating material of varying thickness. During the daytime, due to the higher thermal resistance of insulating material resulting there is a lesser degree of heat penetration towards the interior of the surface. The peak-time external surface temperatures of the test cell could be higher than the original cell with a delta of 34°C for roofs on a hot day as seen in Table 4. However, during the night-time, a reverse phenomenon occurs i.e., the surface temperature of the Test cell becomes cooler than that of the Original cell. This happens due to the fact that the external surfaces emit more heat to the outdoor environment because of the temperature difference between the surface and the outdoor air at night.

Table 4: Result for External and Internal Surfaces from Measured Data on Site

External Surface Temperature	Internal Surface Temperature
Roof 	Ceiling East Wall 	East Wall South Wall 	South Wall 
Internal Surfaces

As observed from the results, the interior surface temperature of the test cell is more stable with less fluctuation as compared to the observations made for the external surface. During the day, the internal surface temperatures of the Test cell remain cooler compared to the Original cell by up to 5°C as seen in Table 4. However, during the night, a reverse phenomenon occurred i.e., the internal surface temperature of the Test cell remain hotter as compared to that of the Original cell. This happens due to the fact that the insulating material prevents the outward flow of heat transfer across through the surfaces of the Test Cell, resulting in less increase in the indoor air temperature by the virtue of radiation through the warmer internal surfaces.

Indoor Air Temperature

It has been observed that the overall peak time, indoor air temperatures of the Test Cell had been lower by up to 4.6°C as compared to the original cell as seen in figure 4. However, during night time, the indoor air temperatures of the Original unit were cooler due to the virtue of higher heat emission rate through the envelope (roof and walls).

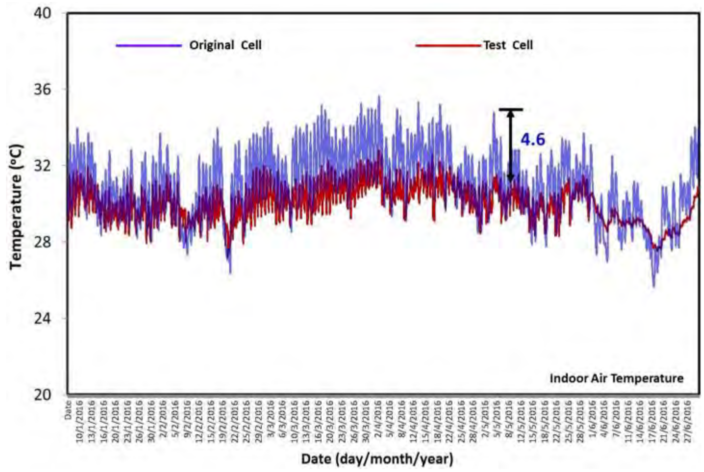

Figure 4: Results for Indoor Air Temperature

Annual Heat Gain, Heat Loss and Net Heat Transfer

In order to quantify the annual heat gain, loss and net transfer the external and internal surface temperatures were considered. The simulation results that were obtained using Energy Plus illustrated, the Test cell provides a significant reduction in the annual heat gain (inward heat transfer during the day time), annual heat loss (outward heat transfer during the night time) and annual net heat gain (summation of inward and outward heat transfer through the day). The computational results suggest that the insulated material was responsible for a significant reduction in the annual heat gain as well as annual net heat gain of 84% and 74% respectively. It was also found that the insulation material was capable of reducing the total building heat gain by 68% and the net heat gain by 39% as seen in figure 5.

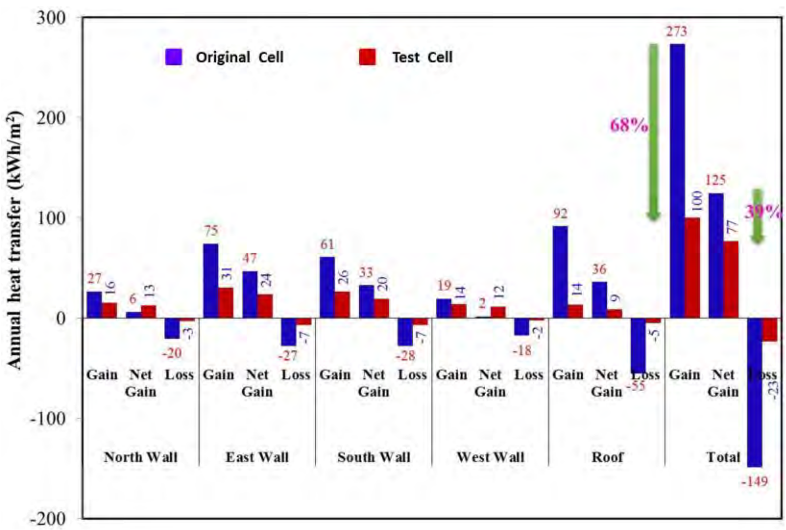

Figure 5: Annual Heat Gain, Heat Loss and Net Heat Transfer

Conclusions and Recommendations

This study investigated the impact of new generation cement based external insulation on traditional reinforced cement concrete construction of a naturally ventilated building in the equatorial tropics. The insulation significantly reduced total building and net heat gains, i.e. the insulation material absorbed more heat during the day, and released less heat at night as compared to uninsulated reinforced concrete structure.

As understood naturally ventilated buildings are design to provide thermal comfort to its occupants without the need of any energy systems for ventilation purpose. Therefore, insulating these buildings would logically not have a direct impact on energy consumption. However, insulating naturally ventilated buildings would reduce the indoor air temperatures in tropical climates, which has a significant impact on the key parameters of occupant's thermal comfort condition. The results also show that there is a considerable reduction in the heat loss (outward movement of internal surface temperatures) by virtue of the insulation material; it is possible to save energy for buildings designed with ACMV systems. A forthcoming paper will soon present the insulation material energy saving potential for such energy intensive buildings in Singapore.

Acknowledgements

We would like to acknowledge Mr. Tomas Krcula, Mr. Tony Renyard and Magortherm for funding this project as well as providing the insulation material for testing. Acknowledgement is also extended to ODFM (Office of Development & Facility Management, NTU) and OAHS (Office of Auxiliary and Housing Services, NTU) for providing testing facility. The entire SSBT team at ERIAN including, Mr. Kishore T. Zingre and Ms. Hansika Gamage who worked on various aspects of measurements and energy simulations. We acknowledge the support lend to us by Mr. Yann Grynberg, Program Director of SSBT at ERIAN & Mr. Nilesh Y. Jadhav, Program Director of Eco- Campus Initiative, NTU and his team who helped in realising this project from the inception. Finally, we thank Prof Werner Lang, Technical University of Munich for providing technical insights on the paper.

Abstract: The "Tendal" prototype exposed emerges from the participation of a team of undergraduate students and lecturers in the "Construye Solar" contest organized by the NGO Solar Route, the Ministry of Housing and Urbanism, and the Ministry of Environment of Chile. Its goal is the development of sustainable housing, orientated to vulnerable environment families. In the last decade, an intense flow of foreign immigrants has arrived in Chile. Currently, there is a disproportionate concentration of foreign population in central areas and precarious access to comfortable and good-quality housing. Public housing is located in the city periphery, which implies a high rate of emitted CO2 and airborne pollution caused by transportation needs. The question that arises is: What are the current needs of social housing in Chile, particularly for immigrants? This article aims to expose the urban, constructive, architectural and socio-technical feasibility of building blocks with low operation and maintenance costs. Universal accessibility, floor areas and cost regulations where given by the contest rules. An innovative solar clothes dryer to prevent indoor humidity is proposed. Environmental performance simulations where made. The prototype is under construction for being tested on May 2017 during the contest.

Keywords: mixed use, solar dryer, migrants housing, innovative prototype, low footprint.

Introduction

The "Construye Solar" competition is a challenge organized by the NGO Solar Route, the Ministry of Housing and Urbanism and the Ministry of Environment of Chile. It invites universities of Chile and world to develop a sustainable public family house prototype, in order to change and improve their environmental quality and construction technologies.

Full scale prototypes are built to be shown in an open public exhibition. They will also be evaluated on the basis of their energy efficiency, comfort and sustainability, among other aspects (http://www.construyesolar.com/el-proyecto/). Through its demands, the contest constitutes itself as an instrument that enhances sustainability inclusion in the academic and professional fields. This concept encompasses design, construction, operation and maintenance of dwellings.

The “Tendal” prototype exposed in this paper emerges from the participation of a team of undergraduate students and lecturers of the Central University of Chile in the "Construye Solar" contest. This article aims to expose the urban, constructive, architectural and socio-technical feasibility of building low rise blocks with low operation and maintenance costs. This residential building is aimed at the immigrant community and located in a consolidated urban area of Santiago Centro District. There are regulations given by the contest such as: universal accessibility, maximum floor areas and cost which were all taken into account. The team decided to design a multilevel building block complex. This was due to the fact that detached housing typology is not an adequate solution for achieving neither urban, nor environmental high standards, given their high area to volume ratio and low land use efficiency. Besides (PLEA, 2012; CIBWBC, 2013), up to date, few examples of sustainable residential buildings exist in Chile, the majority of them are detached single family dwellings. The prototype is under construction by students and volunteers for being tested next May 2017 during the contest.

Public and Private Housing’s current state: urban and building scale

Santiago´s urban structure and expansion model is based on single use zoning, consisting of purely residential large city areas with no associated infrastructure such as education, convenience stores and workplaces. This fact forces the residents to use motorized transport even for simple everyday tasks. Despite government initiatives intended to improve public transport, both buses and metros continue to be overcrowded and run with no fixed timetable (CIBWBC, 2013). At the same time the policies for achieving social housing targets has led to site selection based on low land value, almost always being located on the city limits. As a consequence, occupants have less on site or proximal work opportunities and incredibly high commuting times associated costs. (CIBWBC, 2013).

In Chile, residential developments and their related services carry on with no significant consideration of sustainability or energy efficiency (PLEA, 2012; CIBWBC, 2013). This results in low habitability standards (IC, 2006), such as low comfort levels in winter and summer, unacceptable indoor air RH and quality levels, all of them causing health difficulties and increasing operational and maintenance costs.

High rates of indoor RH existing in Chilean dwellings deserve special attention, having a major impact on thermal comfort and building pathologies. These rates are intensified in public housing, due to combination of indoor production sources and poor quality construction materials. Among all indoor sources, drying clothes and open flame heaters stand out. They derive and can be prevented through good architectural design practices that involve technical innovation and more restrictive associated regulations.

If clothing is dried within an enclosure (Rivera, 2012), about 10 kg of water vapour per day is released in each family laundry. Mould growth due to condensations in building envelope cause serious health problems. Besides, it implies high maintenance costs and shorter durability of dwelling. As the authors of the guide Welfare Housing: Sustainable

Design Guide for Residential Habitat (U. de Chile et al., 2004) states: “Cloth washing and drying activities should be done outside or in an intermediate private or common space”.

Concerning open flame stoves, its use has extended due to the non-obligation of delivering dwellings with heating system, leaving the users the choice of portable heaters. On the other hand, fuel poverty exists for most of inhabitants of the country. These facts force the population to use open flame heaters and poor quality fuels, a polluting and inefficient heating solution. Cheap fuels used by occupants as Kerosene, LPG, and natural gas produce respectively (Rodriguez, 2009) 2.50, 1.60 and 2.25 kg of water vapour per kg of fuel. The production of indoor humidity increases as a result of the thermally inadequate built envelope because it is necessary to use more fuel to reach comfort temperature levels. Indoor air became very polluted as well.

Immigration’s current state

In the last decade, an intense flow of foreign immigrants has arrived to the country increasing from 1.2% of total population in 2002 to 2.17% in 2012 (INE, 2002; INE, 2012). According to various sources in recent years migration has been characterized by being of Latin American origin, feminine, great ethnic heterogeneity and for being in an active age range (Poblete et al., 2014; INE, 2012; DEM, 2014).

The migratory phenomenon has a tendency to concentrate on certain territories, with a preference for certain cities and within these in particular residential areas (Segura et al., 2014; Poblete et al., 2014). This pattern of settlement, explains itself through the existence of attraction centers expressed through what Segura et al. (2014) calls objective variables for improvement of living conditions. These are the existence of employment sources, high connectivity with central urban areas which also allows jobs access and the existence of a possible housing market for rental or purchase combined with the presence of a primary social network in which the immigrant is inserted.

The Metropolitan Region of Santiago (DEM, 2005-2014) englobes 61.5% of foreign resident total population, the highest percentage of country regions. The capital district that concentrates the most immigrant population is Santiago Centro with 54.4%. This area (Segura et al. 2014) is composed by a system of mixed use neighborhoods with their own identity, where housing and trade coexist. The arrival and concentration of this new collective in the district affects the economic, social and urban morphology of this area. There has been an important neighborhood upgrading in certain areas of Santiago Centro (Segura et al., 2014; Poblete et al., 2014) given by the economic dynamism of immigrants who commonly open new stores and make more dynamic public spaces where they settle.

Within the conditions to foreigner status that must be complied to reside in Chile, housing stands out as the main demand and most vulnerable aspect. They must not only have enough money for renting but also fulfill the requirements to do so. These (Segura et al., 2014) constitute one of the main obstacles to get a house with minimum habitability conditions, and largely restrict their possibilities within the real estate market.

Social sustainability

Based on the studies carried out on the migration phenomenon, it was decided to locate the project in Santiago Centro District: Matta Sur neighbourhood, a working deteriorated area by the abandonment of sheds and warehouses.

The housing project enhances integration by providing immigrants a place of residence through government policies and mixing the migrant-national and foreign population in the same neighbourhood. Objective variables for the improvement of living conditions had to exist: location near city centre, reduced transfer times and distances, presence of services and trade and proximity to employment sources.

Mixed-use residential neighborhoods propose an urban model that emphasizes walkable distances. Motorized transportation is reduced as well as the associated carbon footprint. Strategies based on balancing population density and land-use means a request for urban intensity and active neighbourhoods. Considerations on social, economic and environmental sustainability in design, construction, operation and maintenance stages, helps to improve Nationals' Public Housing standards.

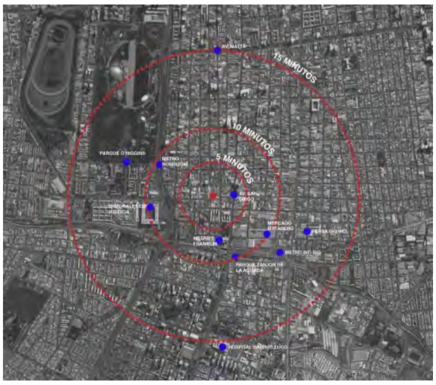

Figure 1. Map of walkable distances from the project site. Figure 2. Housing Complex Image

Locating public housing in a consolidated central urban area and having a mixture of public and private markets helps avoiding socio spatial segregation. Implementing an urban rooftop vegetable garden offers social relation spaces in residential housing, reinforces community strength and social cohesion between neighbors.

The proposed apartment layout is a 59 sq. m. open floor plan with a central core of services and a multiuse walk around arrangement than can create private spaces through sliding doors for different activities. Modular convertible furniture provides a flexible, non hierarquical space. This allows high adaptability to specific needs of immigrant families.

Figure 3. Housing block North façade image

Economical sustainability

Regarding house operation and maintenance, when implementing new technologies would be desirable to have trained tenants to improve certain use habits and to re-enforce their environmental awareness. A manual of active and passive facilities has been made.

When considering economic strategies, the objective is to subsidize the housing complex and the associated equipment with government programmes. A study of the available subsidies has been made, considering among them, one for housing improvement. The house complex will include different values and floor plan apartment typology.

Although renewable energies' implementation is an expensive investment it would reduce operational costs, reflecting these benefits both at personal and public level. The apartment cost, considering construction materials, renewable energy devices, transportation, specialized services and all other costs coming from construction stage reaches $21.000.000 which is the budget allowed for this contest. (aprox. € 30.000)

Environmental sustainability

The project presented is intended for the city of Santiago de Chile. The conceptual design method was Carl Mahoney's, originally orientated to humid tropical climatic zones adapted (Armijo, G. 1974) to be used in other climates such as those existing in Chile.

The climate of Santiago (33º 30´S) has a short and cold winter and a long hot and dry summer, with a mild 15º Celsius annual average. Temperature day and night swings are of 10º to 20º Celsius. This important and differential characteristic leads to design envelope with thermal mass capable to achieve interior moderated peak temperatures. The wind is almost non-existent and rain is about 350 mm per year and only at wintertime.

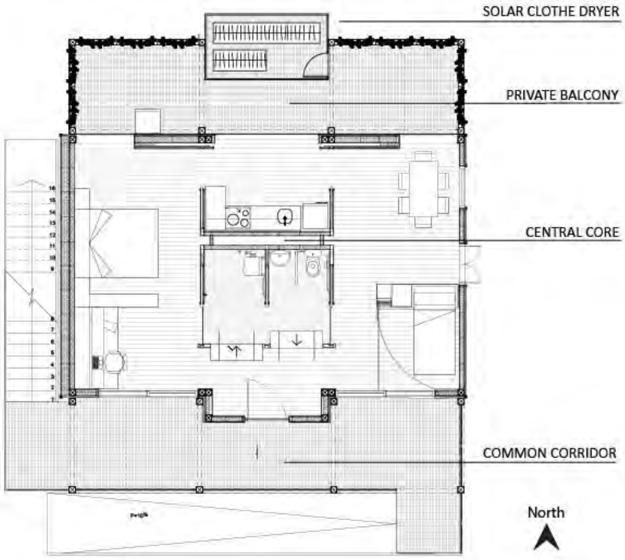

Figure 4. Floor plan"Tendal" housing prototype.

Proper capture of solar energy at block's design is fundamental. After simulations in the equinoxes, solstices at different hours of the day were performed, distance between buildings, shape and dimension of blocks were defined. Good orientation is combined with solar control devices. The single corridor block has its long axis with an east west orientation. The largest façade is facing north - south. In consequence, living spaces are North orientated; access is located South and the facilities in the centre. These facts facilitate cross natural ventilation at summer nights and two-way direction for better daylighting. Central core services are in the most efficient position for facilities and technical services. Balcony floor of galvanized steel grating has double function: outdoor space and semi-transparent solar control device, without blocking air convection. Fully insulated pre-fabricated modules supported by independent steel framed structure with double-glazing and siding with copper impregnated wood, all reduce thermal bridges. The result is a highly efficient dwelling for Chilean standards. The structural system gives the possibility of making light walls with locally certified 120mm sheep wool insulation.

The use of materials with the least possible carbon footprint is considered. Local supplies such as wool and pinewood are chosen. The structural material used is steel, which has a much lower impact than reinforced concrete. Steel can be recycled indefinitely and allows easy assembly and disassembly, turning it into a suitable material for prototype production. Healthy materials are also used, as cooper treated wood frames and exterior façade.

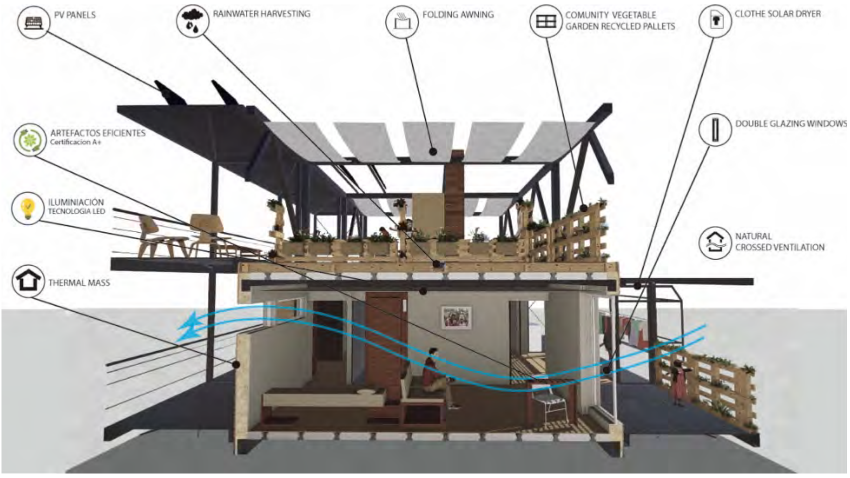

Figure 5. “Tendal” Prototype and community rooftop section.

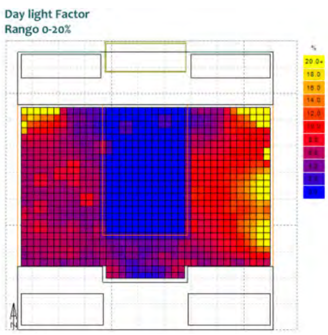
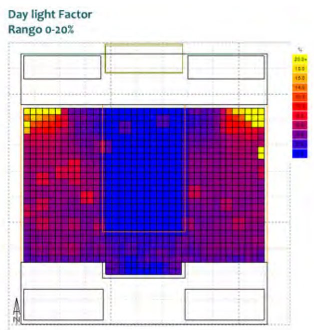
Apartment’s analysis of daylight availability, sun path simulation and Daylight Factor analysis were carried out. Size and location of windows in all four different orientations were defined. Also shape, dimension, layout and solar protections where settled. Design principle of daylighting was light capture coming from north and south. This is associated with summer overheating protection with balconies. Windows principal target it to seek good light distribution, considering the interior furniture space variations.

It is possible to conclude through simulations that the strategies proposed to generate better natural lighting and thermal gain through the radiation improve substantially by incorporating steel grating as the material of corridors and balconies. This allows solar radiation during winter. On the contrary in summer a mobile solar protection is devised in the north balconies.





Figures 6, Daylight factor analysis: favourable apartment case, north, south and east windows.
Figure 7.Daylight factor analysis: unfavourable apartment case, north and south windows.

The solar clothes dryer is a small polycarbonate room attached to the steel frame at north balcony. It has openings at the floor and at the upper front creating natural convective flow. In addition it has a small movable PV to energize a small fan to improve airflow at cold season. It substantially diminishes indoor humidity production, improving hydrothermal comfort and gives an appropriate technical solution.

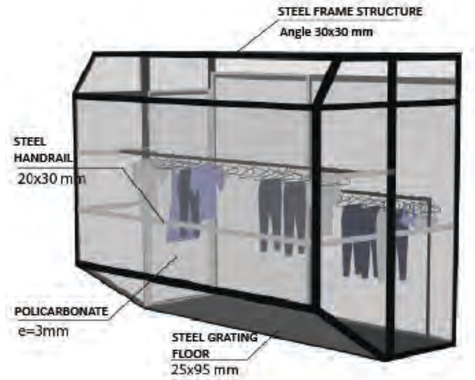


Figure 8. Solar clothes dryer design. Figure 9. Team photo: solar clothes dryer integrated in the prototypes terrace.

Cross ventilation strategy combined with a controlled ventilation system with heat recovery contributes to a good indoor air quality. Natural ventilation should be used in summer mainly at night, periods in which the outside temperature is within the range of comfort (18 to 24 ° C). During winter at cold hours, there is a need of renewing air without opening windows. A heat recovery air to air exchanger will be implemented to reduce the CO2 concentration inside, associated with a CO2 sensor.

Strategies for efficient water use are as follows: economical and efficient faucets and artefacts use and establishing housing energy saving behaviours for occupants at user´s manual. For the housing block wastewater treatment (grey and black waters) the "Tohá System ®" is proposed to be installed. Is a Chilean technology created by Dr. J. Tohá in the University of Chile's Laboratory. The system is also named as Dynamic Aerobic Biofilter.

For hot water supply an electric water heater with integrated heat pump is installed, storing 270 litres at 45°C with COP 4.3. For optimal efficiency, a programme establishing a timetable for its use is settled. The appliance should be working during the day, so the energy comes from the PV panels. During night time water is kept hot with no need for electricity with a minimal loss.

Heating peak demand occurs in August 1st at 6:00 hours, when 2098 watts are needed to keep 19°C. The interior temperature is within comfort parameters range (18 -25 °C) through the entire analysis. A 2 kW convective radiator produces enough energy to cover the demand corresponding to the most unfavourable moment of the year.

The PV panels are located in the rooftop´s steel structure. The on-grid system feeds electrical apartments demand, but energy taken by the grid is valuated only 60% of the regular tariff. As a consequence electrical appliances should be used in daytime so the electricity is provided by the panels. The heat-pump consumes 0.6 Kw and for a 150 liter daily demand 4.8 operation hours are needed. This situation is satisfied between September and April and partially between May and August. Between October and March there would be a surplus for consumption.

Conclusions

Supportive, inclusive mixed and dense house prototype is achieved. As the project is founded in the migration phenomena a sensible design of 4 levels blocks with moderate density is proposed. It is a mixed-use, modular, collective block. It is situated within the deteriorated city centre connecting houses to urban centres, services and jobs. Open plan apartments are flexible for housing different family groups. Vegetable gardens are located at a portion of shaded rooftop for community work and in private balconies for families.

Environmental strategies for Santiago are adopted with design decisions for design for Mediterranean climate. These are: single corridor block with main facade and private balcony facing north; Solar clothes dryer and space for gardening; translucent corridor so light can pass through and envelope U values 21 % of standard Chilean Regulations.

Clothes solar dryer substantially diminishes indoor humidity production, improving hydrothermal comfort and gives an appropriate technical solution.

The construction of this residential building prototype is technically feasible with the current local resources, technologies, knowledge and construction related professionals, with no air pollution emission and with much lower environmental footprint.

At the contest, Tendal prototype won the first prizes in Sustainability, House Comfort Performance (monitoring) and Water Usage; Second prize in Architecture and Urban Design ; third prize in Innovation and Interior Functionality.

The Use of Passive Cooling System for SME Hotel Renovation

Kawin Preechawuttidej[1] and Pattaranan Takkanon[2]

[1] Master of Architecture (Building Innovation), Kasetsart University, Bangkok, Thailand, kawinisoe@gmail.com
[2] Department of Building Innovation, Faculty of Architecture, Kasetsart University, Bangkok, Thailand, pattaranan.t@ku.th

Abstract: Shophouse is the most common building type in Thailand, this type is increasingly popular for small-to-medium enterprise (SME) hotel business. Shophouses have been renovated to be hostels these days. Nonetheless, most of them are closed areas and rely on air conditioning system. The research aims to promote natural ventilation and combine passive cooling techniques for solving problems and saving energy. The experiments are divided into 2 series: 1) CFD simulation to test effects of opening positions and sizes for cross and stack ventilation; 2) Thermal simulation to select case from the first series, then test effects of double roof and night ventilation. Results from the first series show that the best case in terms of air flow rate and wind distribution is the plan with 1.50 meter wide both inlet and outlet which are not in line with the staircase. Average wind speeds range from 1.4 to 2.1 m/s which promote occupants' thermal comfort in a common area. Results from the second series show that night flush is more effective than having double roof especially during the night in winter as the average temperature reduction is 2.4°C. This can alleviate overheating condition in closed area of a guest room.

Keywords: Hostel, Shophouse, CFD (Computational Fluid Dynamics), Passive cooling, Sustainable architecture

Introduction

Hostel is becoming popular in Bangkok and other scenery towns. Thailand is located in hot-humid climatic region experiencing high air temperature and relative humidity. It is more feasible to use passive cooling techniques to provide comfort in shophouse that is renovated to be an SME hotel. The passive design approach might also suit travellers' behaviour better than active design approach since they prefer to spend time outside.

Passive cooling

Passive cooling techniques are part of passive design approach which aim to transfer heat from its sources to sinks such as the sky or water without using electrical equipment (Givoni, 1994). An example of adaptive reused space of a tropical shophouse which is unnecessary for active cooling can be found in Penang as shown in Figure 1 (Omar et al, 2011).

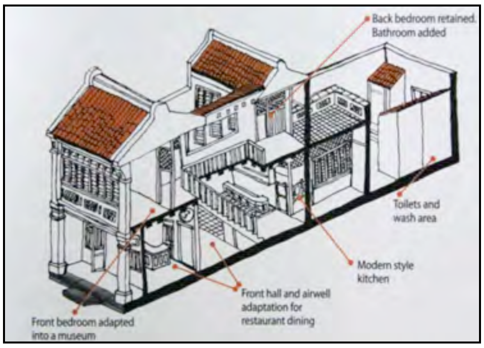

Figure 1. Penang traditional shophouse

This traditional building adopted many techniques including stack ventilation, night flushing and buffer zone to prevent and reduce heat.

Ventilation

A suggestion is the staircase should be in the middle of the shophouse as an atrium for stack ventilation (Prasongsamrit, 2016).

Figure 2. Staircase in the middle

Comfort zone

Cooling effect from air movement can be calculated from equation 1 (Szokolay, 2004).

$$dT = 6\ v_{eff} - 1.6\ v_{eff}^{2} \qquad \text{.....eq.1)}$$

Where v_{eff} is Effective velocity $= v - 0.2$
and neutral temperature can be calculated from equation 2 (Auliciems, 1981).

$$T_n = 17.6 + 0.31\ T_{av} \qquad \text{.....eq.2)}$$

Where T_n = Neutral temperature, °C
T_{av} = Mean monthly outdoor temperature
Then upper comfort limit is T_n + 2.5°C and lower comfort limit is T_n - 2.5°C.

Methodology

The present work starts with field survey to find a typical shophouse hostel. Then using computer simulations, the first series to analyse CFD in the case study building by considering airflow characteristics and velocities. The second series is conducted by adding other strategies from the first series and analysing thermal condition. Finally, appropriate design guidelines will be proposed.

Field work

The field survey involves 10 samples of renovated shophouse hostels nearby the airport link terminal. The methods include questionnaire survey, taking photos and measurement work.

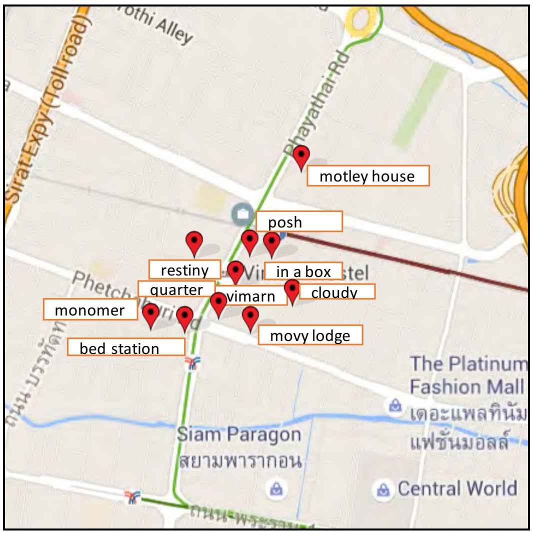

Figure 3. Hostels surveying

Typical plans for simulation

There are 13 possible plans for the study. Their design variables are opening location and opening size that comply with building regulation. Base case has inlet on the first floor and outlet at stair ceiling as it is the common design. Set A has additional inlets on the second and the third floors and set B has additional outlets at the back of the building.

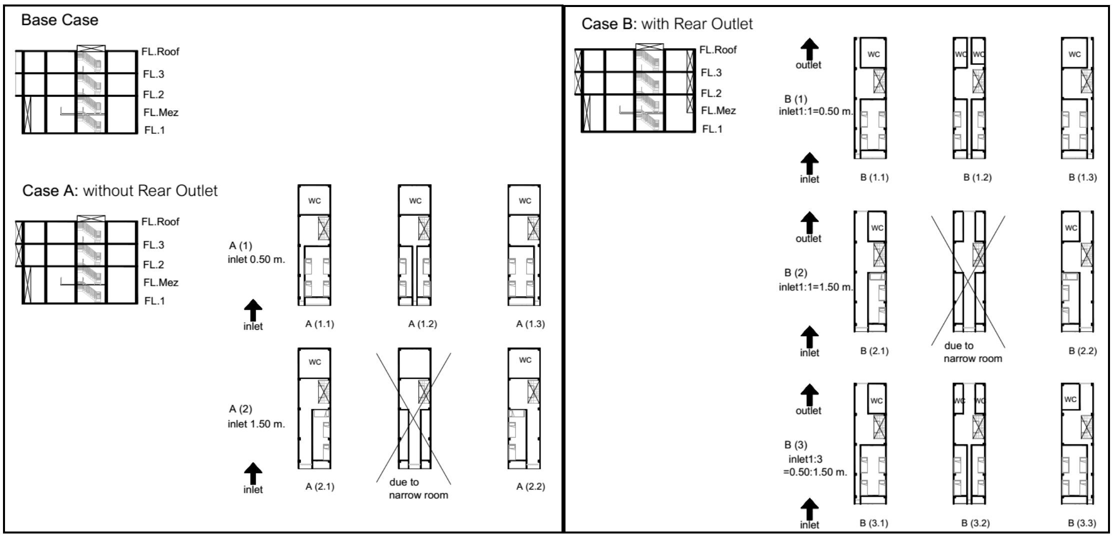

Figure 4. All cases of 13 different plans

CFD Simulation

According to the weather data of Bangkok, an hourly average of wind velocity for the whole year is 1.15 m/s. Frequency of wind velocity ranging from 1 - 1.5 m/s is the biggest as it takes 28.3% of all. Therefore, this study uses 1.2 m/s for the experiment. In each case, indoor air velocities are measured at 14 measurement points locating on plane X and Z in common areas.

Figure 5. Measurement points

13	**B (3.3)**	1.48	1.45	1.81	1.85	1.7	0.5	1.24	0.48	1.72	1.28	1.46	1.56	2.66	1.61

Figure 6 presents indoor air velocities at measurement points of all cases. Data from the table can generate two graphs showing velocities on the sectional planes, 8 points on plane X and 6 points on plane Z.

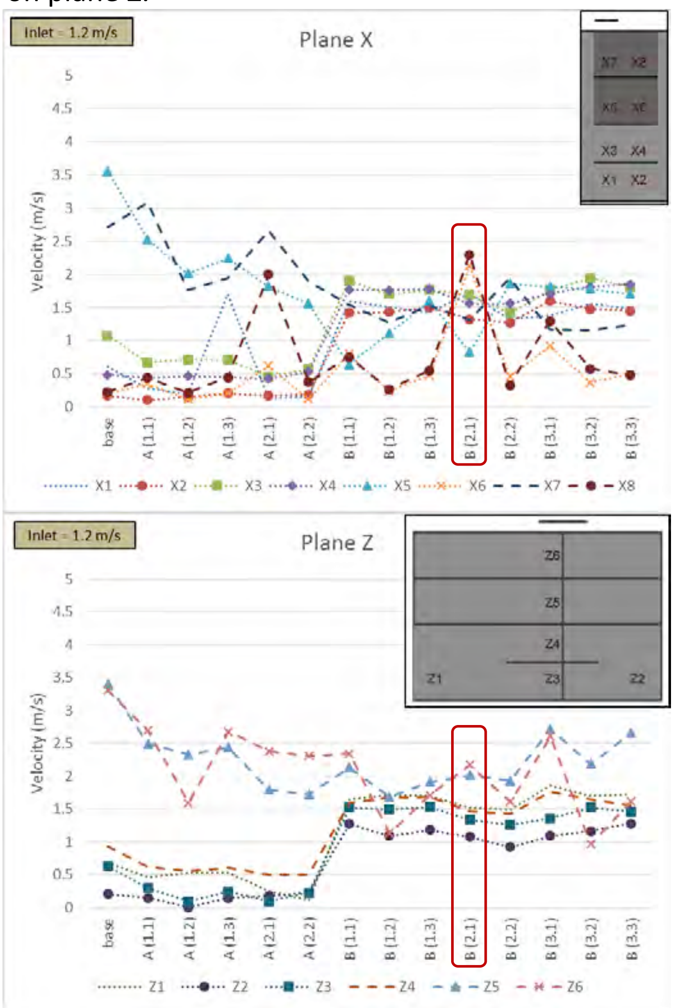

Figure 6. Graph shows indoor velocities

Plane X shows that Case 2.1 of set B gives the highest velocities significantly due to the opposition of inlet and outlet and they are not in line with the staircase. On plane Z, Case 3.1 of set B shows velocities (Z4, Z5 and Z6) much higher than others but there are some points showing low velocities (Z2 and Z3). When considering all 14 points on both plane X and Z which are common areas, Case 2.1 of set B shows the best level of wind distribution consistency and high average wind speed ranging from 1.4 - 2.1 m/s.

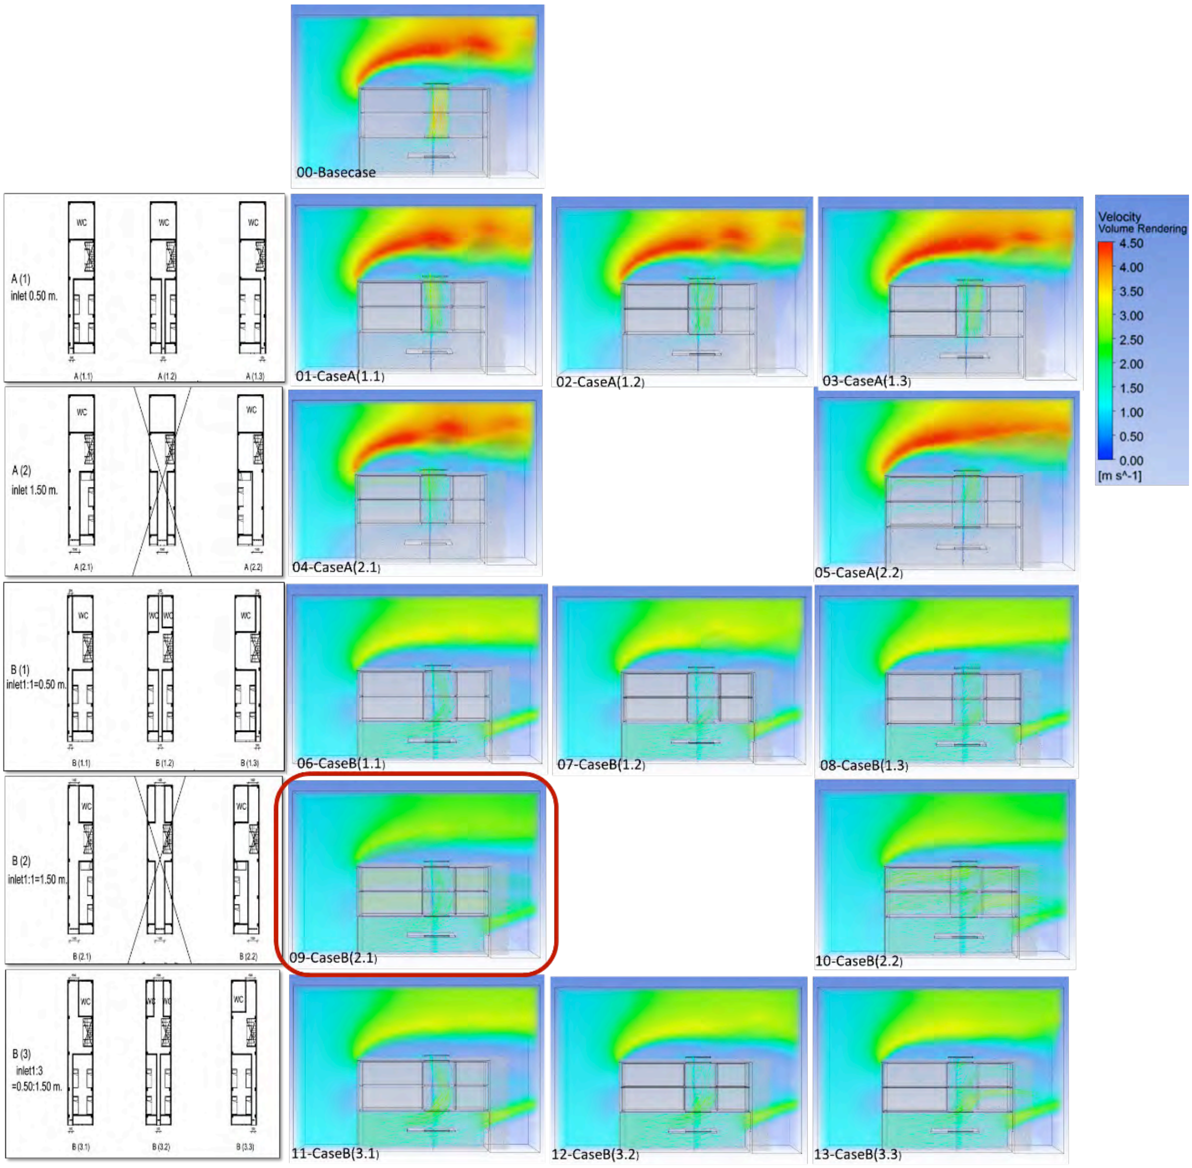

Figure 7. Airflow comparison by colour contour

Figure 7 shows the difference between each case by colour contour. All cases of set A show very high wind velocities (red) about 4.5 m/s at the front top and very low speed (dark blue) at the first floor inlet. Every case of set B with outlets can promote more wind (light blue). However, Case 2.1 of set B, in particular, has the lowest rate of fluctuation.

Thermal simulation

Taking Case 2.1 of B as the best case from previous experiment as it gives highest indoor air velocities by average, this part is aimed to further study other passive design strategies including double roof and night ventilation. The cases for comparison are base case, case 1 with double roof, case 2 with night ventilation (8pm-8am), and case 3 which is the combination of case 1 and 2. Results show that winter season has better efficiency than summer and rainy season because the very low temperatures at night have an impact when opening the building during the night. Besides, double roof gives small temperature reduction in every season.

Table 2. Overall comparison of difference

°C	Double roof	Night flush	Combine
Winter	0.35	2.40	2.70
Summer	0.39	1.32	1.64
Rainy	0.11	1.21	1.30

Since winter shows biggest differences, its results are analysed in terms of indoor air temperatures as shown in Figure 8.

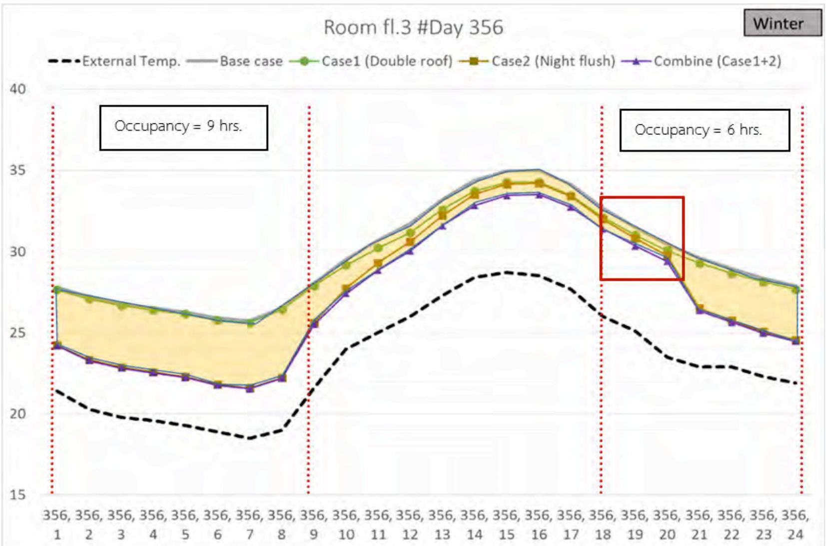

Figure 8. Graph shows air temperature in winter

Table 3. Temperature different between addition strategies and base case in winter

Winter	Hour	External	Base case	Case1 (Double roof)		Case2 (Night flush)		Combine (Case1+2	
Resultant Temp.	356, 1	21.4	27.8	27.65	0.15	24.25	3.55	24.19	3.61

	Temperature diff. from Base case (Hourly)				0.35		2.40		2.70

This table shows the different temperatures from 4 cases. Case 2 (night flush) is very effective since it can reduce air temperature by 2.4°C on the coldest day of the year while Case 1 (double roof) is not obviously effective.

Analysis

The result from Case 2.1 of set B shows that an average velocity from 14 measurement points is 1.60 m/s when velocity at inlet is 1.20 m/s and the cooling effect can then be calculated from equation 1.

$$dT = 6\,(1.6-0.2) - 1.6\,(1.6-0.2)^2 = 5.26°C$$

When the mean temperature (T_{av}) of every month in Bangkok is 29.3°C. Therefore, the neutral temperature can be calculated from equation 2.

$$T_n = 17.6 + 0.31(29.3) = 26.7°C$$

The upper comfort limit becomes 26.7+2.5 = 29.2°C. With the cooling effect from air movement, the comfort limit can be extended by adding dT, thus, 29.2+5.26 = 34.46°C.

Design guidelines

Ventilative cooling

From the results of all cases, it can be concluded that openings for cross ventilation can provide consistent wind distribution when the openings at the front and the back of the shophouse are not in line with the staircase. The minimum opening width for inlet should be 1 meter and it could be located in corridor axis to gain more wind.

Nocturnal ventilation

For further strategies, operational time can be controlled by occupants. During the night, opening windows for night ventilation is recommended.

Using double roof

To use double roof, there should be no obstruction for the wind which can trap the heat. However, using double roof alone is not effective to control internal heat.

Further suggestion

It is recommended to use insulation above the ceiling to prevent incoming heat and fan could be used to enhance cooling effect, thus bringing the indoor condition down to the comfort level (Takkanon, 2006). Plants can also help prevent dust and improve micro-climate.

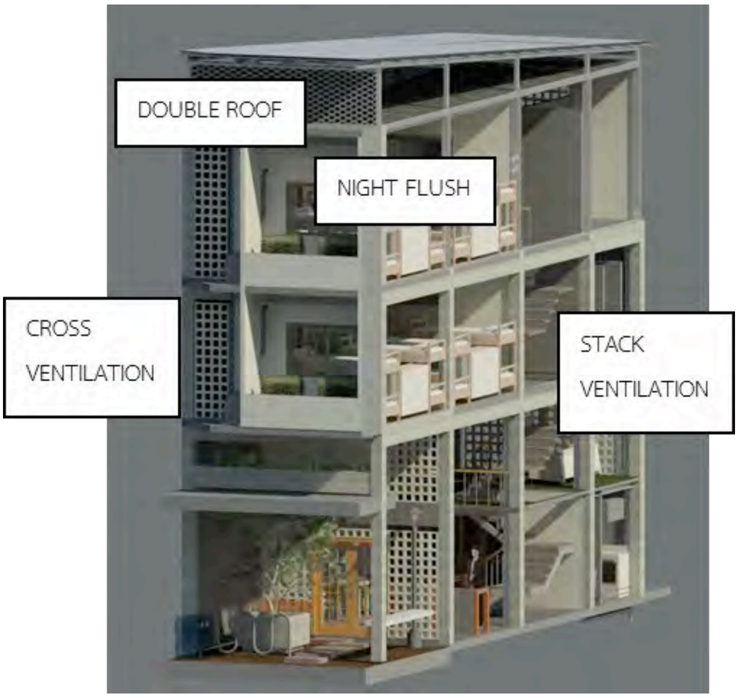

Figure 9. Presentation model

Conclusion

Thermal condition of shophouse hostel can be improved by using passive cooling strategies which are worth an investment. The experiments show an extension of upper comfort limit by up to 5.16°C by providing the openings at the front and the back of the shophouse for cross ventilation and they are not in line with the staircase which promotes stack ventilation. This can solve problems about collecting heat and humidity in common areas such as corridor nearby shared bathroom, community zone, and space under the roof, etc. Night flushing along with double roof also further improve average hourly indoor air temperature by 1.2 – 2.4°C in closed area especially the top floor guest room. Therefore, shophouse SME hotels can improve thermal condition without air conditioning while saving energy and serving the preference and behaviour of guests who normally go out during the daytime.

Environmental Conditions for Improved Productivity: A Case for Adapting Post-war Constructed Office Buildings in UK

Thajnu Rashid[1], Mariam Kapsali[2]

[1] Architectural Association School of Architecture, London, United Kingdom
[2] Architectural Association School of Architecture, London, United Kingdom

Abstract: Post-war constructed office buildings exist within a pre-defined set of physical, aesthetic and environmental constraints. This research proves that revitalising existing structures by tackling their constraints through responsive interventions can be a catalyst for change in an attempt to counter carbon emissions and adapt these buildings to a warming climate. Research was undertaken by doing a comparative field work between two post-war constructed office buildings that are very contrasting in nature, Elizabeth II court, Hampshire has gone through extensive refurbishment using environmental design strategies and Lee Gate House, Lewisham has seen only minimal changes over the years. Findings from field studies were further validated through analytic studies in order to crystallise an environmental design framework that can be used as a refurbishment approach for upgrading these buildings.

Keywords: Urban Regeneration, Office Buildings, Productivity, Refurbishment

Introduction

Energy used by non-domestic buildings approximately contributes 18% of UK's carbon emissions. By 2050 it is estimated that floor area used by non-domestic buildings will increase by 35% and 60% of this will be made by existing building stock (DCLG, 2005b). According to the valuation agency of the UK government, post-war constructed office buildings constitute 40% of the non-domestic building stock in UK today. There will be a huge environmental cost to pay, if a 'demolish and rebuild' path is chosen to replenish the entire non-domestic building stock. This leads to a compelling argument for extending the life of post-war constructed office buildings by refurbishing them.

Current state of post-war constructed office buildings varies widely with some being listed for demolition or left unused, while others are being converted to apartments or continuing to function as offices. Latter has poor internal environmental conditions compared to modern offices. Commonly seen issues in buildings functioning as offices are poor daylight, overheating and substandard indoor air quality (Burton et al, 2000). These issues create poor working conditions for occupants which in turn has a detrimental effect on their productivity (Nicol et al, 2007). This research focuses on refurbishment strategies that could be used to improve internal environmental conditions, consequently enhancing productivity of office users and extending the life of the building.

Building Characteristics

The most common office building typologies constructed during 1960’s are deep plan type and the spinal/rectilinear type (Burton et al, 2000). This research focuses on adaptation strategies for the rectilinear typology, as it provides more flexibility in modifying the building envelope.

Figure1. Deep plan and rectilinear typology of 1960’s Office building construction (Source: Burton et al, 2000)

Rectilinear typology has linear floor plates which were originally designed for cellular workspaces connected by a central corridor. These are heavyweight buildings with two vertical cores. The envelope plays an important role in the overall energy consumption and indoor environment.

These buildings include cavity walls with U-values between 1.3 to 1.7 W/m2K (Baker, 2009). The construction method constitutes of in situ concrete super structure and the fabric is made of pre cast concrete frames with infill panels.

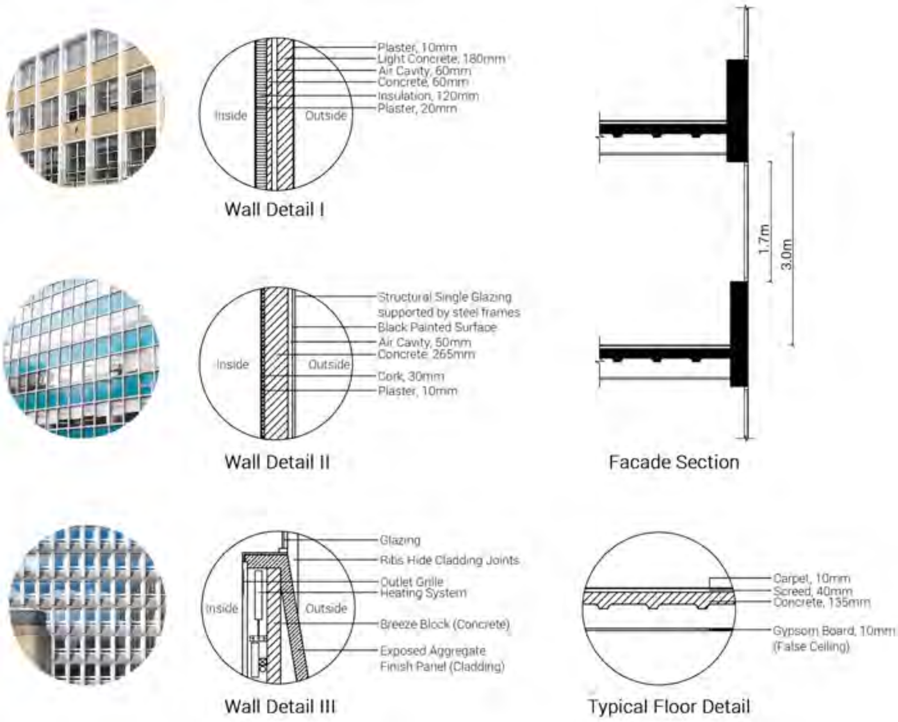

Figure2. Typical wall construction details of office buildings built from 1950’s
(Source: Baker, 2009; Botti, 2012)

Office Buildings under this typology are typically exposed to the outdoor environment with minimal obstructions from surrounding buildings. Environmental conditions may vary depending on the location of building, offering a multitude of design possibilities for retrofit. The top storeys of these buildings are exposed to higher solar gains with minimal or no obstructions, while the lower floors are usually used for retail.

Productivity

A holistic approach to office design or refurbishment should consider the environmental parameters that can be influenced by a designer to make the work space more productive. There is clear evidence from existing research that thermal environment has significant impact on the productivity of office users (Roelofsen, 2002; Nicol et al, 2004). A single temperature value for peak productivity is not justifiable in a free running environment since it does not consider physical and behavioural adaptation of the occupants. Majority of studies on actual office buildings, relating productivity to thermal environment indicates stable productivity conditions can be achieved within the range of 21^{0}C to 25^{0}C and that productivity may drop up to 2% if temperature go above or below this range(Roelofsen, 2002; Sepanen et al, 2006; Nicol et al, 2004; Lan et al, 2010). This research aims to explore design parameters that will have an influence on productivity by improving internal thermal conditions.

Fieldwork

Field studies were conducted in two post war constructed office buildings representative of the rectilinear typology aiming to evaluate the impact of indoor work environment on user's perceived productivity.

Leegate House, Lewisham, London

Typical of the 1960's concrete frame structure, the building envelope is made of pre-cast concrete with thermal plasterboard insulation and facial brick cladding. The building was refurbished in late 1990's, with minor interior and service repairs. Energy bills of 2015 indicate high energy consumption with an annual load of 250 KWh/m^2.

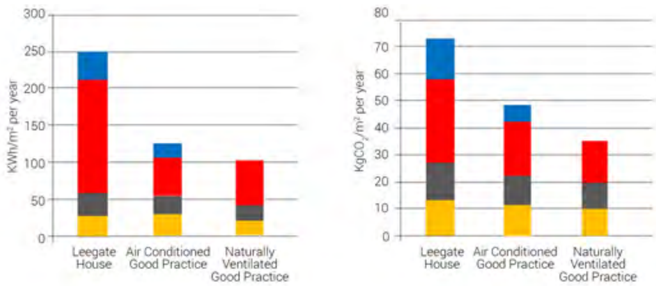

Figure 3. Comparison of annual energy consumption and Carbon emissions with good practice standards, CIBSE guide F.

Figure 4. Aerial view of Leegate House. Sun path (Source- www.gaisma.com) (left) and main elevation of Leegate House facing west (right).

The second and fifth floors of the building were chosen to be studied since the floor layouts are adapted to different working patterns and businesses. The measurements were taken on 13th to 20th of May.

Internal temperature within the workspace follows the fluctuations of outdoor temperature very closely due to the impact of lightweight interiors (Figure 5). Poor envelope performance and uncontrolled infiltration through fenestration has lead to high heat loss during night time, which indicates high heating loads during winter.

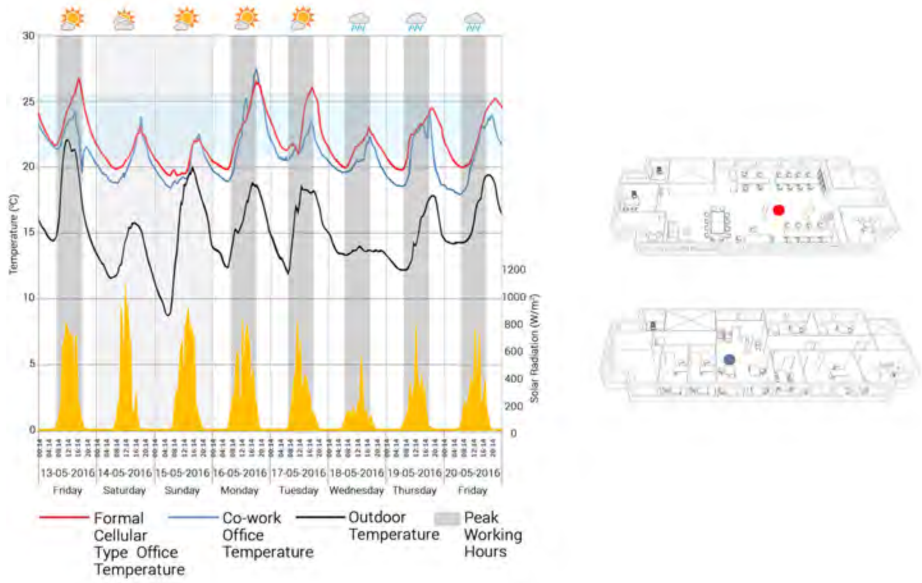

Figure 5. The graph on left shows comparison of data logger readings from Co- work and Formal Cellular type offices in Leegate House. Key Plan shows position of data loggers in both floors.

There is frequent over-heating within the formal office which is free running during summer. Temperature peaks are observed in offices on working days with high occupant density. Current occupant density is low when compared to British Council for Offices density standards. With higher occupant density, the overheating risk is higher. 90% of the occupants reported poor productivity levels due to uncomfortable thermal conditions within the building.

Tenants frequently experienced glare and had to rely on roller blinds to counter this problem and direct solar gains during working hours. This quite often led to a ‘blinds down lights on effect’ with low daylight levels. This field study clearly shows that interventions of this type did not help improve indoor environmental conditions. The design possibilities offered by the structure are often left unexplored and lead to uncomfortable working conditions that may crucially affect the health and wellbeing of the occupants.

Elizabeth II Court, Winchester

Elizabeth II Court was chosen for second field study as it is a good example of refurbishment that made indoor environmental conditions on par with new build offices. The building consumed 260kWh/m^2 of energy before refurbishment with annual carbon emissions of up to 72 kgCO_2/m^2 primarily due to leaky pre-cast concrete facades (Figure 6). The building was stripped back to its concrete frame, new services and innovative natural ventilation systems were integrated within the constraints of an urban context.

Fieldwork was carried out on third and fourth floors of this building, since third floor retains original concrete frame and fourth is an extension to the existing structure. Spot measurements were taken, measuring air temperature, air velocities, surface temperature and lux levels at different floors. Data loggers were placed on these floors from 2nd July to 9th July in order to track temperature and humidity variations throughout day and night.

Users of these two floors were surveyed through a set of questionnaires on occupant comfort and satisfaction of the work environment.

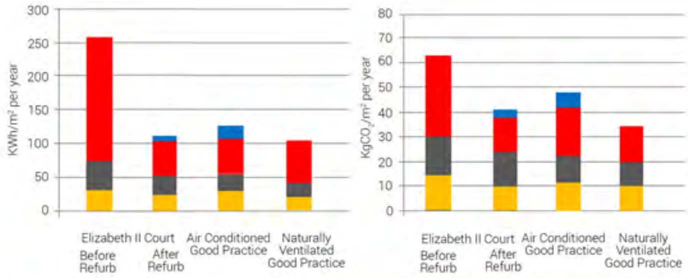

Figure 6. Comparison of annual energy consumption and Carbon emissions with good practice standards, CIBSE guide F

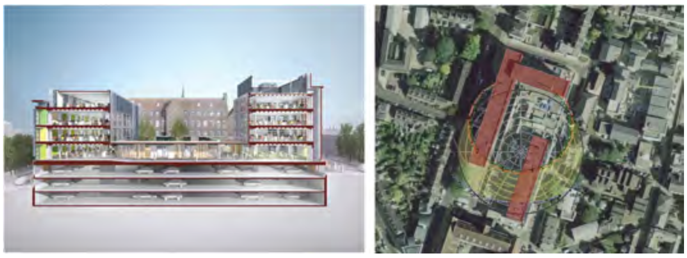

Figure 7. Sectional elevation of the building facing South (left). Lower three floors are used as car park and workspaces are located on the upper floors. The complex is bound by busy roads on the North, East and West sides (Fisher, 2008). Aerial view of Elizabeth II Court in Winchester (right) Sun path (Source- www.gaisma.com)

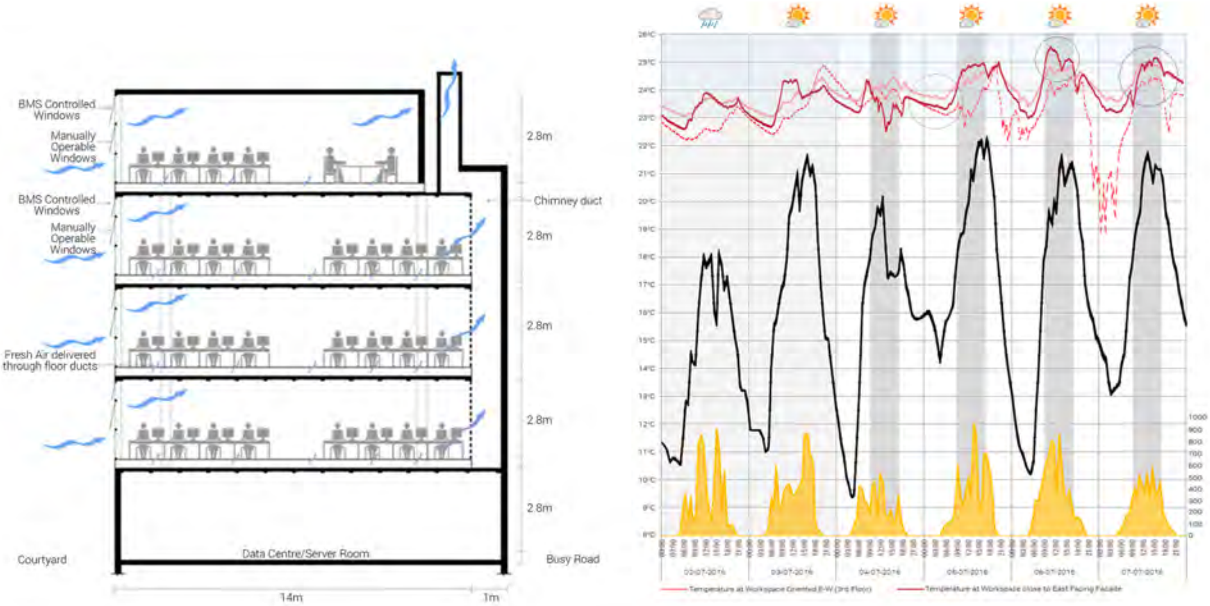

Figure 8. Image on left shows wind driven ventilation system, driven by air movement facilitated through automatically controlled windows facing internal courtyard to pass through a series of chimneys along the facades facing the streets. Graph shows temperature variation within block facing East-West (right). Data loggers were placed on three locations- close to the facade, centre of the workspace and inside the chimney.

On site spot measurements showed that average indoor temperature was around 3.5°K above the outdoor temperature. The effect of night ventilation and thermal mass of the existing structure can be seen on 7th of July where stable indoor thermal conditions are maintained through opening of the chimney shafts (Figure 8).

The temperature fluctuations within fourth floor extension had shown unstable thermal conditions. Users of this floor perceived low productivity levels when compared to third floor. Survey results revealed that occupants are concerned by the operation of automated windows, controlled by building management system. The set point temperature when windows open is set to 15^{0}C during mild and summer season. Users expressed discomfort especially during mild climate as temperature often dropped below comfort. Fine-tuning the settings with slightly higher set points during mild season can help to resolve this problem.

Overall occupant survey results showed highly satisfactory working conditions. And occupants were sensitive in the ability to have an influence on their immediate surroundings. The most valued aspects included ventilation control, window operability, shading control and daylight quality of the workspace. Although users expressed discomfort at temperature above 25^{0}C, they were able to maintain comfort with the help of desk fans. This highlights that in a free running building, provision of adaptive opportunities to users helps to maintain productivity at higher temperatures (Baker, 2009).

Refurbishment Strategies

Simulation Studies

Office spaces in post-war constructed buildings are either owner occupied or leased out to the tenants. Strategies for improving the indoor environment range from possibilities of minimal to deep refurbishment practices. Three levels of refurbishment strategies are tested based on the potential of passive environmental strategies.

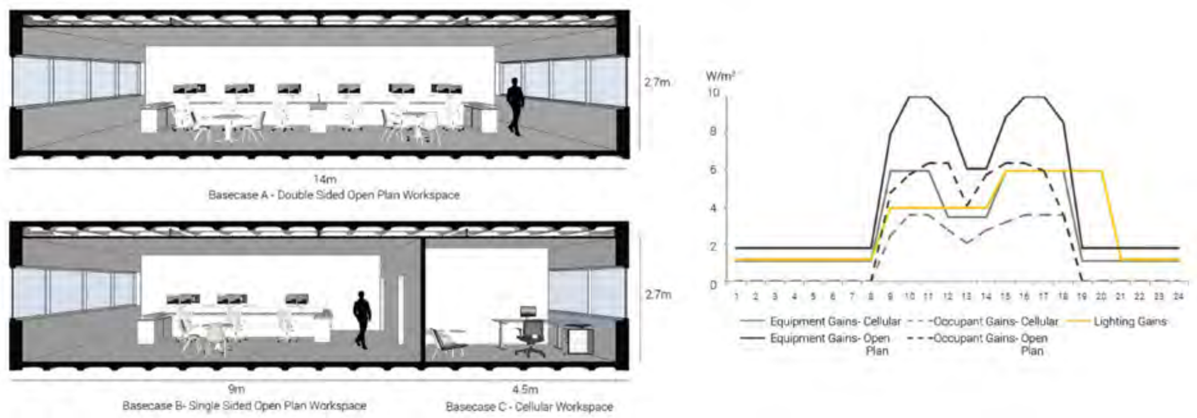

Figure 9. Image on left shows framework for base case, derived from structural characteristics of 1960's office building typology. Graph on right shows internal gains considered for the analytic study.

Aim of analytic study is to identify different intervention options and to estimate how these would result in improving comfort and productivity of the occupants. Improvement in productivity is measured using the criteria defined under the productivity section of this paper. The potential of the existing facade typology and structural characteristics of the buildings were analysed to develop simple and practical solutions for refurbishment. Open studio and Energy plus software were used for thermal simulations and DIVA plug-in for Rhinoceros 5 software was used for daylight simulations.

- × Strategy 1 implementation includes only internal changes without altering facade elements or services.
- × Strategy 2 implementation includes Scenario 1 changes plus facade re-cladding.
- × Strategy 3 implementation includes replacement of the facade and services

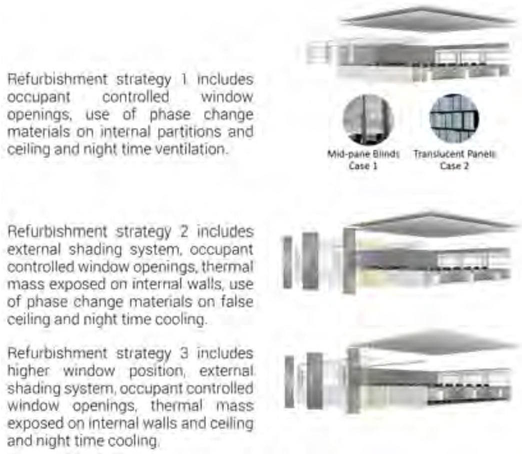

Figure 10. Illustration of three refurbishment strategies

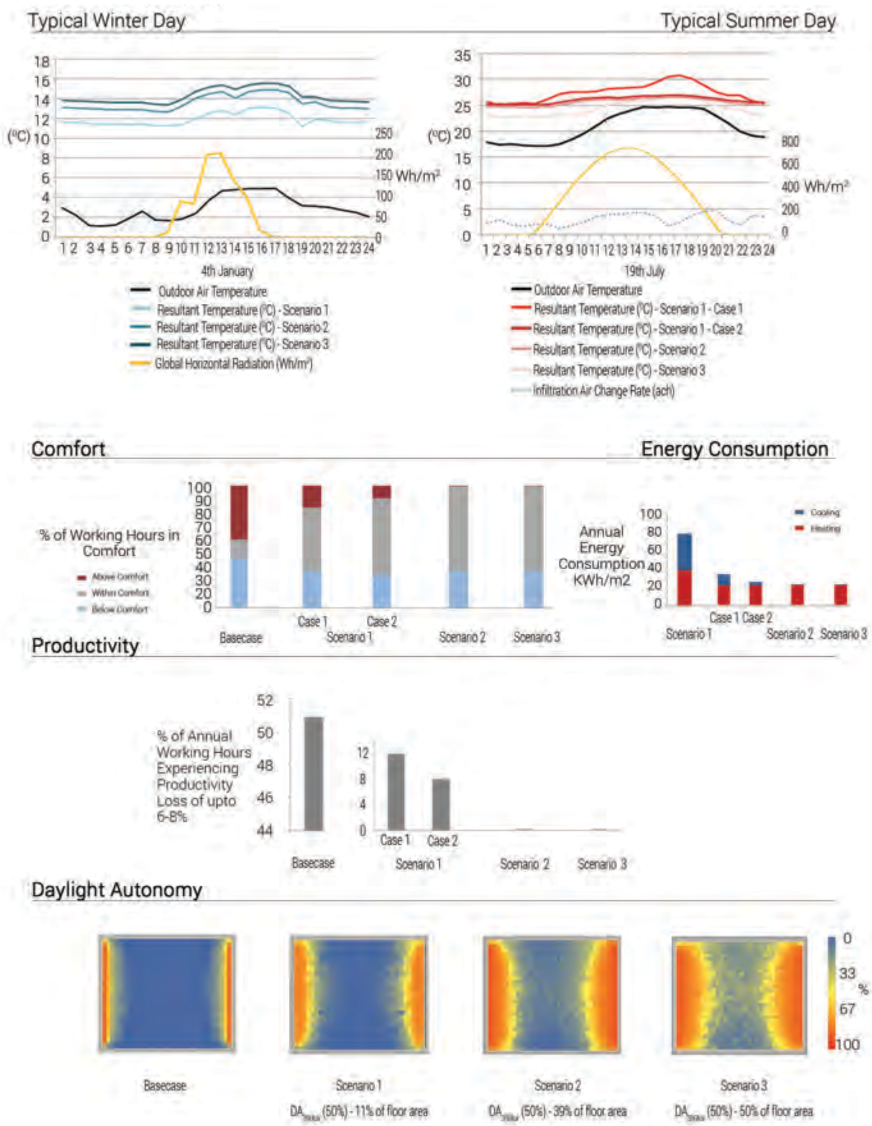

Figure 11. Simulation results for refurbishment strategies 1,2 and 3 (Source: Open Studio, Energy Plus, DIVA)

Outcome from analytic studies implies that 5-6K temperature difference can be achieved by application of night cooling with exposure of thermal mass. Further, use of overhangs increases the number of occupied hours within comfort by 24% when compared to the base case with no shading device. Significant improvements in visual and thermal performance can be achieved through refurbishment strategies 2 and 3. Productivity loss is completely minimised in both cases due to improved thermal comfort.

Strategy 3 improves daylight quality of the work-space remarkably by achieving mean daylight autonomy of 50%. Simultaneously the adaptive nature of external shading devices minimises glare problems.

Adaptability of facade elements to external environmental conditions is an efficient method to achieve a range of comfortable conditions within the workspace whilst simultaneously providing occupants an option to control their immediate surroundings.

Conclusion

This research aimed to extend the life of post war constructed office buildings and improve occupant productivity through the application of environmental design strategies. In this built typology, envelope plays an important role in overall energy consumption and in regulating indoor environmental conditions. Integration of passive solar and daylight strategies was proven effective to counter thermal and visual discomfort. Further application of passive cooling measures significantly minimised overheating and energy consumption achieving free running conditions during mild and summer period.

Thus revitalizing the existing structure by tackling the constraints through responsive interventions can be a catalyst for change to counter carbon emissions and adaptation of these buildings to global warming.

The proposed design framework influences productivity through a responsive physical work environment. After provision of a shell which offers physical comfort, psychological and functional factors are the other aspects which influences occupant productivity in workspace. Further research needs to be done in this area to understand the role a designer can play in influencing these factors.

Abstract: A reduced shape factor of the building has become a general recommendation in order to achieve eco-efficient architecture in any climate in spite of the fact that it was made to be applied to cold climates. As a result, this pattern of compact shapes is widespread all over the world. However, it is based on a simplified model of the interaction of architecture with its environment in which the air surrounding the building is considered to be at the same temperature. Nevertheless, this paper will show that in climates such as the Mediterranean, the existence of microclimates induced by the building itself, for instance inside internal courtyards, indicate a more dynamic interaction. In spite of a higher shape factor, more complex shapes can be explored that take advantage of these microclimates to achieve more eco-efficient buildings.

Keywords: microclimates, shape factor, Mediterranean climates, courtyard, eco-efficiency.

Introduction

The most efficient strategies for increasing eco-efficiency in buildings are those adopted in the early stages of design (Olgyay & Olgyay 1963). The shape of the building, the most prominent aspect of the architect's responsibility, is one of these. It would therefore be useful to provide clear and simple criteria to be used by architects to orientate them from the first sketches. Unfortunately, it is not this simple as we will show in this document.

One of these criteria is the shape factor that relates the envelope of the building and its interior volume (F_f=S/V). Widespread recommendations on energy-efficient building design, such as, “Passivhaus primer: Designer’s Guide” (International Passive House Association 2014) advise reducing the envelope transmittance as well as reducing the surface to volume ratio of the building. That is to say, they suggest compact designs that reduce the shape factor. The objective is to limit the energy flow, preserving the largest quantity of energy possible in the interior. It is true that the recommendations, such as Passivhaus, permit greater shape factors but in exchange for an uneconomical increase of insulation.

In spite of the fact that it was created for cold climates, this simple paradigm has been imposed by different administrations in many countries with warm climates (Spain being among them), by means of laws, criteria for public tenders or mandatory energy ratings.

This has led to the increasingly widespread appearance of buildings with very simplified shapes. Designing buildings with the shape of very compact boxes, cylinders or spheres is considered a good solution to guarantee better energy efficiency. This condition in current architectural design in both warm and cold climates may result in architecture with more complex shapes and spaces like internal courtyards becoming less common. Several authors express doubts about the validity of this shape factor for warm climates (Depecker et al. 2001) and even for colder climates (McLeod et al. 2013; Sameni et al. 2015).

Hypothesis for homogeneous outside temperature

The recommendations that limit the shape factor are based on physical principles taken into account in energy simulation programs. The energy exchange with the outside is transmitted through the building surface, the envelope. Therefore, limiting this exchange, by decreasing the surface of a given volume, can help to maintain the difference in temperature between the inside and outside with less energy consumption.

Energy simulation programs, such as EnergyPlus TM, that assume these principles have served as the basis for numerous scientific papers (Gratia & De Herde 2003). This scientific information was used in turn to justify the recommendations and energy regulations which favour the restriction of shape factor. Official programs for the mandatory evaluation of energy performance certificate for buildings, such as Lider-Calener in Spain, use the same approach, favouring more compact designs for buildings (Díaz Guirado & Allepuz Pedreño 2016), that is to say, with a lower shape factor in the warmer regions of Spain (Fig. 1a).

b

Figure 1: a) Energy for cooling and heating different building shape with same volume according to Lider-Calener (official Spanish software). b) Comparative analysis of different energy calculation software.

At this point, an important issue arises: the bases for calculation of these programs accept the hypothesis that there exists only one external reference temperature for the Outside Surface Heat Balance in any weather. In cases such as EnergyPlus, they allow a reduction in the outside temperature when increasing the height of the centroid of the thermal zone/surface, at a rate of about 1ºC per 150m of height (The Ernest Orlando Lawrence Berkeley National Laboratory 2015). Therefore, these simulations assume the existence of a homogeneous exterior space that allows the adoption of a simplified exterior-interior heat transfer model.

Different energy calculation software has been analysed (Fig. 1b). Despite the fact that some of them, such as EMVI-met or Green Canyon, allow an approximation of different aspects of microclimatic behaviour in courtyards, only original numerical simulations with FreeFem++ have been able to calculate a precise difference in air temperature from that of the air temperature outside (Rojas-Fernández et al. 2012).

Experimental

To verify precisely if there is a single homogeneous exterior temperature, as most programs assume, a monitoring campaign has been developed, analysing real existing buildings in Andalusia (Spain). The outdoor spaces selected are very characteristic of the architecture in the area: courtyards (Fig. 2). The buildings are located in Córdoba and Málaga, constituting a good representation of different variants of the Mediterranean climate in Spain. Courtyards of different sizes and types have been chosen. Wind speed and direction, surface temperature of walls, boundary layer temperature, humidity and temperature, simultaneously in different parts of these spaces and on the roof of the buildings, have been recorded. The data loggers are specific for measuring outdoor temperatures and have been protected from the direct incidence of solar radiation.

a

b

Figure 2a,2b: Courtyard studied in the present research: a) 17th Century building, Córdoba, Spain. b) Contemporary hotel in Málaga, Spain (Hombre de Piedra Architects).

Measurement campaigns were conducted between June and October, repeated over three consecutive years and a week was recorded for each courtyard.

Results

The distribution of the temperature drop from the outside in the courtyards of Cordoba and Malaga are shown in the following figures.

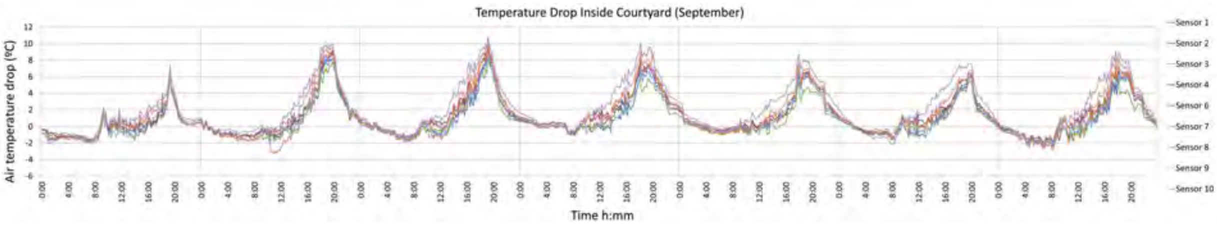

Figure 3: Temperature drop in the Córdoba courtyard from outside temperature.

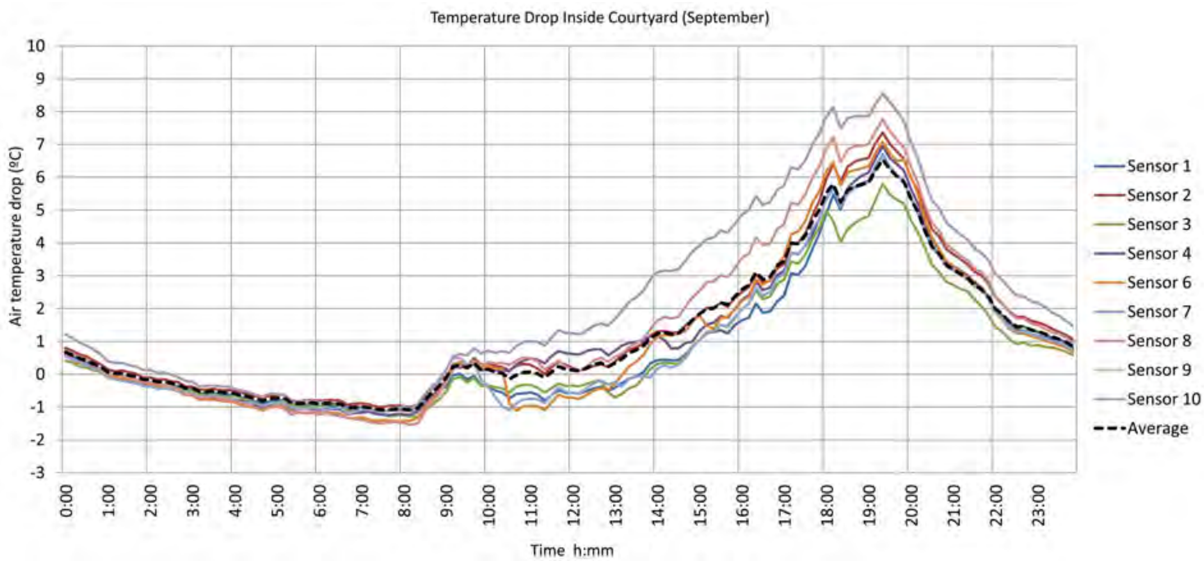

Figure 4: Average temperature drop in the Córdoba courtyard from outside temperature

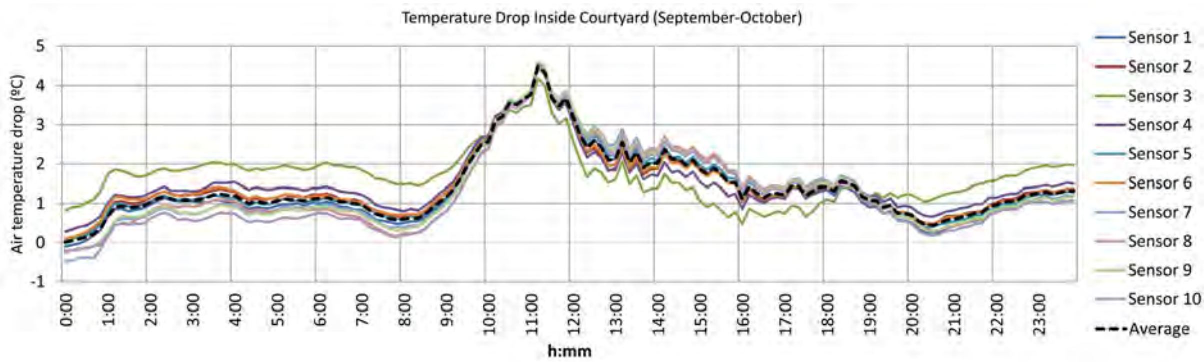

Figure 5: Average temperature drop in the Málaga courtyard from outside temperature.

Figures 4 and 5 show the average air temperature differences at every hour of the day between the inside and the outside of the courtyard over a week. The behaviour of the courtyards is more remarkable if we observe only the evolution of the temperatures in the ground floor. This floor is the most interesting because it is normally where Mediterranean buildings are most open to the courtyard and as such is where the majority of air is taken in. It is also the level where this space is used and inhabited. Figure 6 shows, in the case of the courtyard in Cordoba, air temperatures outside and inside the courtyard for a given summer week (June). During the day, lower temperatures were recorded inside the courtyard than outside.

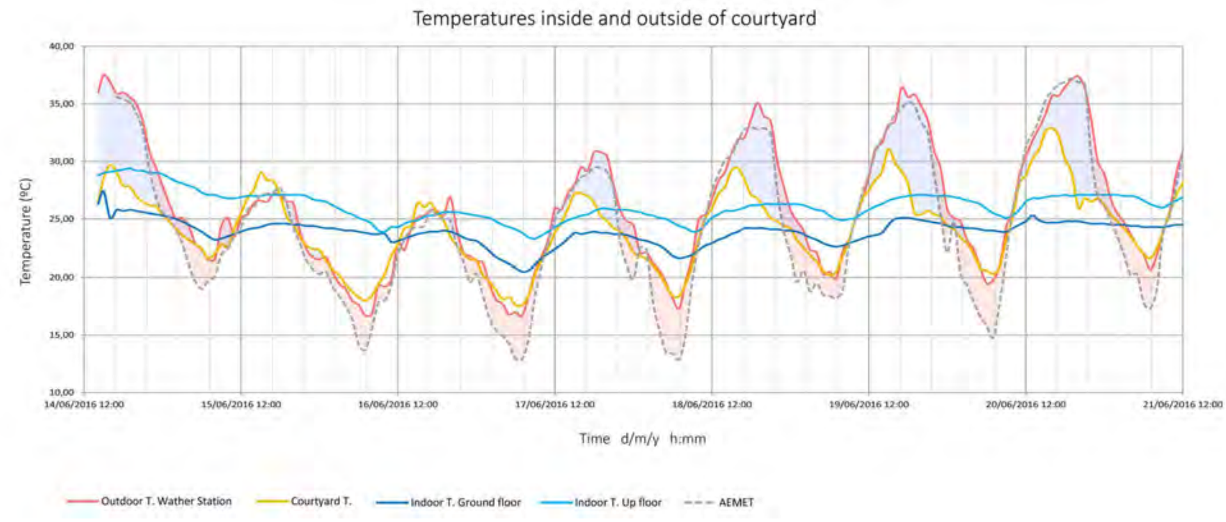

Figure 6: Registered temperatures inside and outside the ground floor of courtyard, Córdoba, Spain.

The external thermal sensor shown in figure 6 (red line) is on the roof of the building as a part of the weather station. In spite of the fact that this sensor is specially shaded and ventilated, we had to be sure that it wasn't recording the effect of the high radiations that is typical in this climate, in addition to air temperature. For this reason, the record of our sensor was compared to the air temperature record on this day in Córdoba by the Official Spanish Agency of Meteorology (AEMET. Gobierno de España 2016). On one hand, this is the most reliable source of meteorological data. On the other hand, we must take into account that this official weather station is not located in the centre of Cordoba, where the studied building is, but at the airport, situated 6.94 km away in the outskirts of the city. It can be observed that the maximum temperatures recorded by our sensor are very similar to the temperatures recorded by the official AEMET weather station at the airport. This clears any doubts about overheating in our weather station. However, the minimum temperatures recorded by our sensor are higher than those recorded at the airport. This is as a result of the well-known Urban Heat Island Effect.

The experimentation campaign shows the dynamic thermal relation between the walls of the courtyard and the air confined between them. Comparative measurements have been made between the surface temperature of the building walls and the air in contact with them in the courtyard space. Therefore, two sets of thermocouple probes have been placed, some in contact with the wall to measure the surface temperature and others in the space in front of it 10mm away to measure the air temperature in the layer of air in contact with the wall (boundary layer). These measurements will allow us to check the direction of heat flow between the inside and outside of the building. The results obtained are shown below.

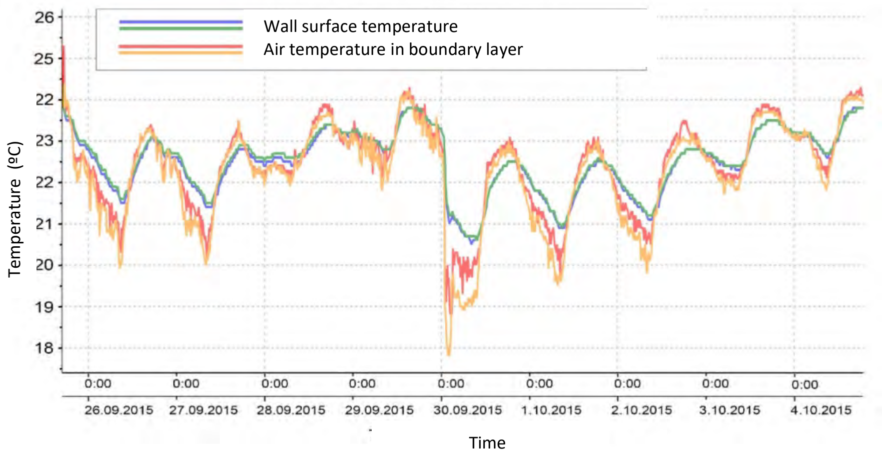

Figure 7: Wall Surface temperature and air temperature in the air layer in contact with the wall (boundary layer temperature) in the courtyard of Málaga, Spain.

At this time of the year, the outside air temperature at night is always lower than the surface temperature of the wall (sometimes up to 3ºC lower as shown in the peak for figure 7). Therefore, in these Mediterranean climates, the considerable difference in night temperature allows the building to lose heat to the outside by conduction, convection and radiation through its envelope.

Discussion

It can be observed that courtyards, mainly in Mediterranean climates, generate a microclimate, in which the temperatures differ from that of other external areas around the building. The maximum average difference for the building in Córdoba, with this climate and this time of year, was found at 19:00 solar time and reached more than 8°C (Fig. 4). This is consistent with the differences recorded by other research (Alvarez 2001). It is remarkable that it is around this same time that the outside temperatures reach their maximum. For this reason, the positive effect of a courtyard's microclimate on the building is more significant. There is also a drop in temperature in the courtyard in Malaga (Fig. 5) although it is somewhat lower because the outside temperatures were lower than in Córdoba (Fig. 4). Due to the milder climate in Malaga and the different architecture of the patio, the maximum difference of 4.5 °C occurs in the morning. The parallel evolution of temperatures at different heights in the Córdoba courtyard (Fig. 4) shows the existence of a stratification phenomenon. Figure 6 shows a very clear thermal pattern inside the courtyard with remarkably lower temperatures than outside during the day. These differences are going to disappear at nightfall. In fact, the graph shows that sometimes the courtyard temperatures can be a few degrees higher than outside during the night and early morning. It is also necessary to highlight the stable evolution of the interior temperature in the ground floor of the building and first floor (dark blue and light blue respectively) that are within the range of comfort in this naturally ventilated building. The effect of the courtyard can contribute considerably to the positive behaviour of the interior temperatures. The differences between day and night temperatures are remarkable. In the airport, this difference reached 23.1ºC and a few degrees lower around the studied building where it reached 17.3ºC. This means that in this warm climate there are opportunities to propose designs that favour heat transfer during the night by conduction, convection and radiation. For instance, one possibility could be to design a low, compact form to allow wider and closer contact between buildings and the outside environment. Figure 7 shows, in the courtyard, this heat flow between the inside and outside of the building.

The data shows that the actual behaviour of the air in these climates is complex due to its interaction with the architecture. Thus, it is not correct to consider that all the surroundings of a certain building in any climate are exposed to the same conditions and outside temperature. The exterior temperature around the building is not homogeneous due to existing microclimates like those in courtyards. There are other phenomena around buildings that also generate well-known microclimates in warm regions such as urban canyons (the narrow streets of Mediterranean cities) and microclimates generated by vegetation (evapotranspiration phenomenon), amongst others. The results obtained lead to reconsidering the preciseness of conventional energy simulation models. By not contemplating the existence of these microclimates, most widespread conventional energy simulations are not able to balance the importance and potential of these spaces. Moreover, in these simulations, the introduction of spaces such as courtyard results in a poorer energy performance of the building by increasing the facade surface without taking into account any of their advantages. Nevertheless, designs with low shape factor and over-insulation are at risk of overheating, both in Mediterranean climates and even in colder climates.

Conclusion

In light of the experimental results, it is possible to conclude that designing courtyards in Mediterranean buildings has the following advantages:

- To allow the creation of outdoor spaces with microclimates that moderate temperature. These microclimates have been traditionally used in a passive way to improve the performance of these buildings. However, it is also possible to use this technique in contemporary designs, introducing this fresher air in the air conditioning system and improving the energy performance of the building. To evaluate this, a better quantitative knowledge of these phenomena is required.

- To provide a bigger surface for heat transfer to the surrounding environment during the night. This is done both by conduction through the air in contact with the walls and by radiation, releasing heat into the typically cloudless night sky of these climates. In contrast to this, exposing more facade surfaces could assume a greater heat gain during the day, especially under the incidence of solar radiation. However, covered shapes can be designed to enable many of these walls to be sufficiently shaded during the day.

-To improve ventilation conditions, avoiding overheating. Complex shapes and courtyards allow smaller widths of the interior spaces of buildings, facades at different orientations with different wind pressure and temperature conditions, and all of these favour the possibilities of cross-ventilation.

- Last but not least, in Mediterranean climates, the architecture of more complex shapes and courtyards is usually more interesting and provides a more satisfactory human experience by keeping contact with nature. This improves the adaptive thermal comfort (Nicol et al. 2012) and saves energy by keeping the air conditioning off for longer.

The development of precise energy tools to be used during a buildings inception is a priority for achieving energy efficiency. The present study highlights the fact that, as long as more sophisticated tools are not integrated in building design, general recommendations such as a reduced shape factor do not have validity in warm climates, due to the complex interaction of shape and climate. These over-simplified techniques can even be harmful when attempting to achieve higher eco-efficiency in construction: they increase the risk of overheating and create a strong paradigm that complicates the exploration of new innovative strategies based on more complex shapes, for instance by using internal courtyards and their microclimatic conditions.

Improving the Ambient Air Temperature in Small Outdoor Spaces

Nihal Al Sabbagh

Architectural Association Graduate School, London, UK

Abstract: The hot weather conditions in Dubai have discouraged the use of outdoor urban spaces, leading to huge dependence on mechanical cooling and its use indoors. The purpose of this study is to investigate the cooling effect of selected strategies on the outdoor ambient air temperature using the numerical model ENVI-met. Variables of three strategies were tested initially: orientation, geometry and vegetation, where the coolest parameter of each was incorporated into one scenario, named the enhanced scenario. This scenario was compared later with the existing scenario, representing the site conditions of an educational campus in Dubai, and a worst-case scenario, combining the warmest parameters. Results revealed that the SW-NE orientation, the highest height to width ratio (H/W) ratio of 4 and the groups of trees and continuous grass achieved the highest reduction of air temperature. The EW orientation, 0.5 H/W ratio and no vegetation recorded the highest temperature levels. The comparative results highlight a slight improvement in the enhanced scenario over both the worst-case scenario (of 1.1K) and the existing scenario (of 0.9K). The air temperature patterns and wind movement on this campus helped to understand several outdoor behaviours useful for guiding a sensible design for combating extreme heat conditions in urban spaces.

Keywords: bioclimatic, ENVI-met, landscape, microclimate, thermal comfort, outdoor space

Introduction

Building settings creates urban patterns that control the wind direction and the solar access; hence the thermal comfort levels of outdoor spaces and the energy consumption in indoor ones. Empirical research has recently accumulated seeking to understand the relationship between the built environment and the microclimate in many urban situations. At street level, the space morphology, orientation, materiality, components and vegetation are considered the main factors shaping the thermal environment. Therefore, improving the outdoor thermal environment ought to manage such variables sensibly, where an optimum balance between diurnal gains and nocturnal losses is achieved. The present research investigates the synthesized influence of space geometry, orientation and vegetation on the ambient air temperature. Parameters within each variable that demonstrate a cooling effect have been considered; they are examined through the microclimatic simulation tool ENVI-met (Bruse, 2007). The aim was to provide insightful information on the effectiveness of each factor when applied solely or with others.

Geometry and orientation

The distance between buildings defining an open space, their settings and heights play a major role in the incoming and outgoing heat radiation and the wind speed (Johansson, 2006). The negative effect of improper space geometry tends to increase the solar gain and prevent wind circulation on the site. According to Ali Toudert (2005), narrow urban canyons with a lower height to width (H/W) ratio amplify the cooling effect during peak hours of the day more than wider canyons with a bigger H/W ratio do, mainly due to the increased shade. Their study suggests that shading is an effective means of mitigating heat stress in outdoor spaces. A study conducted by K. S. (1994) in the hot humid environment of Dhaka found that on average the daily maximum temperatures decreased by 4.5K when the H/W ratio increased from 0.3 to 2.8, which was fair for achieving thermal comfort levels. However, denser spaces contribute to higher levels of air pollution, due to the entrapment of air particles and ventilation, which raises the temperature levels. Therefore, a balance between shade and ventilation should always be considered (Krüger et al., 2011). Following a proper urban design ratio seems a promising way of improving thermal comfort levels within urban spaces and the surrounding buildings should be planned with this in mind.

The space orientation has more effect on the distribution of the surface temperatures and net absorbed solar energy than on the absorbed quantities. Ali-Toudert and Mayer (2005) argue that the heat stress of an East-West oriented canyon was higher than that of one with North-South orientation and provided a better thermal environment. For Northeast-Southwest or Northwest-Southeast orientations, these canyons have been shown to attain better comfort levels as the shading increases, but with a slight difference, nonetheless. In some cases, a compromise should be made so that the orientation for summer and winter suits the comfort levels of both periods. The orientation factor appears to be less sensitive to the air temperature variations when compared to the H/W ratio of the space. The consequences of N-S and E-W orientations could be modified by the H/W ratio. Furthermore, orientations with higher solar exposure require deeper spaces (a larger H/W ratio), while orientations with shorter periods of solar exposure can tolerate wider spaces with a smaller H/W ratio. Shashua-Bar and Hoffman (2003) reconcile the geometry orientation and greenery factors, where space orientation variations between N-S and E-W orientations have proved to be only slightly different. N-S orientation provided 83% of the shaded areas while E-W orientation provided less shade, only 74%. A recent study by Krüger et al. (2011) demonstrates the effect of orientation not on the percentage of shaded periods but on wind flow and air quality. Studies validate the relation between the wind flow and air quality, since air movement prevents air stagnation and thus pollution blockage. Pollution has been shown to contribute to lower air quality levels and higher temperature levels. This study recommended orienting urban canyons parallel to the wind direction, which would increase the air inflow in the outdoor spaces.

Vegetation

Greenery is apparently the most effective parameter for improving the microclimate, with numerous benefits. Shashua-Bar and Hoffman (2003) demonstrate that 80% of the cooling effect provided within 11 sites in a Tel-Aviv urban complex was due to the shading effect obtained from trees. During the day, trees reduce the penetration of solar radiation by their shade and by the attenuation of the thermal gains due to their thermal mass. A model was used for testing such effects but it ignored the marked passive cooling effect on their surroundings. The process of air exchange of the long and short wave radiations between the trees and their surroundings as contributing to the cooling effect. The dissipation of the heat load is due to evapo-transpiration and convective heat exchange with the air (Al-Sabbagh, 2011).

The consideration of the layout orientation is revealed to be essential for enhancing the cooling effect. The wind factor tends to spread the cooled air around the layout (Robitu et al., 2006). The cooling effect obtained from a green site is due to the low ability of its soil to absorb heat, whilst the vegetation surfaces are shown to absorb much less heat. Givoni (1991) cites various studies that were carried out on the thermal effect of plants in urban areas. The studies reveal the use of greenery as an energy saving method due to the reduction of cooling loads on the surrounding buildings. The effect of landscaping (consisting of trees and shrubs) on the cooling loads of its surrounding buildings was marked by around 50% savings, in that the loads dropped from 5.56kw to 2.28kw and was even more marked during peak load periods (8.65kw to 3.67kw). Givoni's study concludes that applying vegetation confers several benefits such as pollution reduction, noise attenuation and social cohesion.

Regarding vegetation and the microclimate, (Masmoudi and Mazouz, 2004) have evidence that these two are related. The reduction of air temperature on the ground level was found to be about 5^{o}C for the different plan forms tested (square form and rectangular form). The examination of the results showed that the simple presence of vegetation is more effective than its quantity. The increase in the quantity of vegetable masses had no great significance when compared to the influence of applying trees in highly thermally-stressed locations. The study guided the best orientation of trees to be that of north-east/south-west due to the reduction of the solar energy absorbed by the ground surfaces. Densely vegetated areas, however, find it difficult to dissipate heat during the night due to the large concentration of vegetable masses (Wong et al., 2007). Grass surfaces are considered to be of great cooling effect, but still a proposed design ratio between the numbers of trees and the area of grass ratio should be suggested. It is believed to be effective in the cooling process if distributed with enough intervals. An area of 100 m^2 and recommended that 8 trees can be planted 5m apart to achieve a desirable thermal comfort balance throughout the year (Shashua-Bar and Hoffman, 2000).

Methodology and Microclimatic Simulation

ENVI-met is a three-dimensional microclimatic model that incorporates all the parameters that govern an outdoor environment and attains validated results. Due to the various numbers of variables investigated, a test matrix (Table 1) was created to make the simulation procedures easier. Nineteen simulations were run, investigating three scenarios in both summer (August) and winter (January), besides examining the three main parameters of the bioclimatic principles (the orientation, geometry and vegetation). Each of these parameters included several variables, while there were four orientations (NS, EW, NW-SE, SW-NE), three height-to-width ratios (0.5, 2, 4) and six strategies for vegetation (no trees, a continuous line of trees, groups of trees, areas of grass, continuous grass). One parameter at a time was tested during conditions of extreme thermal stress while all others were fixed according to the existing state of the conditions. Dubai Knowledge Village (DKV) was selected for investigation; it is an international educational campus located in a lively business hub named Internet City. The three main comparative scenarios (existing, enhanced and worst) were tested in both on August and January and between 8am and 10 pm. The temperature values given in the output files were averaged that represented the temperature of the whole site during that specific hour. The enhanced model scenario is considered the concluding model for the present study, which incorporates the most effective parameters of the bioclimatic variables under investigation. The present simulation results are based upon a configuration of SW-NE as the orientation, an 0.5 ratio, continuous grass and trees in groups. Simulations were run on the exact duration of the existing and the worst-case scenario, namely, August and January (representing summer and winter respectively) from 8.00am to 10.00pm.

Table 1: The test matrix used for the simulation analysis. Red cells represent the fixed variables during simulation.

Independent variables	Orientation	H:W ratio	Grass	Trees
Existing scenario	20°NW-SE	0.8	No	Tree every 12m
Independent variables	NS	0.5	Continuous	No
	EW	2	Grass pieces	Continuous linear
	SE-NW	3	No Grass	Tree groups
	NE-SW		No Grass	Tree every 12m
Enhanced scenario	NE-SW	0.5	Continuous	Tree groups
Worst case scenario	EW	3	No	No

Effect of Orientation

The four orientations tested were those of the NS and EW and, with a 45o inclination, the SW-NE and SE-NW. The results reveal the SW-NE to have the lowest average temperature followed by the NS, SE-NW and finally the EW orientation, where the highest average temperature values were recorded. The south-facing walls of an EW orientated space are thought to receive the highest levels of solar radiation. These findings corresponded to many studies (e.g. (Ali-Toudert and Mayer, 2005, Shashua-Bar and Hoffman, 2003, (Masmoudi and Mazouz, 2004). Comparing the two warmest orientations, EW and SE-NW, accounts for such values, for where the south-facing facades in the EW orientation receive the highest levels of solar radiation, followed by those in the SE-NW orientation. Building on this interpretation, the NS-oriented space should have recorded the lowest temperature values, yet the SW-NE was revealed to be the lowest of all. The reason for such a finding is identified as the influence on orientation of the shading within the space. The SW-NE orientation created a balance between the two concepts, recording the lowest average temperature values.

The average difference between the four orientations was small, yet a wide variation was observed in the temperature distribution, indicating the importance of orientation for improving the outdoor temperature. The maps indicate a lower maximum temperature in the SW-NE orientation than those of the EW and SE-NW orientation. However, the SW-NE orientation, which gave the lowest temperatures had the lowest average wind speed values, followed by the EW, NS and SE-NW orientations. The SE-NW orientation runs parallel to the prevailing wind, which blows from the NW; and yet it recorded the second highest temperature values. The wind factor, then, was seen to have no cooling effect on the spaces but it does have a 'spreading effect' depending very much on the orientation (Figure 1). This means that a visual analysis sequel to the temperature distribution should be conducted, to forestall a warming effect. In this case, the wind aspect also contributed to enabling the SW-NE orientation to yield the lowest average temperatures.

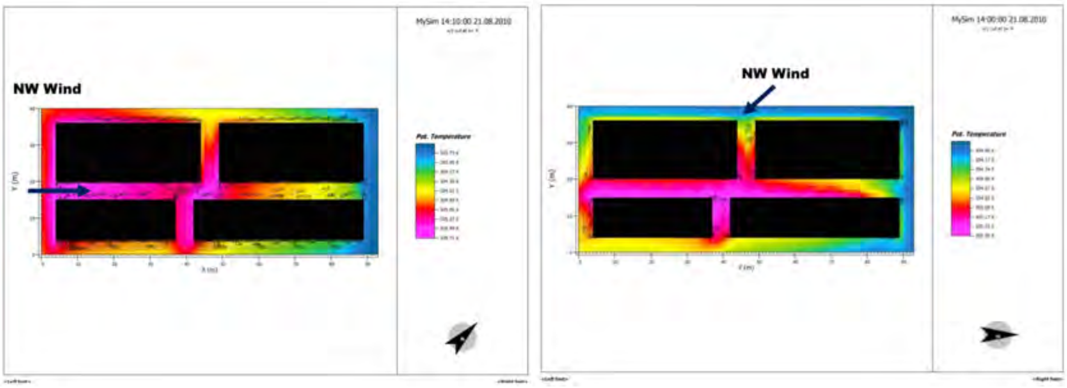

Figure 1: Thermal maps for SE-NW orientation(left) and NS orientation(right) with the spreading effect of wind.

Effect of Geometry

A slight variation was revealed between the three configurations with the highest ratio of 4 that recorded the lowest average temperature values. An inverse relationship between the H/W ratio and the temperature was found. Wide spaces receive more solar penetration and thus more solar gain, while deep ones are sheltered from solar access in proportion to the ratio. The H/W aspect ratio can reduce the maximum temperature levels during the peak thermal stress period when maximum temperatures are recorded, and thus can reduce the average temperature accordingly. As the ratio of the space exceeds 2, the temperature variation is reduced, unlike that of the spaces with ratios below 2, which are considered to strike a balance in the cycle between diurnal heat gain and nocturnal heat loss. The ratio 2 simulations had moderate maximum and average temperature values between the three configurations and yet recorded the lowest minimum temperature (Figure 2). This occurred in the early morning, as a result of the low night flushing and heat entrapped. The 'spreading effect' of wind also seems to be applicable in the geometry simulation results. The 0.5 ratio shows more contours within the space, indicating the turbulence resulting from the wind speed slightly extending the cooled area, but this does not apply to the two other ratios. Moreover, the highest ratio of 4, recording the highest temperature values, revealed the lowest average wind speed values similar to the orientation wind speed and behavior of the temperature. Narrower spaces were shown to provide more shade which in turn reduced the number of surfaces exposed to solar gain and thus enhanced the air temperature more than wide spaces could. The guide is an understanding of the behavior of the temperature and wind in accordance with the reasons for the solar gains.

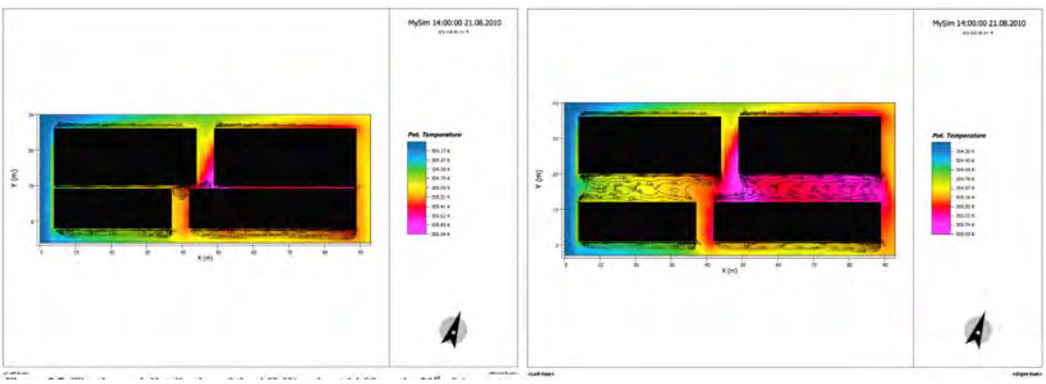

Figure 2: Thermal maps for 4 H:W (left) and 0.5 H:W (right) showing the amount of heat inside the lower ratio.

Effect of Vegetation

As with the two previously investigated variables, the differences obtained between the options for landscape strategies were not high, yet the vegetation proved to be the most effective variable of all. It showed an improvement of 0.6K of the average temperature and 0.7K of the maximum temperature during the peak thermal stress period for the groups of trees and continuous grass option. The maximum temperature difference was greater than the average difference which supports the view that the effect of vegetation increases during the hottest times of day, the reverse of the effect of orientation and in compliance with the geometry in the same periods. The average temperature results comparing the six landscape strategies reveals that the strategy of planting both grass and trees yields the lowest temperature values contributing to a better passive cooling effect. The resulting differences between the no trees scenario and that of continuous grass was 0.3K, which was lower than the difference between the scenario of no trees and that of groups of trees, which was 0.5K. Comparing these carefully makes it clear that the wind is affected by the different strategies. The effect of groups of trees recorded slightly higher average and maximum temperatures than the effect of a central continuous line of trees. Groups of trees, however, interrupted the wind flow vastly more than a central line; they obviously blocked the cooler breeze coming from the north-west from blowing across the space (Figure 3).

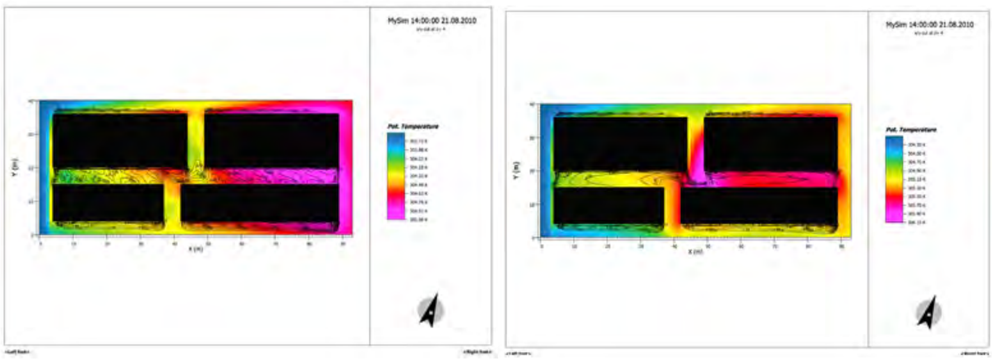

Figure 3: Thermal maps for groups of trees and continuous grass (left) and no trees no grass (right) showing the wind turbulence caused by the trees.

Comparing the three scenarios

The enhanced scenario slightly improved the average outdoor air temperature of the existing conditions by 0.5K in summer and 0.3K in winter, while the enhanced scenario improved the worst-case scenario's outdoor average summer air temperature by 1.1K. The efficiency of the bioclimatic principles applied in the enhanced scenarios was maximized during the peak thermal stress periods. The balance created by the enhanced scenario at these periods of the day in the two seasons was considered vital, yet its efficiency was relatively reduced during winter evenings. The results and findings obtained highlight the presence of a threshold in the size of the bioclimatic parameters applied. The worst scenario recorded the highest temperature values in the summer and lowest in the winter. The enhanced scenario incorporated all the variables revealed to have the greatest cooling effect and thus reduced the air temperature more than either of the two preceding scenarios. It was concluded that the cooling effect of the orientation was 0.7K, the H/W ratio was 0.6K and the vegetation was 1K during the daily peak thermal stress period in summer. The enhanced scenario was based upon the incorporation of the three variables yet the total cooling effect obtained was 1.1K, almost equivalent to that of applying the vegetation effect only. The behavior of the outdoor parameters is quite complex where some variables, such as orientation, are revealed to be less effective during peak thermal stress periods while others, such as geometry and vegetation, proved to be more effective during these periods. This non-uniform pattern is repeated when observing the effect of each bioclimatic principle dependently and in combination.

Wind has more of a spreading effect than a cooling effect. Cool areas should be facing the wind to broaden the cooling effect, while hot points within the space should be sheltered from the wind to prevent this effect. In the case with the enhanced scenario, the breeze comes from the NW and is blocked by the building facing it. The worst scenario recorded much higher values of wind speed, since the model was bare of trees and the space was wide, with a low H/W ratio; hence, it enhanced the wind flow in the space, with almost no turbulence. The existing scenario had a central value between the worst case and the enhanced scenario, where the central line of trees created more wind turbulence.

Conclusion

Vegetation had the most cooling effect of all the three parameters, followed by orientation. Masmoudi and Mazouz (2004) tested the three independent variables investigated here, but in different conditions; their results support the cooling sequence observed in this study. Generally, shading proved to be very efficient in reducing the air temperature during the daily peak thermal stress period, contributing in particular to lower average daily temperatures. Nevertheless, excessive shading is not recommended, since it reduces the heat radiation loss process, ultimately leading to higher temperatures (Hwang, 2010). It was noted that dense vegetation is not preferable and very high H/W space ratios are not recommended.

The coolest orientation that recorded the lowest average temperature values and in turn achieves the longest periods of improvement was revealed to be the SW-NE orientation, followed by the NS, SE-NW and the EW in that order. There are three reasons for this result: the shade provided in the space by each orientation, the temperature of the area facing the prevailing wind, and the position of the southern facades with reference to the angle of the sun in each orientation. The SW-NE orientation reconciled all the above reasons for the lowest values of temperature. The coolest geometry was the one with the highest aspect ratio of 4, where the H/W ratio was shown to be inversely proportional to the temperature. A slight difference was observed between the ratio of 2 and 4 and that between the ratios 0.5 and 2. The reason for this is that narrow spaces find it difficult to radiate their heat to the environment; thus, the inverse relation mentioned has a threshold where the temperature starts to increase again. The coolest vegetation strategy was recorded as the one with both grass and trees, where trees provided shade and evaporative cooling while grass had the advantage of reducing the surface radiation and adding an evaporative effect. Landscape strategies are much too wide to be tested in a single study, although the strategies proposed were based on earlier recommendations. Generally, it was concluded that in extremely hot countries such as Dubai, achieving outdoor air temperatures close enough to the thermal comfort values is impossible in the summer but they can be slightly improved. The application of the proper orientation of SW-NE, a high space ratio of 4, groups of trees and grass considered as the 'bioclimatic application' enhanced the air temperature by a value of 1.1K. This value proved to be acceptable when dealing with the outdoor environment where more significant changes were not possible.

However, the results obtained are promising for passive cooling techniques of the outdoor environment.

Natural Ventilation Potential in Kuala Lumpur: Assumptions, Realities and Future

Mohd Firrdhaus Mohd Sahabuddin[1], Cristina Gonzalez-Longo[1]

[1] Department of Architecture, University of Strathclyde, Glasgow, United Kingdom

Abstract: Malaysia accounts for 11% of Southeast Asia's carbon emissions in recent years, is the third highest emissions contributor in the region. It has been estimated that 25% of these carbon emissions are generated from the buildings, especially from the electrical and mechanical equipment that are present in residential buildings. Malaysia's capital, Kuala Lumpur, has 81.5% of the high-rise buildings in the country and half of the buildings are residential. They have supposedly been designed as predominantly naturally ventilated, but the occupants had to add inefficient mechanical ventilation to achieve the required cooling. It is due to the lack of acknowledgement of the hot-humid climate of Malaysia by the current building regulations and the fact that the requirements for energy use are not customised for residential buildings. Recent developments concerning the use of green rating tools are helping to improve the sustainable design of buildings. This paper reviews these existing regulations and green rating tools and explores the full potential for natural ventilation in Kuala Lumpur, to substantially reduce carbon emissions while considering both the health and comfort of the occupants. It concludes that the building regulations should be revised to deal with current and future climatic conditions and to achieve the critical conditions that allow for natural ventilation in Kuala Lumpur.

Keywords: Natural ventilation, indoor comfort, indoor air quality, building regulations, Kuala Lumpur

Introduction

The implications of climate change, including heat stress and air pollution, contribute to a wide range of impacts on human's health and comfort in urban areas (IPCC, 2014). More than half of the carbon emissions in the world, that are causing the climate change, will be produced by Asian cities in the next 20 years and it is estimated that 1.2 billion Asians will migrate to the cities over the next 35 years (ADB, 2015).

The carbon emission in the Southeast Asia (SEA) region has increased rapidly from 1990 to 2010 (ADB, 2015). Five countries that are Indonesia, Malaysia, Philippines, Thailand and Vietnam, have collectively contributed 90% of the carbon emissions in the SEA region (Raitzer et al., 2015). Malaysia accounts for the 11% of these emissions in recent years, ranking as the third highest emission contributor in 2014 (ADB, 2015). In order to address this problem, the government of the country has recently signed the Paris Agreement, committing to reduce 45% of carbon emissions by 2030 in accordance to the 2005 baseline (UNFCCC, 2017).

The building sector is one of the largest carbon emissions contributors in the world (IPCC, 2014). In the case of Malaysia, the carbon emissions from this particular sector have been doubled from the 1970s, representing now the 25% of the total country's emissions (Lucon et al., 2014). The residential buildings, construction of which has been quintupled during the last four decades (Lucon et al., 2014), and in particular their mechanical and electrical cooling equipment are the greatest contributors to the emissions. Thereafter, the appropriate ventilation design in these residential buildings, in particular high-risers, is a key element to find solutions to reduce carbon emissions and to overcome the damaging effects of climate change in the future. For example, the buildings in the urban areas such as Malaysia's capital, Kuala Lumpur. There are many challenges concerning the provision of natural ventilation in dense urban areas such as Kuala Lumpur, including the problems associated with the urban heat island effect and air pollution. The current practices in building design have failed to achieve the required environmental conditions for health and comfort and the occupants had to afterwards increase the amount of mechanical ventilation to achieve cooling.

The current building regulations in Malaysia (UBBL) were implemented in 1984 and these are based on the recommendations provided by the United Kingdom's Building Research Station (BRS), which is currently known as Building Research Establishment (BRE); these recommendations were previously applied in Kuala Lumpur and Singapore, both British colonies until 1957 (Said, 2011). The UBBL 1984 does not take Malaysia's hot-humid climate and the issues concerning carbon emissions in full account (Mohd Sahabuddin and Gonzalez-Longo, 2015). The regulations establish that the minimum size of openings for natural ventilation purposes in residential buildings should not be less than 10% of the total clear area of the room (UBBL, 2013), a requirement which remained unchanged for 33 years. There have been recent developments concerning the use of green rating tools in Malaysia, which are helping to improve the sustainable design of buildings and the health of their occupants. This paper reviews these existing regulations and green rating tools and explores the full potential for natural ventilation in Kuala Lumpur, in order to substantially reduce carbon emissions while ensuring a healthy and comfortable internal environment for the occupants of high-rise residential buildings.

Identifying the critical issues for natural ventilation in consolidated urban areas

Kuala Lumpur accommodates 81.5% of the total number of high-rise buildings in Malaysia, and half of these buildings are residential buildings (CTBUH, 2016). Although most of these buildings were initially designed as naturally ventilated, the majority of their occupants have included inefficient mechanical ventilation to achieve indoor cooling (Aflaki et al., 2016). Other capital cities in the SEA region, such as Singapore and Bangkok, have also experienced the same problem (Aldossary et al., 2016, Oswald and Riewe, 2013).

The three common factors associated with indoor discomfort and unhealthy environment in high-rise residential buildings in SEA cities are high air temperature, high air pollution and low air movement. The high ambient air temperature resulted from urban heat island effects, is the result of the combination of direct solar radiation, diffused radiation from the sky dome and reflected radiation from both adjacent buildings and hard surfaces in urban areas. It has increased heat penetrates into indoor spaces through convection, conduction and radiation mechanisms (Chenvidyakarn, 2013, Nave, 2012).

The high levels of carbon emissions are directly linked to increments in temperature (Lucon et al., 2014). The scientific report of Climate Change Scenarios for Malaysia 2001-2099 produced by the Malaysian Meteorological Department (MMD) in 2009, has projected a temperature increment of 1.1^{o}C to 3.6^{o}C by 2095 in Peninsular Malaysia. It has also been recorded that the average dry-bulb temperature in Kuala Lumpur in 2015, was 27^{o}C and that by 2050 this figure is expected to increase by 1.2^{o}C (ESRI, 2015, MMD, 2010 - 2016).

As in many other cities, air pollution causes unhealthy environment in Kuala Lumpur's urban areas, as it contains airborne particulate matter and toxic gases from fuel vehicles, (Leh et al., 2012). Moreover, during the dry months of February to March and June to August in the past few decades, haze has become a regular event in Kuala Lumpur (Payus et al., 2013, Elsayed, 2012).

Both temperature and pollution issues are worsened by the insufficient wind movement in Kuala Lumpur, potentially reducing the possibilities of natural ventilation (Payus et al., 2013, Tahir et al., 2010). The city's average monthly wind speed was 1.1 m/s in 2015 (MMD, 2010 - 2016); this low figure together with the high air temperature, the presence of airborne particulate matter and urban roughness produce a series of challenges in order to implement natural ventilation strategies in buildings within the city. These factors have been so far considered in isolation and it is necessary to analyse them in an integrated way to inform the design which allows achieving a healthier and more comfortable indoor environment in high-rise residential buildings in an urban area in hot-humid climate such as Kuala Lumpur while reducing carbon emissions (Fig. 1).

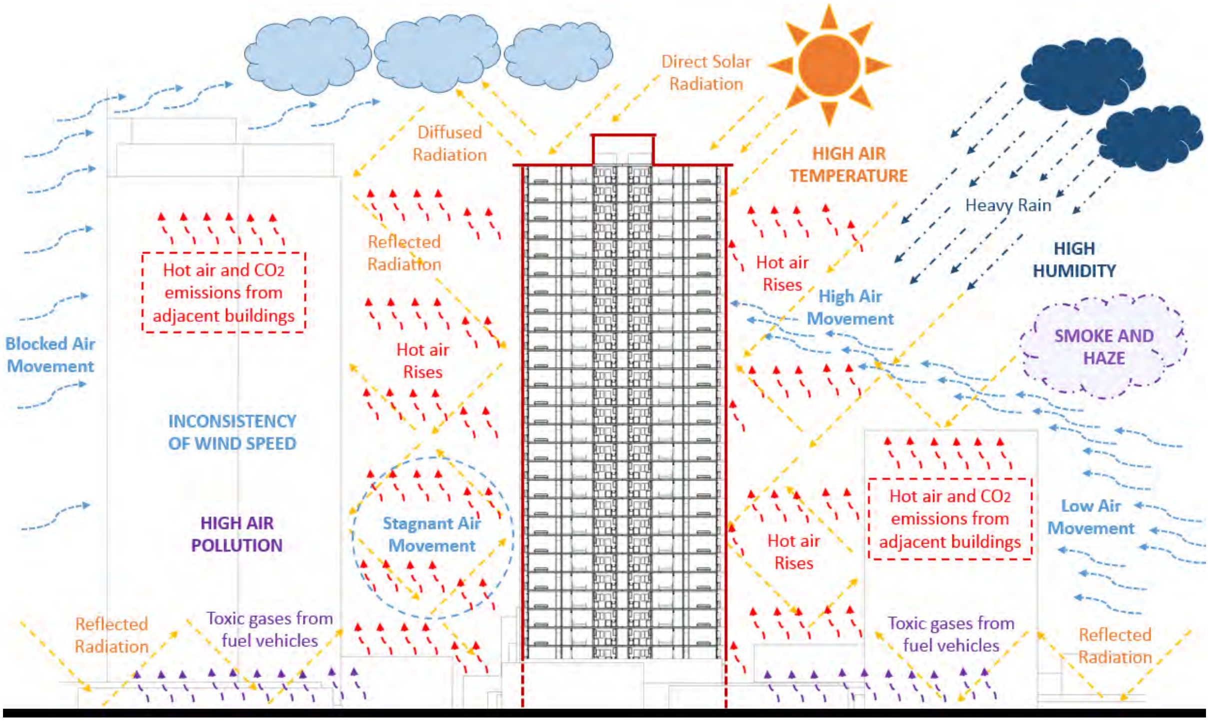

Figure 1: Factors affecting natural ventilation in a typical high-rise building within an urban area in hot-humid climate

Current Building Regulations, Standards and Green Ratings

The mandatory building regulations in Malaysia are called the 'Uniform Building By-Laws' (UBBL) 1984 and are contained within the 'Street, Drainage and Building Act' (SDBA) 1974. The requirements for natural ventilation in residential buildings are established in the 3rd part of the regulations: 'Space, Light and Ventilation' under clauses 39(1), 39(4), 40(1) and 40(2). However, they are only concerned about the proportion of windows and size of light-wells and there are not more specific regulations on achieving healthy indoor air quality.

Clause 39(1) states that '*every room designed, adapted or used for residential purposes, shall be provided with natural ventilation by means of one or more windows having a total area of not less than 10% of the clear floor area of such room and shall have openings capable of allowing a free uninterrupted passage of air of not less than 5% of such floor area*' (UBBL, 2013). Clause 39(4) determines that '*every water-closet, latrine, urinal and bathroom* *should be provided with natural ventilation by means of one or more openings having a total area of not less than 0.2 sqm*' from the room's total area (UBBL, 2013).

For buildings that are more than 8 storied high, clause 40(1), establishes that the minimum size of light-wells should be not less than 15 sqm, being the minimum width 2.5 meters and clause 40(2) requires the minimum size of each light-well for lavatories, water closets and bathrooms shall be 5.5 sqm and 2.0 meters minimum width (UBBL, 2013). These could not provide an acceptable ventilation by natural means in high-rise residential buildings where weaker stack effect due to lower temperature differences and heat build-up at the top of the light-wells might happen at certain levels (Prajongsan, 2014, Kotani et al., 2003).

Concerning energy use, UBBL 1984 only refers to the Malaysian Standard 1525:2014 - 'Energy Efficiency and Use of Renewable Energy for Non-Residential Buildings', which proposes several passive design strategies for natural ventilation such as cross ventilation and stack ventilation. However, the standard only suggests using CO_2 sensors to control indoor air pollution. For indoor comfort cooling in air-conditioned spaces, this standard recommends the maximum air movement of 0.7 m/s and air temperature of 24^oC to 26^oC.

Malaysia, like many other countries, has recently developed several green rating tools. Three most popular green rating tools used by both private and public sectors, are the Green Building Index (GBI), the Green Real Estate (GreenRE) and Malaysian Carbon Reduction & Environmental Sustainability Tool (MyCREST). However, only GBI and GreenRE have been used for residential buildings so far (MGBC, 2014, REHDA, 2015).

The first green rating tool used in Malaysia was the GBI, initiated in 2009 by a private organisation, the Malaysian Green Building Corporation (MGBC, 2014). Until October 2015, approximately 327 buildings have been rated by GBI and 41% of them are residential (MGBC, 2017). Although the tool refers to UBBL 1984 for minimum percentage of openings, in its latest version for 'Residential New Construction' published in 2014, some natural ventilation strategies have been proposed. These include the provision of light-wells to promote the stack effect (as we have seen already considered by UBBL), open plan layouts to promote cross ventilation, shading devices or overhangs to protect windows from sun radiation and naturally ventilated public spaces. This rating tool also encourages the use of low Volatile Organic Compounds (VOC) materials and finishes to reduce the indoor air pollutants, but there is no minimum air movement and indoor air temperature recommendation.

Another private organisation, the Real Estate Housing Development Association, created GreenRE in 2013 (REHDA, 2015). This tool proposes several strategies to enhance natural ventilation in residential buildings. In addition to the strategies previously proposed by GBI such as the use of open plan layouts to promote cross ventilation and the provision of public spaces naturally ventilated, GreenRE encourages a more appropriate orientation of buildings, so that they face prevailing winds. The latest version of the tool, 'Design Reference Guide for Residential Building and Landed Home' published in 2015, recommends a provision of no less than 0.6 m/s average air movement in indoor spaces (REHDA, 2015) and avoiding VOC materials to achieve good indoor air quality. As in the case of GBI there are no recommendations for the minimum percentage of openings or indoor air temperature set.

MyCREST was created by a collaborative effort of several government agencies such as the Ministry of Works, Public Works Department of Malaysia (PWD) and the Construction Industry Development Board Malaysia (CIDB) in 2016 (CIDB, 2016). This document is at the moment available only for non-residential buildings. In order to maintain good quality in the indoor air, this tool requires that all naturally ventilated spaces should be '*permanently open to and within 7.6 meters of operable wall or roof openings and that operable area is at least*

4% of the net occupiable area' (CIDB, 2016). This figure is much lower than the 10% required by Clause 39 in UBBL 1984 and researchers have considered that the minimum opening percentage in high-rise residential buildings should be not considered equally and should have a variety of sizes depending on the location and height (Mohd Sahabuddin and Gonzalez-Longo, 2015). MyCREST proposes that the minimum average of air movement for naturally ventilated spaces should be no less than 0.6 m/s. Similar to the other two green rating tools, MyCREST considers that the sources of air pollution are mainly from materials that contain VOC only (CIDB, 2016).

This entire situation in the current scenario is concerned about the regulations and green rating tools, needs some clarification concerning the parameters they consider. Table 1 shows the comparison of natural ventilation strategies in the regulations, standards and the green rating tools used in Malaysia, as discussed above. Although there are significant improvements, in particular, the development of the recent MyCREST tool, Malaysia needs to address the need for a revision of its building regulations so that residential buildings are designed to minimise their carbon emissions and to improve the health and comfort of the occupants.

Learning from the Vernacular Architecture

In the residential buildings at tropical regions cooling is more important than heating. According to the chapter of 'Buildings: Mitigation of Climate Change' in the 5th Climate Change Assessment Report produced by the Intergovernmental Panel on Climate Change (IPCC) in 2014, residential buildings in tropical regions could lower the carbon emissions by introducing a design that could maintain indoor comfort temperatures without using any mechanical equipment. The clear precedent is vernacular houses, which design have succeeded in achieving cooling and comfort (Lucon et al., 2014). Although, obviously, they were not built in a dense urban context such as Kuala Lumpur.

In the case of traditional houses in Malaysia, it took hundreds of years to refine a well-adapted design to the local climate. The key factors for achieving healthy indoor comfort in Malaysia's rural areas are the integration of building form, the use of lightweight materials and green surroundings. Large overhangs, for example, prevent direct solar radiation and rain from entering the houses and timber-gap-floor on stilts promote fresh air intake from beneath the floor. High pitched roofs with ventilation at the top exhaust warm air by the stack effect. Lightweight materials immediately release solar heat (Lim, 1987), and large openings on the facades, which effectively balance the external and internal air temperatures (Kubota and Toe, 2015). An integrated natural ventilation strategy informed by these vernacular precedents has a great potential to reduce carbon emissions directly and at the same time ensuring the health and increased comfort of the occupants.

A study on the possible adaptation of these vernacular strategies to a modern social housing building has proved that an appropriate envelope and layout configuration could achieve the acceptable operative temperature of 25.2^{o}C to 27.2^{o}C, increase the indoor air movement up to 80% and reduce 67% of the carbon emission as well as energy consumption (Mohd Sahabuddin and Gonzalez-Longo, 2015). This study, which has introduced the concept of an 'Airhouse' standard for hot-humid climates, established that the percentage of openings in the building façade should be between 15% to 45% depending on the height of the residential units, increasing or decreasing the area depending non the height of the residential unit. A full-height opening configuration was proposed with three elements and these are - main windows, fixed louvres and adjustable louvres. Fixed louvres are introduced at the upper level of the internal walls to allow air to circulate throughout the units at every time. The proposed standard has also suggested that the depth of rooms should be decreased to enhance cross ventilation and the overhangs should be provided to protect all windows from solar radiation at any angles. Further studies are being carried out to refine and validate the standard.

Conclusion and recommendations

Although current building regulations, standards and green rating tools have proposed many natural ventilation strategies in Malaysia, they have not been able to acknowledge the current and future climatic conditions of Kuala Lumpur. At the same time, they are not able to address the required improvements in occupant's health and comfort as well as the reduction of the carbon emissions. The UBBL, especially the clauses 39(1) and 40(1) that regulate sizes of openings and light well requirements, were informed by British building standards and have not been reviewed and further researched in accordance with local climate conditions. These clauses, which have been used for 33 years without revision, should be revised and improved in order to reduce carbon emissions while ensuring occupant's health and comfort. Likewise, the standards (MS1525:2014) and green rating tools (GBI, GreenRE and MyCREST) have failed to devise strategies that could reduce airborne particulate matter and toxic gases as well as to prevent convective, conductive and radiative heat from entering and permeating high-rise residential units in Kuala Lumpur.

As per the clause 39(1), the minimum size of openings for ventilation purposes in a residential building in Malaysia should not less than 10% of the total clear area of the room. However, this sole figure seems to be inappropriate to provide ventilation and filter airborne particulate matter from entering indoor spaces in high-rise residential buildings due to different heights factor. Clause 40(1) of UBBL sets the requirement for a light-well of 15 sqm in buildings higher than 8 stories, which could not provide an acceptable ventilation by natural means in high-rise buildings due to weak stack effect and the absence of wind-force ventilation. Further studies should be carried out to test the appropriateness of these requirements to achieve suitable ventilation while ensuring the health of the building occupants and increase comfort levels in indoor spaces.

Building regulations in Malaysia, which are concerned about the natural ventilation, should be revised in order to reduce energy consumption and carbon emissions as well as to deal with the challenges of heat stress and air pollution which affect the comfort and health of the building's occupants. This revision should take into consideration the critical conditions, which allow for natural ventilation to enhance air movement, reduce the airborne particulate matter and maintain the acceptable operative temperature. By improving the regulations and maximising the potential of natural ventilation, high-rise residential buildings in Kuala Lumpur would become healthy and comfortable places to live in and great contributors to the mitigation of climate change.

PLEA 2017 EDINBURGH
Design to Thrive

What heavy weight buildings in hot climates can tell us about their thermal performance

Philippe H. Saleh[1], Rosa Schiano-Phan[1] and Colin Gleeson[2]

[1] Department of Architecture and Environmental Design, Faculty of Architecture and Built Environment, University of Westminster, London, UK. w1510075@my.westminster.ac.
[2] Department of Property and Construction, Architecture and Environmental Design, Faculty of Architecture and Built Environment, University of Westminster, London, UK.

Abstract: Concrete, masonry walls and stone finishes are high density materials and have high thermal capacity, they are referred to as heavy-weight construction or thermal mass, which is the main construction type in Lebanon. Although thermal mass construction is usually recommended in hot climates in order to reduce internal temperature fluctuation, its actual thermal behavior in Lebanon is not well documented through direct observation, relying instead on its theoretical performance. This study's main objective is to characterize the actual thermal performance of such construction, in the context of building occupancy and intermittent A/C usage. The paper starts with a brief introduction of the residential typologies in Lebanon followed by the description of the three thermally monitored apartments, in use or empty, located in one same neighborhood of Beirut, Lebanon. The monitoring was undertaken during summer 2015 using hourly data loggers. The analysis of the recorded data provides a clear and empirical understanding on: 1. how heavy weight buildings interact within the hot and humid climate of Beirut; 2. how the effect of regulating the internal thermal fluctuation is shown; and 3. what are the most influential factors that would further enhance thermal performance of thermal mass construction.

Keywords: Thermal-mass, building-performance, residential, Lebanon, warm climate

Introduction

This paper investigates the thermal performance of apartment buildings within the coastal climate of Beirut, Lebanon. Three apartments are here presented out of a sample of five, which have been thermally monitored during summer 2015. The analysis of the recorded data provides an empirical understanding on how typical residential buildings using heavy to medium-weight construction perform within the warm and humid climate of Beirut. Furthermore, this analysis shows the effect of the thermal mass associated to the heavy-weight construction in regulating the internal temperature fluctuation, and the factors that can further influence and enhance the thermal performance of the typical Lebanese construction.

Typology

Two main types of residential units prevail in Lebanon, the detached house type and the apartment building. The apartment typology is the most common, located in buildings of four to eight floors. The average area for a small apartment is 120sqm including two bedrooms, a family den, a kitchen, main living and reception area and two to three WCs (CDR, 2004). Open balconies are an intrinsic part of the apartment, however they are commonly glazed and turned into conservatories in order to provide extra space (Melki, 2009).

A/C is extensively used for cooling, to the extent that finding a free running, occupied apartment to monitor is difficult. The individual split-system A/C is the most commonly used type.

Thermal Mass

The term Thermal Mass refers to any material that has the capacity to absorb, store and release heat (Littlefield, 2007; Szokolay, 2004). Concrete, masonry walls and stone finishes are high density materials with high thermal capacity, hence the term heavy-weight refers to that type of construction, which is the main construction type in Lebanon. Thermal performance of heavy-weight construction in hot climates is described as taking longer to warm up when exposed to solar gains and slower to respond to temperature variation (Littelfield, 2007; Szokolay, 2004). In the same way, it takes longer to cool down and loose the extra heat. This stored heat will dissipate during the night, when air temperatures are lower. This situation is ideal to maintain a comfortable indoor temperature when the temperature difference between day and night is considerable. Furthermore, Szokolay (2004) considers it a practical free-running solution to keep internal conditions within comfort. When it comes to expressing the thermal properties of thermal mass, the U-value is not relevant, instead the time lag, decrement factor and admittance or Y-value (Szokolay, 2008) are more appropriate for such materials. The time lag, expressed in hours, is the delay between the ambient temperature peak and the peak temperature of the space where thermal mass is applied. The decrement factor is the ratio of the actual heat reaching the thermal mass, and the heat that would be post emitted, and, since it is a ratio it is non-dimensional. The admittance or the Y-value expresses the thermal mass ability to store heat within itself, while ambient temperature fluctuates, it is expressed in W/m^2K although the same unit as the U-value, yet it expresses a different physical property, the larger it is the less internal thermal fluctuation is to be expected.

With the absence of local references for any of the above thermal property values of the different local construction materials and types, both Szokolay's (2008) and CIBSE Guide A (2006) are used to calculate or to find the nearest construction match for U-values and Y-values of the different types of walls and slabs encountered within the monitored buildings, as shown in the table 1. It can be noted that although the walls in apartment 3 have a better U-value than in apartment 1 and 2, all the apartments have similar admission values.

Methodology

During summer 2015, three different apartments have been thermally monitored, for a period of two weeks to three months, these are located within one of Beirut's suburban neighbourhood of Ain er-Remeneh, the period of monitoring stretched from August to October. The historical weather files for the entire monitored period is available from the main, official weather station, located at the nearby airport some 3 to 4 Km away.

The fieldwork was mainly based on the monitoring of thermal performance of selected rooms in each apartment, interviews of the occupants and observations. Instrumentation for the thermal monitoring of the various apartment included 16 Gemini Tiny Tag data loggers for Dry Bulb Temperature and Relative Humidity. Four of these included probe sensors specially recommended for outdoor monitoring.

Table 1. Ranges of U-Values and Y-values for the wall and slab constructions contained within the research

	Constrcution Type	Building	U-Value (W/m²k)	Admittance Y-Value (W/m²k)
	21mm Ext render + 150mm Hollow Concrete (dense) Block + 21mm Int Plaster	1 & 2	2.13	3.7
	21mm Ext render + 100mm Hollow Concrete (dense) Block + 21mm Int Plaster	1, 2 & 3 (internal partitions)	2.57	3.4

	30mm Stone Tiling 25mm Cement Mortar 50mm Aggregates 230mm Hollow Concrete Slab Cast in-Situ 21mm Int Plaster	1, 2 & 3	1.96	5.5

Climate

Beirut is located on the eastern Mediterranean coast. Based on the Koppen-Gieger classification (Kottek et al; 2006), it falls within the Csa zone, which stands for warm temperate winter and no precipitation in the hot summer. From the representative Beirut weather file (Meteronorm 7), the following descriptive statements can be derived. Beirut has long hours of sun that provide high solar irradiation. Summer humidity fluctuates between 60 and 80% with an average above 70%, peaking during the night. August is the hottest month with maximum dry bulb temperature reaching 33°C and a minimum of 25°C. Furthermore, the diurnal difference ranges between 5 and 7°C. Summer months extend from June till mid-October, with an average monthly temperature ranging between 25 and 28°C, and maximum temperature reaching 33°C (July, August) and minimum 20°C (June, October). The average annual wind velocity is less than 3m/s with monthly averages varying between 2.5 to 3.2m/s.

Case Studies fieldwork analysis

Apartment #1 –Full time cooling

This 1960s east facing apartment building has five floors with 4 apartments per floor. In each apartment, the floors and ceiling slabs are tiled and plastered concrete respectively, whereas the walls are plastered hollow concrete blocks. Windows are single glazed panes with steel frames, which are, according to the occupants, permeable to wind, and thus infiltration is high. The monitored apartment is located on the third floor, and it was surveyed from mid-September till end of October, monitoring internal temperature in a continuously cooled space. The apartment is for a family of three, with all occupants spending much of their day at home. The apartment has an east orientation for the living and bedrooms. Individual , old window type A/C is continuously on in the living/dining space.

Apartment #2 – Mixed-mode cooling

This building was also built in the 1960s and it is made of 5 floors, with two apartments on each, the ground floor is for commercial use. The main façade where the living areas are facing is south-west oriented. Its eastern façade is blank and exposed. The building is made of concrete slabs, plastered hollow concrete block walls, and all the windows are single glazing with timber frames. The monitored apartment is on the fourth floors, hence an intermediate floor. The apartment has two bedrooms, one main living area, a dining area and a kitchen, for a family of four. Father is at work all day, as well as one of the sons, whereas the other, a university student is more often at home. Mother is mainly at home. Data loggers for dry bulb temperature are located in the living area, the bedroom and the semi outdoor space with a perforated lightweight brick called *clostra*. The monitoring took place between from August and early October.

The apartment has individual A/C units installed in each bedroom and the living-dining area. The latter one is seldom used, whereas the bedrooms' A/C are used during the night at random times and for varying length. Otherwise in the living area a fan and the open windows are used to provide some comfort from the heat and humidity. When A/C is used in whatever room, the internal timber door is closed in order to keep the coolness contained.

Apartment #3 – Free running, Unoccupied

This monitored apartment is within a newly constructed building and is still unfurnished and unoccupied. The building has an East orientation for the living areas, and is made of concrete slabs and double cavity hollow concrete block walls. As per the current planning regulation, the east façade is cladded with natural white and yellow stones; whereas the west facade is rendered and painted. Data loggers for dry bulb temperature are placed in the main living area on the east side, as well as in one room on the west side. The monitored phase spanned from August to the end of October. This apartment is on the 7^{th} floor of a 9-story building, hence an intermediate location, and since it is unoccupied, neither A/C nor any other power or heat source is available. Furthermore, based on the recommendation of the building owner, one data logger is placed in the staircase leading to the underground basement, an area that is never used by any of the building's inhabitants. This area is ventilated through the main entrance gate without being hit by direct sun light.

In table 2 below the different cooling modes of each room is listed as well as the calculated overall room admittance, which sums all the products of the respective surface areas of external and internal walls along with the floor and ceilings multiplied by the corresponding admittance of each, and is expressed in W/K (Balcom, 1983).

Table 2. Recap of each monitored room cooling mode and the corresponding calculated weighted Y-values

	Internal Space	Cooling Status	Σ [Y*Area] (W/K)
Apartment #1	Dining	Full time	**180**
	Entrance	Full time	**257**
Apartment #2	Dining	Seldom	**311**
	Bedroom	Mixed mode	**374**
Apartment #3	Living	Free running	**348**
	Bedroom	Free running	**197**

Results

The current study investigated the thermal performance of existing apartments with different envelope construction, cooling patterns and living habits.

Apartment 1 has continuous cooling which pushes the indoor temperatures almost always within a 29°C average, yet due to poor envelope performance, high infiltration levels, and undersized old A/C, there is a discrepancy between the cooling set point at 26°C and the actual recorded temperature, which is shown to fluctuate above 29°C in the early afternoon when the sun start to hit the external west wall, and windows nearer to the data logger (Dining temperature - days 266, 267 and 268). The Entrance area presents a temperature profile that is more stable as not affected by direct solar gains. On the night of day 268 to 269 the cooling is turned off till late morning, without windows opening, but the expected high infiltration is taking the temperature trend parallel to the outdoors' with 1K warmer, whereas once the sun is up and till midday internal temperatures are considerably cooler from 3 to 4k

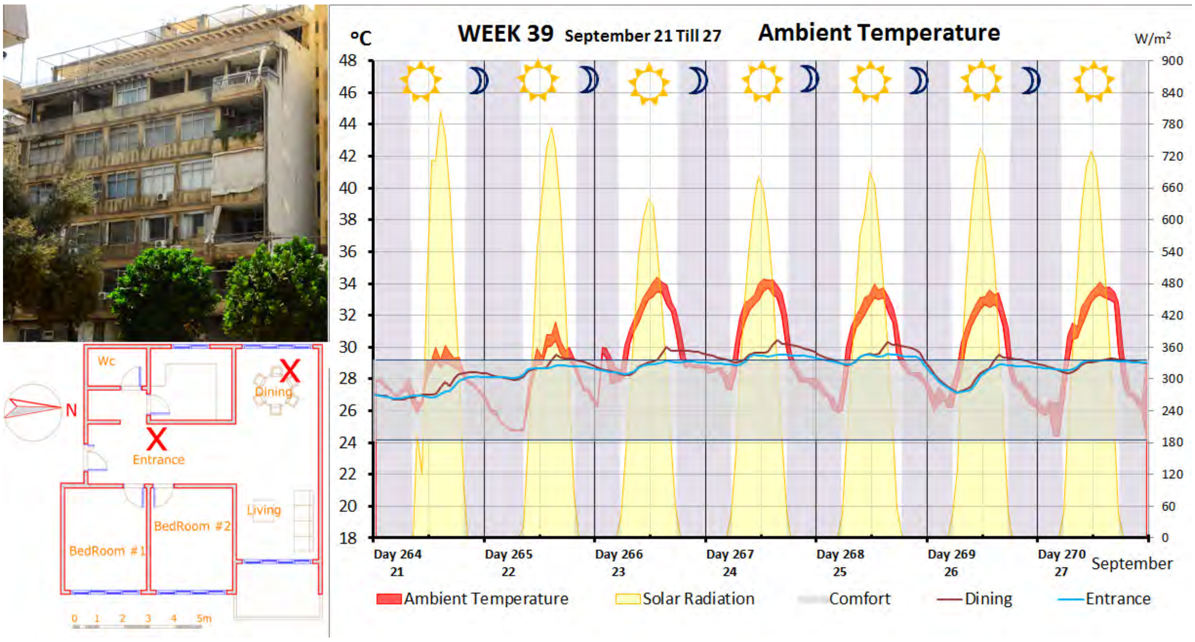

Figure 1. Building of apartment 1 in continuous cooling mode with the corresponding plan showing location of data loggers, along with the thermal graph for week 39

Discussions of observation are focused herein on week 32, August 1 till 7 for apartments 2 and 3.

Apartment 2 in mixed mode cooling, three spaces have been observed: the bed room, the dining area and the *clostra*, which is a sheltered semi-outdoor space. Extended night cooling and limited daytime cooling provide the bedroom with temperatures lower than the external temperature, yet when there is no night cooling, internal temperatures are 2 to 3 K higher and following the same trend as the external temperatures. Cooling in the dining area is limited to no more than a couple of hours on alternate days. Observations show that maximum day and night temperatures have limited fluctuation of no more than 4K when outdoor ambient air temperature fluctuation reaches 9K. Internal daytime temperatures are down to 4K lower; whereas night temperature are warmer than outside temperature. The *clostra*'s thermal behavior is similarly 2 to 3K cooler than the outdoors' day temperature and 2K warmer during the night, with a day/night fluctuation of 4-5K higher than the living area.

Looking closely on day 216, both the time lag and the decrement factor are clearly shown: the former is the time difference (horizontal axis) between the day's ambient peak temperature after midday (1pm) and both the *clostra*' and the dining's peak a couple of hours later (around 3pm). The latter is the temperature difference from the 34^{o}C peak ambient temperature to the 31-32^{o}C peak temperature of the dining and *clostra*'s.

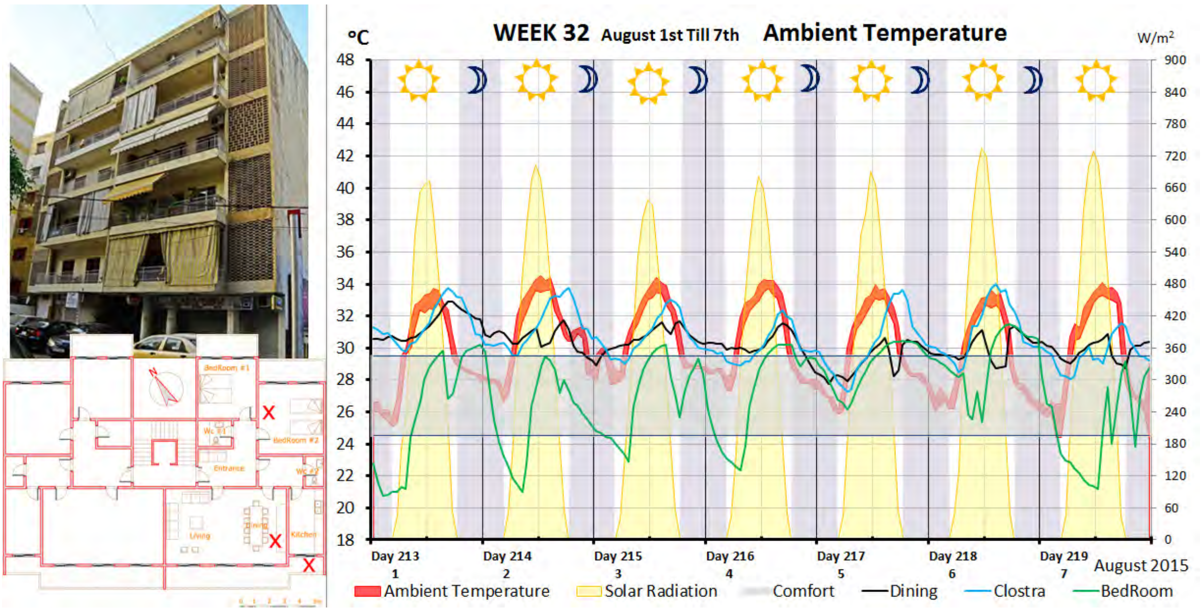

Figure 2. Building of apartment 2 in mixed mode cooling with the corresponding plan showing location of data loggers, along with the thermal graph for week 32

In the free running and unoccupied **apartment 3,** the dry bulb temperature of the living area and bedroom are recorded where the windows are kept 50% open. In addition, ground floor staircase leading to the basement is also monitored. Sun hit the living area data loggers directly around early afternoon and gave instantaneous thermal peaks, yet that aside, the temperature trend can be read with 2K cooler during the day and 3K warmer during the night, with a fluctuation ranging between 2 and 3K. As for the bedroom's day temperature, they are similarly 2K cooler than the outdoors but 4K warmer than the night temperature, and the daily fluctuation is only 2K; much less than the outdoors' 9K fluctuation. This reduced fluctuation is the effect of the surface admittance. Finally, the air temperature within the staircase leading to the basement is cooler than the apartment temperature and 2K cooler than the outdoors during the day and 2K warmer during the night with max fluctuation of 3K.

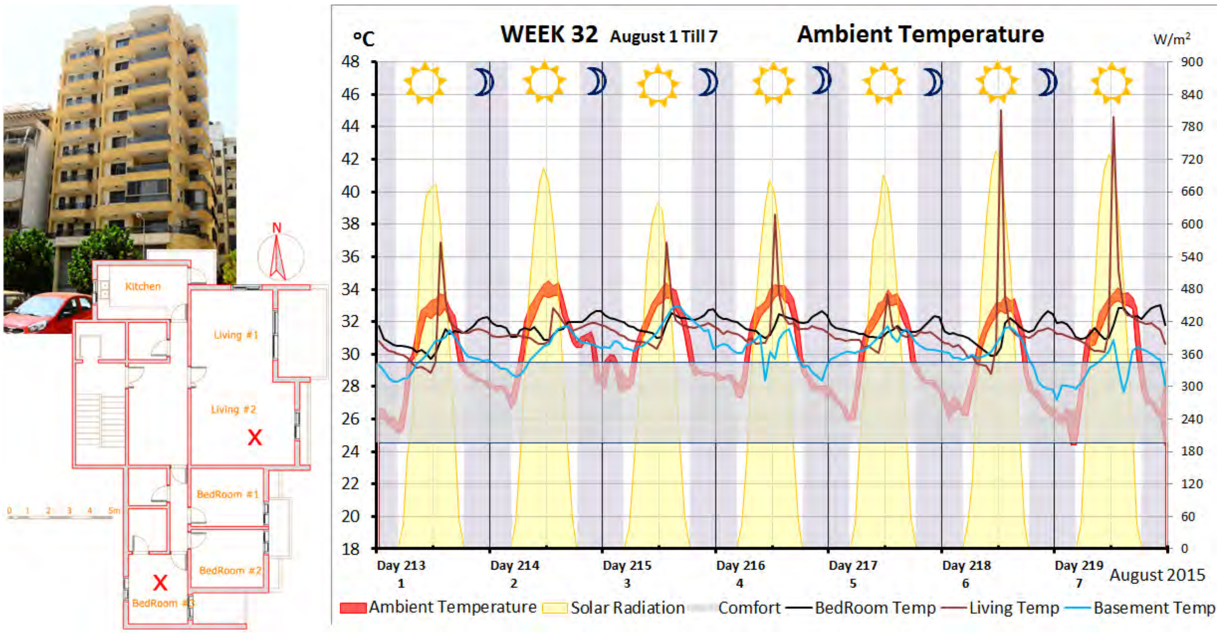

Figure 4. Building of apartment 3 free running with the corresponding plan showing location of data loggers, along with the thermal graph for week 32

Discussion

The above observations are the direct result of the thermal mass all those buildings have in common, combined with some ventilation. This is happening with high infiltration while A/C is running in apartment 1, windows are open when A/C is off in apartment 2 and apartment 3 has no A/C and windows are kept open. Based on the official weather station the wind is more often still during the day, whereas during the night it can reach an average velocity slightly above 2m/s, this creates low night air exchange varying from 0.9 to 4.5ach as shown in figure 5 and based on Szokolay (2008) and Brown (2001) calculation methods. Those air exchange are not enough to flush all the stored heat within the thermal mass during the night.

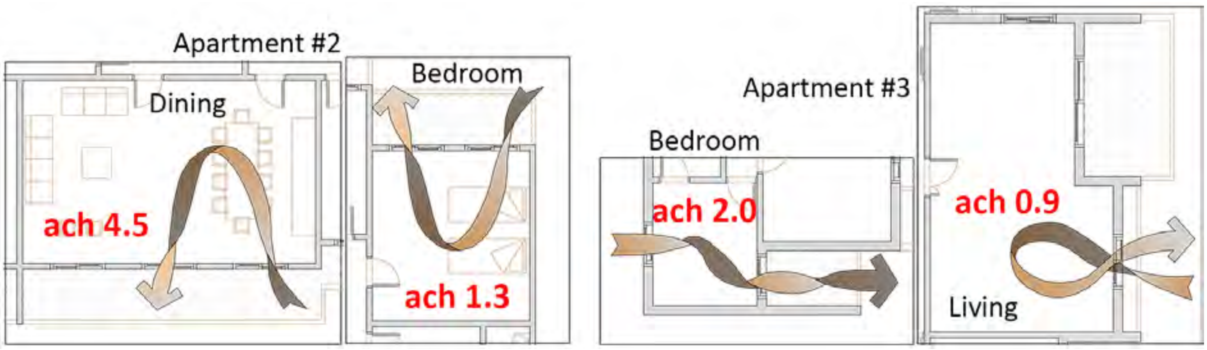

Figure 5. Calculated air exchange per hour (ach) in the different monitored rooms of apartment 2 and 3, based on the recorded air velocity of 2m/s. Also, the visualization of the internal air patterns is shown.

Concentrating on dining room of apartment 2 and living of apartment 3 with the data shown in table 3, the following observations can be stated: (1) the effect of almost similar Y-Values and weighted admittance responsible for heat storage within the envelop is shown in the day's cooler internal temperature. (2) The insufficient night air exchange is not able to get the internal temperature as low as the outdoors; yet the higher air exchange in the dining is maintaining its temperature cooler than in the living with much lower air exchange. (3) This lead to the role of the envelope's U-value with apartment 3 low value of $0.54W/m^2K$ that is not aiding in the dissipation of the night remaining heat and thus contributing to warmer internal temperature comparted to apartment 2 which has higher U-Value at 2.13W/m^{2}K, that are further helping in heat dissipation.

Table 3. Comparative data for dining room and living area

Apart	Room	Orientation	**Y-Values** (W/m^{2}K) Walls	Slabs	Walls **U-Values** (W/m2K)	Weighted admittance (W/K)	Air exchange (ach)	**Cooler** Δt Day (K)	**Warmer** Δt Night (K)
2	Dining	South	3.7	5.5	2.13	311	4.5	4	2-3
3	Living	East	3.4	5.5	0.54	348	0.9	2	4

Conclusion

The paper reviewed the theoretical background of the thermal mass effect, as reducing the internal thermal fluctuation and keeping the day temperature cooler than the outdoors. It also explained the relevant physical properties that best express the thermal behavior of thermal mass and calculated the admittance or Y-value of the encountered relevant construction in the different monitored cases. Next the research thermally monitored three different apartments within the same Beirut neighborhood, with different cooling modes. Based on these observations the research showed how exposed thermal mass with Y-values ranging from 3.4 and 5.5 W/m^{2}K combined with limited night air exchanges varying from 0.9 to 4.5 ach are able to: (1) reduce the internal temperature fluctuation from the outdoors' 9K to less than half at 4 and even 2K, (2) keep the internal day temperature between 2 to 4K cooler than the outdoors' but also are (3) not able to flush the night excess heat with night temperature 2 to 4K warmer than the outdoors'. (4) Reduced night time ventilation and low wall U-values of 0.54 W/m^{2}K reduce the effect of night thermal flushing compared to a higher U-value of 2.13.

Acknowledgment

The authors wish to thanks all those who helped during the monitoring phase by granting access to their respective apartments: Mr. Ravin Abou Rjeileh, Mr. Alaa Anka, Mr. Mohamad Mortada. This work was conducted as part of a doctoral research in the Faculty of Architecture and Built Environment, University of Westminster.

Abstract: Since 2005 various publications have proposed different U-values to be used in Lebanon to reduce the buildings' energy demand, creating confusion and a lack of specific and authoritative recommendation. Moreover, the various thermal performance guidelines are not easily comparable due to unexplained basic assumptions and guidance on the calculation of internal gains.

This study has two interrelated objectives: a) test the most appropriate U-values for the climate of Beirut, b) study the consequence of increased internal gains have on the cooling energy load in low U-value construction. The paper does dynamic thermal simulation of the various U-values from local and international sources. The analysis allows the comparison and ranking of these various U-values based on the overall yearly energy demand for cooling. This is followed by a sensitivity study where a range of increased internal heat gains are inputted onto a low and a high U-value model to demonstrate that an increase in internal gains results in both models having the same cooling loads. Low U-values under this scenario due not result in a lower annual energy load.

The study concludes that, although finding the appropriate U-value for hot climates seems uncontroversial, the effect of internal gains must be taken into consideration. Hence the importance of having consistent and harmonized national and regional benchmark values for U-values and internal gains.

Keywords: Internal gains, U-Values, Hot Climate, Lebanon

Introduction

Building energy codes in general identify U-values as their principal method of annual energy reduction. A number of local and international publications have proposed different U-values to be used in Lebanon and similar climate zones to reduce the buildings' energy demand for cooling and heating. With both national and international construction actors operating in Lebanon, this situation creates confusion and shows a lack of specific and authoritative recommendation, with many guidelines being provided by organizations with no regulatory or mandatory power. Moreover, the various thermal performance guidelines are not easily comparable as most of these publications either ignore or offer without justification guidance on the calculation of internal gains. Further complicating matters, Lebanon has four recognized climate zones where Beirut, the center of most development is exemplified by a coastal climate of a long hot and humid summer without precipitation and warm short winters (TSB, 2010 & Kottek et al; 2006). In addition, the dominant construction materials making up the building stock is almost entirely stone, concrete and related combinations, all fitting within the definition of heavy weight construction. Based on known benefits of thermal mass (Nicol et al, 2012; Szokolay, 2004; Yannas 1994; Littlefield, 2007), one would expect to find a very good example of low energy performing buildings. Yet it appears that Beirut's occupants, indoors summer thermal comfort is highly reliant on mechanical cooling.

Objectives

This study has two interrelated objectives: a) test, through thermal modeling, the impact of these different U-value standards on the annual energy load for Beirut and b) to study the consequences of increased internal gains on the annual energy load in low U-value construction.

Methodology

The paper reviews the impact of different U-values from the two editions of the Thermal Standard for Buildings in Lebanon (2005 & 2010), those from the Lebanon Center for Energy Conservation LCEC guidelines (2014) and finally, those proposed for similar climates. This is followed by energy benchmarks listing for yearly cooling and heating values, before checking the internal heat gains available values. The first phase of the research starts with dynamic thermal simulations to test the proposed U-values in conjunction with typical local construction materials in Beirut. The analysis allows the comparison and ranking of the various U-values based on the overall yearly energy demand for cooling and heating. In the second phase of the research a range of internal heat gains are inputted onto a low and a high U-value models to demonstrate that as these increase, the impact is disproportionate on and resulting in both models having similar cooling loads.

The study concludes that, although Building codes provide U-values for hot climate construction, an apparently uncontroversial focus, the need for providing internal gain parameters is of equal consideration for modeling annual energy demand in hot climates.

Envelope U-Values

U-Values for each of the external walls, the roof and the windows, from the different local and international sources are listed in table 1. The values are considerably different from one source to the other: the roof U-values range from 0.1 to 0.75 W/m^{2}K, the external walls from 0.18 to 1.62 W/m^{2}K. In both cases the lowest values are the LCEC guidelines (2014), which did not specify any value for the windows. Otherwise those windows U-Values range from 1.81 to 6.2 W/m^{2}K which encompass triple glazing with low-e coating; to single glazed windows, as well as the intermediate double glazing. When the source gives the values in imperial units for U-factor, a conversion factor of 5.678 is used to change into SI units to U-Values (ASHRAE 2013).

The yearly cooling and heating energy demand benchmarks from sources where available are shown in table 2. The standard values are defined by the LCEC (2014) as "business as usual" in reference for any typical building without energy consideration, it is set for residential at 118 kWh/m^2 per year out of which only 3 are for heating. On the other hand, the benchmark value for a building to start being considered as energy efficient is 80 kWh/m^2 per year.

Table 1. All U-Values from different local and foreign sources expressed in W/m^2K

	Title	Year	Roof	Walls	Window	Notes

Table 2. Yearly energy values in $kWh/m^2/year$ standards and benchmarks for residential

Title	Year	Residential Standard	Residential Benchmark
RT2005 H3*	**2006**		80**
Thermal Standard for Buildings (Lebanon)	**2010**		80
LCEC Guidelines on Preparing Technical Proposal for Non-Certified High Energy Performance Building (Lebanon)	**2014**	118	80

* French Thermal standards for the H3 Zone : Mediterranean area of south France
** Based on fossil fuel heating (as opposed to electrical heating which has higher value)

When it comes to the internal heat gains from occupants, lights and equipment, LCEC & CIBSE values are shown in table 3 below. LCEC mentions the occupants' in terms of W/m^2 whereas the lighting's is given in total energy per year kWh/m^2, values which are then calculated to fit in the table in terms of W/m^2.

Table 3. Internal gains values and ranges of values including totals expressed in W/m^2 from LCEC and CIBSE

Source	Type	Occupants	Lighting	Equipment	Total
LCEC	Residential	5	1.5*	n.a.	**6.5**
LCEC	Offices	14	1.9*	n.a.	**15.9**
CIBSE	Offices	5-6.7	8-12	15	**28-33.7**

* Values Calculated from 13 and 17 kWh/m^2/year

Building sample

For this study, an actual apartment is taken as a reference for the dynamic thermal simulation. It is located in the Ain er-Remmeneh area, on the outskirts of Beirut. Made of 5 floors, with two apartments on each, and a commercial ground floor, it has a south-west main orientation for the living areas and blank exposed walls to its eastern and western façades. The building is made out of concrete slabs, plastered hollow concrete block walls, and all the windows have wooden frames. Each apartment is 110sqm and is made out of two bedrooms, one living and dining area, kitchen, two WCs and one entrance functioning as a small family living. The apartment is occupied by a family of four. The occupants' behavior along with the schedule of lighting and equipment are recorded to be inputted as the internal gains in the thermal simulation model.

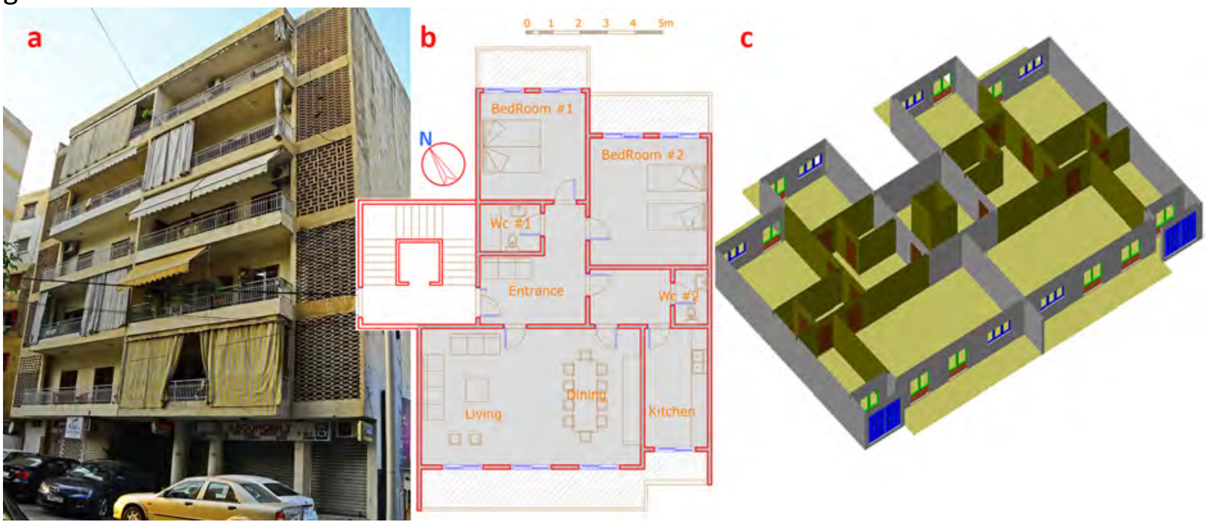

Figure 1. (a)The Building used as a model for the simulation; (b) Typical plan of one apartment; (c) 3D axonometric of the thermal model showing one entire floor with both apartments.

Thermal Simulation

The EDSL TAS 9.3.2 thermal simulation software is used with the Bayrouth weather file 2000-2009 (Meteonorm 7). Four typical floors are modelled, each with the two adjacent apartments. The orientation is kept the same with the living areas facing South-West, and cooling and heating yearly values per area are shown herein for the third and fourth floors, with the fourth considered as the top floor and third as intermediate floor.

The annual loads for cooling and heating are calculated for intermittent mode only when users are there, and occupancy is based on the observed apartment users' living patterns and remained unchanged in all the different simulations with the same input for internal gains as observed and computed to be 4.8 W/m^2. Cooling temperature is based on 24^{o}C set-point and 50% RH threshold; whereas heating temperature is set at 20 ^{o}C. The internal heat gains from lighting, users and equipment are based on the observed, recorded and calculated data, and consequently are kept the same throughout. Although each reference has different U-value for windows, the simulations are keeping the same value of 5.68 W/m^{2}K for all the simulation in order to limit the variable, and focus on the basic argument of the research.

Results

Run #1 The cooling and heating annual loads using the different U-values from the references are shown in figure 2. The cooling load is always considerably higher than the heating load, up to three to four times larger. Although this difference is expected in a hot climate like Beirut's, nevertheless what is not expected is to see that local references miss to highlight the important role thermal mass plays in reducing the internal temperature fluctuation, but instead focus on insulated construction.

The top floor has higher heating and cooling values than the intermittent floor with the cooling values differences, much more pronounced: they start at a maximum of 10% higher with the base case at 57 and 52 kWh/m^2

The cooling yearly values for the intermediate floor changes between 48 and 54 kWh/m^2 for the LCEC values and the TSB2005 respectively. Whereas the top floor cooling values ranged between 49 and 57 kWh/m^2 with again the LCEC and the base case values respectively.

All runs reached values lower than the 80 kWh/m^2 set as a benchmark (table 2). This again raises the issue of the relevancy of the local sources when no specific guidelines or ranges of values for any of the many parameters involved in the thermal simulation are available (table 3).

Run # 2 This run carries the research to its second phase where the basic internal gains of 4.8 W/m^2, used in the first runs, and which were based on actual observation, are now raised to 2.5 times, and 5 times larger (table 4). The TSB2005 and the LCEC models are used for highest and lowest initial cooling load at 54 and 48 kWh/m^2 respectively.

The calculation of the cumulative total internal gains in all the different zones from users, equipment and lighting combined is done in two steps: starting with the total energy from these gains expressed in kWh/year, then this value is divided by the 365 days of the year, the 24 hours of the day and 110sqm of the total area, to have a final value expressed in W/m^2. Noting that the total energy is calculated by inputting the area of each zone with a specific schedule along a with a heat value also expressed in W/m^2.

Comparing the raised values of the internal gains to the available limited references, shown in table 3, both the base and the 2.5 times at 4.8 and 11.9W/m^2 respectively appears to be relatively lower than the expected at 6.5 and 15.9 W/m^2, even if compared to an office rather than a residential. Similarly, the 5 times larger value is still less than the expected range in offices varying between 28 and 33.7W/m^2. As a note, internal gains can change by having more people in the room, or even having the unprotected window allowing the unaccounted sun rays to penetrate the room at any time of the day.

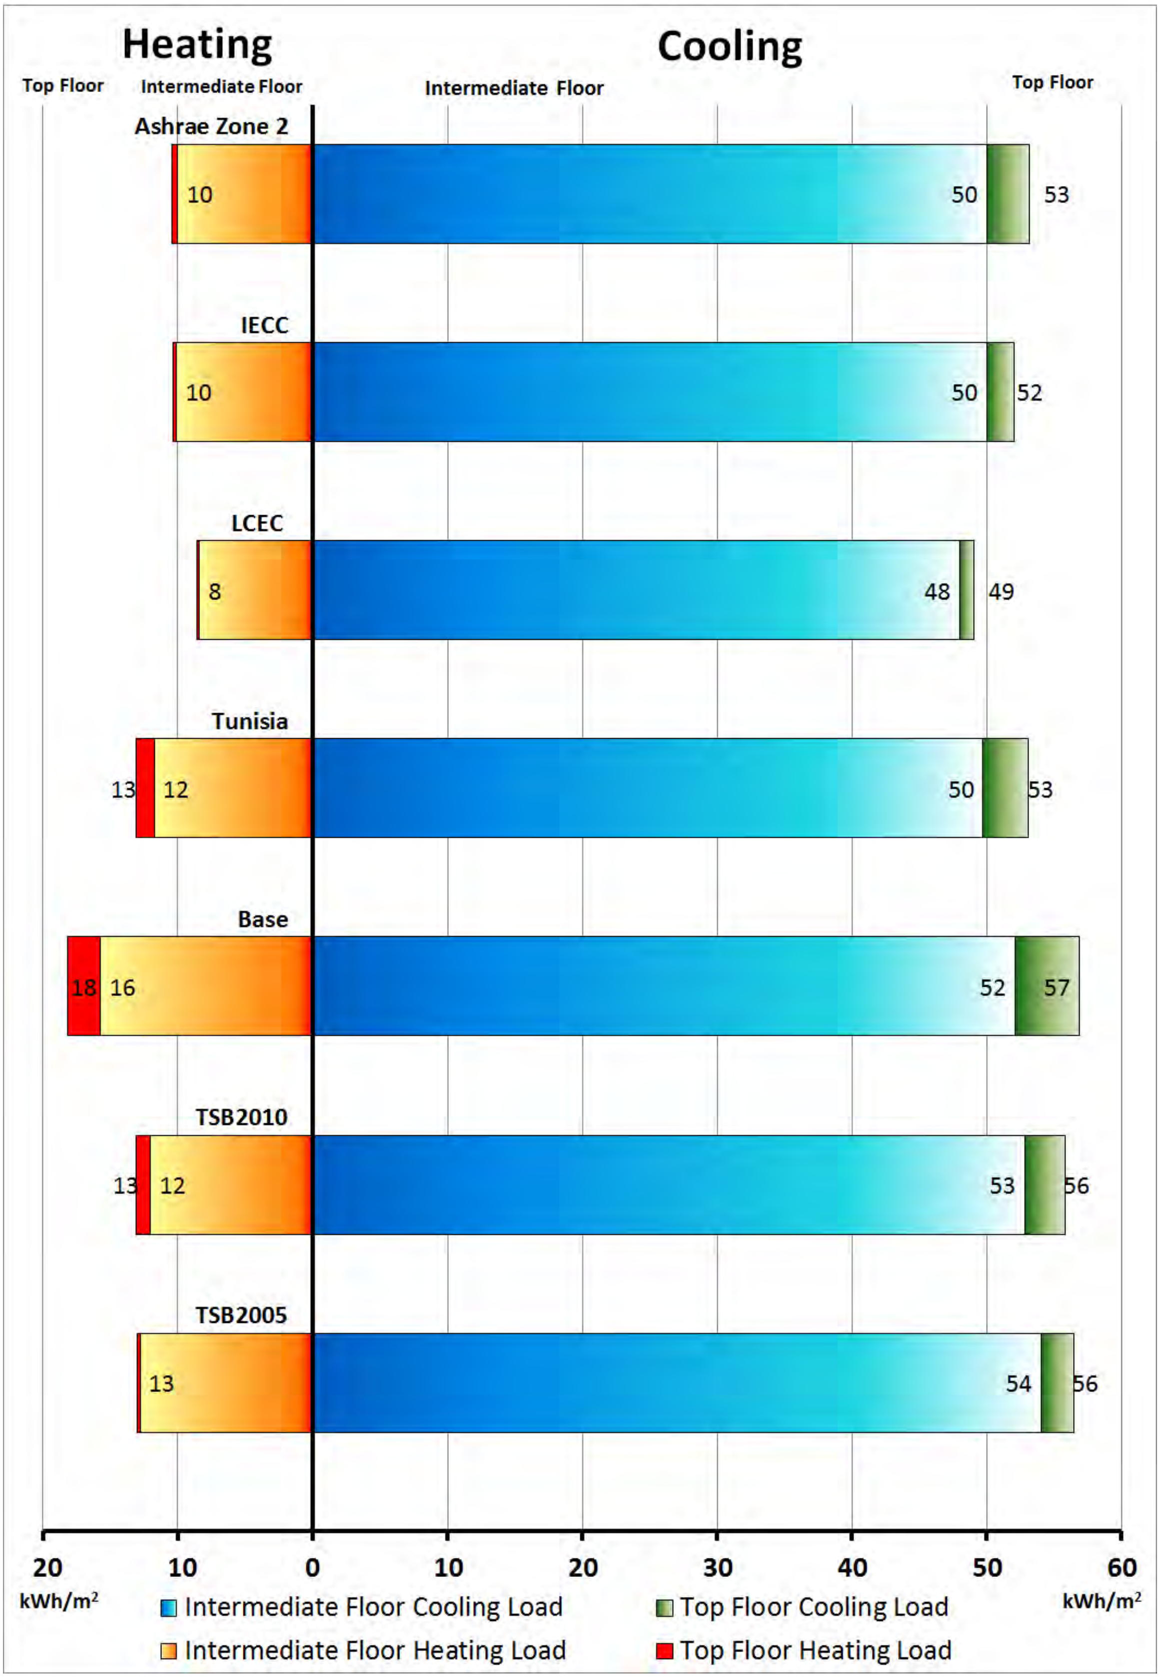

Figure 2 Overall summary of the cooling and heating load based on the different U-values from local, regional and international sources for a 110sqm residential apartment in Beirut.

Yet what should be noted here, is the critical point where low U-values construction is not performing well, when internal gains are high. In this case the percentage difference between the TSB and LCEC models are decreasing with the increase of the internal gains. Starting at 13% for the base case drops directly to 2% with the 2.5 time increase and reaches minus 4% difference.

Table 4. Showing in the first two columns the increasing internal gains in total yearly and daily per area with the available benchmarks, followed by the corresponding energy values for both the LCEC & TSB along with the percentage difference between both.

	Internal Gains			Energy Cooling Values		
	Total kWh (per Year)	**Daily Total** (W/m^2)	**Benchmark (Table 2)** (W/m^2)	**LCEC Base** (kWh/m^2)	**TSB Base** (kWh/m^2)	**% difference** (LCEC/TSB)
Base	4622	**4.8**	6.5	48	54	**13%**
x2.5 Internal Gains	11556	**11.9**	15.9	83	85	**2%**
x5 Internal Gains	23112	**24.2**	28-33.7	160	153	**-4%**

Conclusion

The paper reviewed the numerous U-values from different local and international sources, through thermal modeling, and carried on studying the consequence increased internal gains have on the cooling energy load in low U-value construction. In the first part and based on the thermal simulation the following statements apply: (a) cooling is typically 3 to 4 times higher than the heating, (b) cooling loads of the top floor range between 49-57 kWh/m^2 and are up to 10% higher than in intermediate floor ranging between 48-54 kWh/m^2. (c) all energy values are well below the 80 kWh/m^2 value set as a benchmark for a building to start being considered low energy. As for the second part when internal gains are increase 2.5 times, but still kept within the given range of values from local and international references, the difference between the previously lowest and highest energy model is reduced from 13% to only 2%. When they are increased 5 times, the difference becomes negative 4%, hence the previously best performing model with the low U-Values is now consuming 4% more energy than the model with the high U-Values. Finally, the paper concludes that set benchmark for internal gains are important for comparative studies, and more emphasis should be given for the effect thermal mass has on regulating the internal temperature in hot climates such as Beirut's.

Acknowledgement

The authors wish to thanks Mr. Ravin Abou Rjaileh and his entire family for allowing the thermal monitoring of their apartment for an extended 3 months during summer 2015. This work was conducted as part of a doctoral research in the Faculty of Architecture and the Built Environment, University of Westminster.

Energy sufficiency in buildings, a synonym for passive and low energy architecture (PLEA)

Abstract: PLEA has promoted, for over 35 years, all avenues for energy sufficiency in buildings through the wise exploitation of 'sound architectural' design potentialities. From the millenary approach of vernacular architecture, particularly relevant in the Mediterranean basin, to energy sufficiency, a clear necessity now appears for designing and retrofitting buildings by expanding the PLEA perspective. That is an opportunity to undergo a new pathway for reducing energy use in buildings, going beyond efficiency, by exploring the potentialities of passive approaches to comfort through design. The concept of sufficiency, when and where applicable, must play its preemptive role in reducing energy needs to their strictly unavoidable levels and, consequently, reducing the CO_2 emissions associated with the building sector. Faced with these, the authorities have an obligation to be clear in what regards the priority and the values of sufficiency and efficiency, i.e. first sufficiency and then efficiency. While their result is the reduction of CO_2 emissions, those two approaches implicate very different means: the sufficiency is intrinsic to the building location, design and construction, while efficiency is related to add-on procedures whose expected outcomes are frequently defeated by a rebound effect.

Keywords: energy sufficiency, designing with the climate, adaptive comfort concepts

Introduction

Buildings, representing 40% of primary energy use and 35% of the global greenhouse gas emissions, can and shall call upon decision makers and designers to play a fundamental role towards environmental sustainability. Human beings spend 80% of their lives within buildings where energy for thermal comfort and health are basic needs. Whenever a building, and particularly its envelope, is not duly designed, the result is frequently seen in, either higher energy needs or, conversely, unreached proper conditions. When correctly used, buildings should act as true extensions of the environment fully in dialogue with the local climate and using insulation and shading as needed but, in any case, always taking advantage of the Sun and local amenities. However, the modern society has led to large urban conglomerates where buildings became strongly dependent on mechanical heating and cooling systems, in effect isolating them from their surroundings and inhibiting their frequently beneficial dialogue with the climate in temperate regions. In these cases, thermal comfort and wellbeing of the occupants became dependent on strict technological paths requiring intensive energy use. Continued technological advances and recent climate change threats have only further stimulated the fulfilment of thermal energy needs exclusively through more and more efficient systems and equipment, while tending to decouple building design from indoor comfort and wellbeing (Santos et al., 2016).

The built environment has been the heart of social, cultural and economic development of human beings (Holtz, 1989). Moreover, as the center of human activities, the built environment is the key element on the road to sustainability (de Oliveira Fernandes, 2016). While the first buildings were mainly makeshift shelters to keep humans protected, the interface between the built and natural environments has undergone various changes. After the industrial revolution, there was a shift to an architecture dependent on additional technological systems due to new demands for space, mobility, privacy and socialization. In the United States, for instance, the living space per person has tripled in comparison to fifty years ago (Blackburn, 2015). Passive and Low Energy Architecture (PLEA) is founded on the principles of passive design and vernacular and bioclimatic architectures, seeking for natural and innovative techniques for sustainable architecture and urban design. The final aim of PLEA is to reduce the energy use and cost of buildings while maintaining thermal comfort for humans (Cole et al., 2010). Current trends in terminology put all of the energy-demand reduction strategies within the single encompassing classification of 'energy efficiency'. One could argue, however, that energy efficiency is only strictly applicable, by thermodynamic definition, to the cases where devices and equipment are used, i.e. when there is a defined ratio between energy input and output from a system. Yet, many solutions cannot adequately be defined or measured in this manner. When energy has the potential for such an impact on the environment, the rigor of language and technology becomes necessary. That is particularly relevant to PLEA.

In fact, passive architectural solutions and climate-aware design aim to reduce the needs for energy. In this case, the demand for final energy (i.e. the 'energy' that people pay for) is reduced not because the same output can be achieved with lower energy input (efficiency) but because the building architecture and physics make better use of the potentialities of its climate and specific location to reduce the upfront energy needs (sufficiency). Relying exclusively on energy efficient equipment to cope with situations that could have been adequately addressed through the design itself is not only non-intelligent by itself, but also unethical and, in the current case of climate change, absurd. Recent regulations in Europe are calling for optimum cost solution packages, implying that a cost-benefit analysis, based solely on investment cost versus savings on energy over the systems' lifecycle, can adequately represent the relative merits of the solutions. However, what experience has shown is that many of the simplistic calculations based on estimated energy savings tend to be quite disconnected from the real-world use of buildings and systems by people. A well-designed building, which relies mostly on passive solutions, is intrinsically more resilient to time and usage patterns than technical systems tend to be. The latter tends to be plagued by the rebound effect and to struggle more drastically with the typical peculiarities of individuals and cultures.

The efforts done by PLEA focusing on climate and natural energy resources suggests looking at energy sufficiency as a preemptive action before considering energy efficiency. Some authors, (Lysen, 1996) and (Van Den Dobbelsteen, 2008), prioritized energy demand reduction before considering renewable energy and efficient supply in the three stepped strategy "Trias energetica" toward sustainability. As it can be seen in figure 1, even the International Energy Agency (IEA) has explicitly recommended exploring energy sufficiency prior to energy efficiency and renewable energy towards low-energy and low-carbon buildings (International Energy Agency (IEA), 2013).

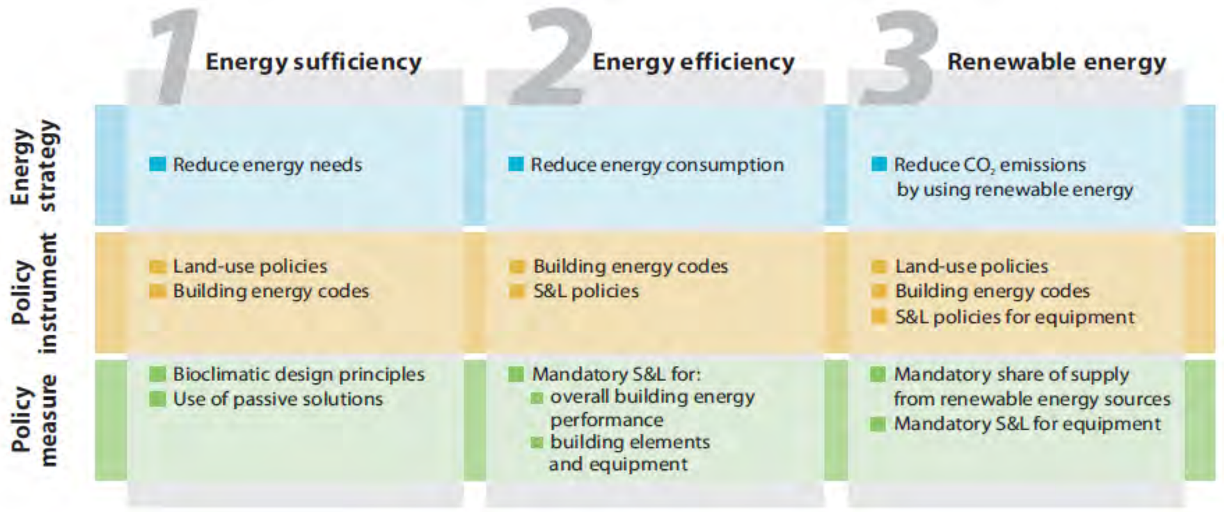

Figure 1. The path to follow at the design stage to achieve low-energy and low-carbon building by the IEA (International Energy Agency (IEA), 2013).

Since the early 80's, PLEA has been paying attention to the evolution of knowledge and technologies for exploring the Sun and the potentialities of the climate towards providing thermal comfort for occupants through sensible design and without any additional technical systems. While the former thermal comfort models were based on the indoor air indicators and suitable for air-conditioned buildings, they neglected various factors related to the occupants and their interactions with the building and the outdoor environment. Subsequently, adaptive comfort models were met taking into account other factors such as the expectation, preference and adaptation of the occupants. The adaptive thermal comfort models are vitally important in understanding the thermal performance of free-running buildings and identifying the potential of other strategies than through efficient technical systems. Adaptive comfort models are in tune and syntonic with the passive and solar approach proclaimed by PLEA. To clarify, that evolution of science and technologies are not at all in opposition to PLEA or to sufficiency, but what must be questioned is the 'one path' approach relying on hard energy technologies, its expected energy savings (ignoring rebound effects), and exacerbated automatisms to justify a rational that they do not have.

PLEA and energy sufficiency can be considered to be at a meeting point between science, technology and architecture towards sustainability. This meeting point not only does not limit the creativity of architects, but also supports them in designing more unique solutions without the need for technical interventions (de Oliveira Fernandes and Yannas, 1989). It is noteworthy that analytical tools, next to the existing complex, time consuming and non-accurate simulation tools, can be very useful in evaluating the design process, taking into account the engineering criteria for architects and vice-versa. Another important point is the local climate, culture, and the users' interferences that can drastically influence the building's performance. Therefore, the solution for each building is unique, rather than something that can be generalized and obtained in catalogues (de Oliveira Fernandes, 1989).

Energy sufficiency in buildings

There are two important points to note when conceptually differentiating energy efficiency and energy sufficiency. First, energy sufficiency creates a better framework to considering both quantitative and qualitative aspects when analyzing and defining the demand for energy. For instance, when a decision is made to promote public transport or carpooling instead of private cars (a sufficiency strategy), the demand for individual motorized mobility is shifted towards a shared ride that can be less desirable in terms of duration, space, time flexibility, route, etc. None of these aspects can be easily incorporated within an energy input vs. output analysis (or their associated costs) that would characterize the energy efficiency analysis. Instead, by focusing more on aspects such as the role of passiveness, system-dependent energy needs, and the users' behaviors, energy sufficiency should better accommodate the qualitative values of particular solutions and regulations.

Second, sufficiency is not only about directly asking or convincing users to reduce their energy use and influence their behaviors (explicit approach), but must mainly be about addressing modifications and adjustments in the built environment that result in natural decreases in energy needs even if the users are not aware of them (implicit approach). The latter is especially important in addressing sufficiency approaches within the building sector where the objective is to provide thermal comfort for the occupants with little or no requirements for technical interventions or user action.

Despite seeming to be clear-cut, the concept of sufficiency has yet not been fully recognized by scholars or policymakers (even in spite of the aforementioned IEA document). Many of its most relevant aspects are already well known and recognized but this knowledge is lost in the midst of a confusion in terminology and inexactitude of concepts that blurs the lines between passive and technical, ultimately drowning many of the opportunities that should have been explored. This is the case in most academic works discussing sufficiency by addressing it (inaccurately) as 'energy efficiency'. For instance, (Junghans, 2012) refers to principles such as sensible selection of the location and orientation of the building and its opening, thermal protection, solar energy use, etc. as 'energy-efficient' architecture. This is also found in the texts of regulations and directives, which ends up having a pernicious impact, opening the door to the more lucrative and frequently easier to implement technical solutions, despite being known that these may not be adequate for a particular setting. In this sense, the law fails to correctly direct actions by ignoring the nuances and failing to recognize and discuss the inherent differences between various options.

For the particular case of temperate climates, and particularly the ones in the Mediterranean basin, the sufficiency approach shows that the building must be designed, first, in a way that captures the useful energy from the sun, storing it effectively, and later diffusing it back indoors with little or no need for technical systems. Of course, proper shading must then avoid excessive solar gains in the summer, giving space to thermal inertia to keep the indoor temperatures cool during the hot days. The PLEA approaches mainly target these two parameters and many architecture examples worldwide can testimony to that. Designing small windows and doors is one of the evident examples of solar protection in vernacular architecture. There are various cases of using small openings in buildings today in southern Portugal, Italy or Greece. Enclosed balconies (which can serve as buffer zones to increase solar gain and prevent the heat loss) are explored in regions with cold and windy winter such as Beira Alta region in Portugal today. Examples of patios can be found even in the American continent, indicating how vernacular architecture has been conveyed between countries.

A common aspect between all these PLEA approaches is that they are mainly changes in the building arrangement and architecture (energy sufficiency), concerning the local climate, and effectively decreasing the energy needs before requiring any additional technical system.

Discussion and conclusions

It is known that energy efficiency approaches tend to struggle with the issues of rebound effect. Individuals tend to use many of the more energy efficient devices more frequently or more intensely, counting on their lower energy consumption (i.e. on their lower costs to run). The result is that energy savings are generally much lower than could be expected from the energy efficiency gains. Furthermore, in addition to this 'direct' rebound effect, there may also be an 'indirect' rebound effect when an increase in disposable income results in increased energy use in other activities by the same user or by others (Chitnis et al., 2014). Energy sufficiency approaches, particularly within the buildings sector (i.e. using PLEA's principles), per definition are free of any rebound effect, thus justifying giving it a higher order of merit than any of the technical energy efficiency options.

By reviewing the PLEA approaches, one can conclude that they contribute to energy demand reduction through sensible design of the building and its adaptability to the environment. It is clear that what the PLEA proposes must be unrelated with the technical add-ons at different stages of the energy flow or how efficiently useful energy fits to the energy demand (efficiency), but it is indeed all about reducing the demand itself to the actual needs (sufficiency). Therefore, the PLEA concept can be encompassed within the concept of energy sufficiency. Nowadays, the term 'efficient building' is increasingly being used here and there, most of the time in the wrong context. Likewise, energy efficiency has been widely addressed for PLEA approaches even in regulatory documents and standards. However, the common characteristic of the bases of PLEA (i.e. passive design and vernacular and bioclimatic architectures) is independency from additional energy-consuming HVAC systems, the stage where energy efficiency can play its role. It is noteworthy that in addition to addressing the building to reduce the energy demand (implicit approach), energy sufficiency also includes asking individuals to decrease their demands and avoid indulgence (explicit approach). What PLEA proposes, indeed, is comparable with the implicit approaches of energy sufficiency, but energy sufficiency is a broader concept than PLEA and embraces the user behavior as well.

While the concept of energy sufficiency proves to be effective and applicable within the building sector, nowadays many building designers and occupants disregard its potentials and rely on pollution-causing and costly options of HVAC technical systems. In this front, the regulations are of no help and are lacking in their role of directing appropriate decisions and actions. Currently, construction firms tend to replicate the same building from one country to another with very different climate, culture and user behaviors. The current standardization of buildings, around the globe, are mainly based on non-adaptive thermal comfort models and use of technical add-ons. For instance in the United States, the Green Building Council (USGBC) grades buildings through the Leading in Energy and Environment Design (LEED) certification. However, this certification does not accredit bioclimatic and passive solar designs. It is noteworthy that while it is possible to get the silver grade without any improvement in the energy performance of the building, it is impossible to achieve a high score in Energy and Atmosphere (EA) category of LEED without using mechanical systems (Shaviv, 2008).

Remarking the discussed order of merit of energy sufficiency over energy efficiency, the question then arises: why is there so much attention being paid to energy efficiency, and not enough to energy sufficiency? The first answer is that in that case, energy efficiency is encompassing all of the solutions of real efficiency and sufficiency. As described above, this ultimately results in bad solutions propagating inconsequently. Another interpretation is that energy efficiency is essentially linked to technology and technical options related to new and profitable opportunities. The existence of a demand leads to a market opportunity and decreasing that demand to the actual needs, would mean endangering various business opportunities. Energy sufficiency is not a solution from the past, but for the future. Understanding and recognizing the concept of energy sufficiency can lead to the evolution of the PLEA to an 'effective' or 'actual' PLEA as a preemptive approach to reducing energy needs and, consequently, cutting down the CO_2 emissions associated with the building sector.

A Bioclimatic Reading About the Chandigarh Tower of Shadows

Heitor da Costa Silva

Faculty of Architecture, University of Rio Grande do Sul, Porto Alegre, Brazil,
heitordcs@gmail.com

Abstract: The objective of this paper is to discuss the qualifications of the built environment by the focus of Bioclimatic Architecture. The Tower of Shadows building designed by Le Corbusier and built in the Capitol of The Parliament in Chandigarh is the reference subject for the discussion. The discussion of the model is limited to the solar access in the buildings and the use of shading devices by means of the “brise soleil”. For modelling simulations it was used the “Sketchup” and “Energy Plus” softwares. The software “Sketchup” was used to produce an architectural model and the “Energy Plus” was used to test climate responses of the building. The outcome of the investigation point out that the building responds to Modern Architecture ideas as one archetype and for Bioclimatic Architecture the building illustrates a the solar control rule for environment adaptation of the building by means of solar control in the harsh climate of India.

Keywords: bioclimatic architecture, modern architecture, Tower of Shadows

Introduction

The Tower of Shadows is a peculiar building conceived by Le Corbusier to deal with the hot environment in Chandigarh, India, 30.73N Latitude and 76.77 Longitude. Also the material used a reinforced concrete structure and the general shape adopted for the building is iconic. Additionally the space has no specific use, it is said to be for rest. Le Corbusier described it as “a very open hall, very high and shadowy”. “Architecture has always been a transformation of material into human shelters in various types of natural and social spaces”.

Figure 1. Tower of Shadows, esplanade of Capitol, Chandigarh. (© Fernanda Antonio)

Figure 1 above shows the Tower of shadows view from East and far away in the picture is the Assembly Palace of Chandigarh.

About the Tower of Shadows

The Le Corbusier approach to control sunlight was considered “empirical”, due to the bad repercussion, regarding to thermal performance of the Salvation Army building, in Paris, in 1929. The low income building was completed in 1933. The main idea used in the concept of the building was a South facing glass wall, a double glazing system of air conditioning that never worked. The glass wall was replaced in 1952 after many summers with the residents dissatisfaction because of the overheated dormitories. This building played important role as experiment for Le Corbusier subsequent constructions. “These buildings played the role of a laboratory...”, it is Le Corbusier himself saying about to the Salvation Army (Armé du Salut) building.

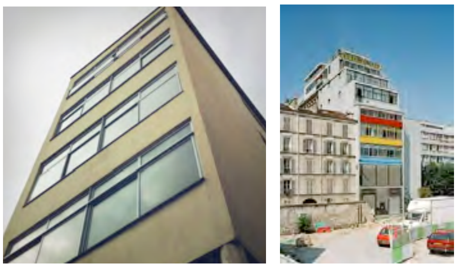

Figure 2. Salvation Army in 1933 and in 1952.

Examining the drawings in Le Corbusier “Ouvre Complete”, the first aspect that has called the attention at the starting of this study was the Tower of Shadows structure, the name of the building that Le Corbusier has given to the construction. Also, the grid used for the complex of edifices, in the area of the Assembly that received a 45°rotation angle used to situate the Tower of Shadows. This rotation provoked the building to adjusting exactly to the Cardial orientations. Also, examining some of the original drawings, there is a Sun Chart which shows the sun azimutes and altitudes in a 30N latitude that is shown close to the Tower of Shadows. See these remarks in figure 3 below.

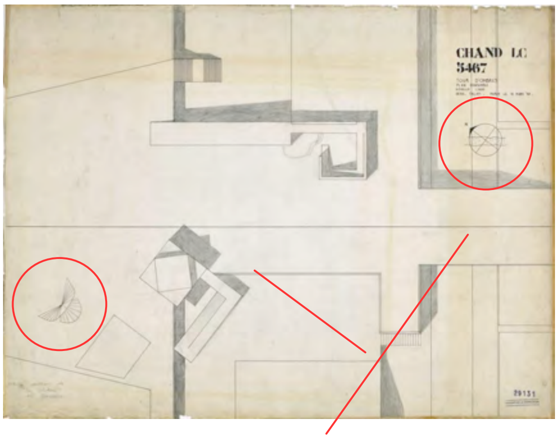

Figure 3. Site Plan for Tower of Shadows (original drawing from LCF, modified with remarks).

The evidences shown in figure 2 has lead to some questioning: - if the building is appropriate for solar control what happens with other climatic parameters? Besides the shadowing, how would behave other parameters affecting users, e.g. temperature?

Considering that the solar geometry and the apparent sun movement is the same, for a given latitude, one can say that Tower of Shadow would cast shadows similarly in Porto Alegre, Latitude 30.07 and 51.23 Longitude, but in South hemisphere.

The next step of the investigation was to develop architectural model using Sketchup to model shadows, this to understand the building geometry for further analysis with the aid of Energy Plus.

Architectural modelling and solar geometry for radiation control

The architectural modelling of the Tower of Shadows was made with the aid of the software Sketchup. Plans and sections of the building were searched to draw a three-dimensional model was specially designed to emulate shadows. The simulations were made specifying 30 Latitude. Also, the angles of the vertical elements of the façade were made variable, individually and in group to allow for variation in order to assess differing areas of shading inside the building.

A series of images were developed to emulate shadows hourly and seasonally, this to assess the efficiency of the “brises soleil” designed by Le Corbusier for The Tower of Shadows. The Figure 4, below shows the SW aspect of the model. This imagem allows visual assessment of the solar access inside the model that can be sectioned horizontally and vertically, so that is possible to “see” the sun inside the model, any time of the day along the year.

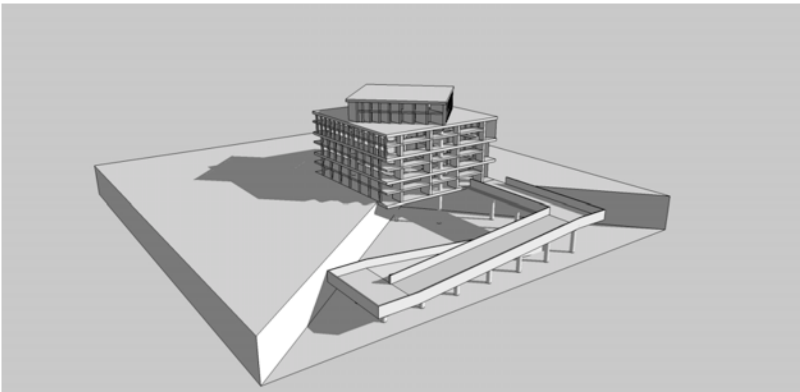

Figure 4. Tower of Shadows - solar geometry modelling for solar control and shading devices with Sketchup.

The modelling allowed to understand access of direct solar radiation. Two assertion can be assumed from the study: a) the building response to sun radiation with respect to shading devices is effective in the periods of high temperatures of summer and b) the vertical and horizontal dimensions of the devices are effective to promote shadows during the critical periods.

Thermal modelling for temperature assessment

The thermal modelling of the Tower of Shadows was made with the aid of the software Energy Plus. In order to attend to the structure of the thermal modelling programme varied adaptations were made in the architectural design. The EP+ software needs a “thermal zone” to identify internal and external environment. As the Tower of Shadows is a structure with the air environment coupled both internal and externally the thermal model had to be closed with a glazing surface.

The modification done to the thermal model altered not only the espacial criteria in terms of architecture but also the resulting internal temperatures, reflecting a environment similar to one winter garden.

The thermal modelling is trick because the EP+ is a powerful tool that requires detailed data for the thermal model and also the climatic data for Chandigarh and any mistake made in the input data can lead to severe errors can that invalidate either the current simulation or all the series of results. Neither physical data concerning the built material of the Tower of Shadows nor the climatic data with "epw" format were obtained for Chandigarh.

Figure 4 below shows results for the modelling produced running with climatic data for Porto Alegre 30S latitude. In this case the simulation produced was used in tentative maner to understanding internal behaviour of the building regarding temperature. Other simulations were developed for the same purpose but the model geometry do not seem to be appropriate some discrepancies were detected. A big effort is been made to produce a reliable model for this intent of understand internal temperature. However until now there is no reliable conclusions.

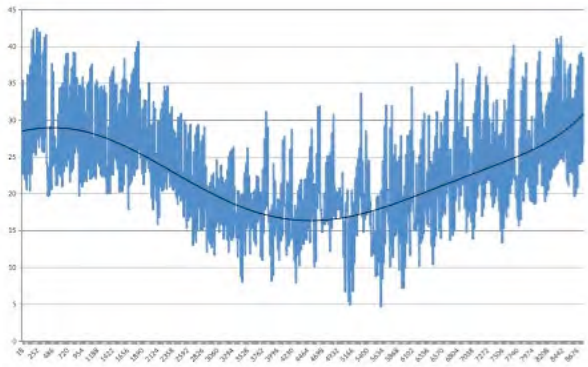

Figure 4. Tower of Shadows – thermal simulation for internal temperature.

Conclusion

The study has shown so far, that the building the Tower of Shadows by Le Corbusier is a very rich source for a bioclimatic reading exercise to understand design strategies to deal building adaptation to environment climates that demands for solar control and shading devices. Also, the Tower of Shadows allow precise investigation on solar control by means of shading devices, the so called "brise soleil" within the universe of the Le Corbusier life work. The building has proved to casts shadow inside its structure. Also Corbusier has given a proper name to the building calling it Tower of Shadows. It is not clear the internal thermal environment is always improved just because of the use of the "brise soleil". The simulations did to better understand the building thermal behaviour were severely limited because of the adaptations did to the model in order to have a comprehensive simulation. Several erros with the model were pointed out by the modelling EnergyPlus.

Abstract: Architectural projects in protected natural areas responding to visitors, education and scientific programmes, require a specific environmental approach and design guidelines, with the aim of protecting and preserving these natural heritage sites, by controlling and minimizing impacts associated with human activities generated by buildings in highly sensitive sites. This paper presents the initiative to promote specific building guidelines in protected areas and national parks of Argentina, through the development of sustainability parameters to implement in new projects. The Nahuel Huapi National Park, Patagonia, Argentina, provides a base to study feasible procedures to implement principles and evaluate sustainability criteria to assess and qualify new projects. International references, were instrumental to develop sustainable building requirements, with emphasis on environmental values related to building design and management, together with innovation criteria for renovation, revitalization and recycling. The proposed Environmentally Responsible Design Methodology was applied to representative buildings providing case studies from the four stages of the National Park development process, to qualify and quantify sustainability issues relating buildings and environments, and analyzing evolution over time. This document emphasizes implementation of innovative approaches, for future interventions applicable to minimize building impacts on sensitive natural sites in the context of sustainability in architecture and environment.

Keywords: Sustainability, Design, Natural areas, Environment.

Introduction

National Parks, located in sensitive areas, aim to preserve the natural and cultural heritage of a nation for future generations. Therefore, they present a valuable test case as their presence not only ensures the conservation of the area involved, but also promote the spread of knowledge on sustainable development issues, provide innovative management practices in neighboring areas, and ensure the presence of an increasingly attractive recognition by national and international tourism industry as registered trademark of prestige. They also provide direct and indirect environmental services of great value to society as a whole, improving the quality of natural habitats.

The existence of protected areas shows the particular consideration of a country towards the care for present and future development. In this framework, National Parks have become icons of sustainable development representing real opportunities for growth, jobs and social equity, as well as stimulation of more dynamic regional economies.

A variety of natural and cultural values, together with immaterial issues, are displayed for visitors, discovering a series of economic criteria, according to international ranking, such as those established by UNESCO, ranging from the architectural isolated sites to well provided routes and cultural landscapes.

In Argentina, protected natural areas have not yet developed certification or assessment procedures to ensure the sustainability of their buildings. Considering the high environmental vulnerability of these sites, maximum care is required, particularly where vacant areas are detected for possible human interventions. In these cases the implementation of special measures to preserve the unique ecosystems is needed by generating and applying sustainability criteria in building projects, carefully combining new technologies and traditions.

The increasing numbers of visitors and flows of ecological tourism, searching for a direct contact with nature and spiritual satisfaction, is promoting a new scope for recreational activities. In this case “sustainable tourism” for visitors represents a significant experience, involving them in environmental issues and promoting eco-friendly practices. Currently, international standards and certification systems, such as BREEAM in the UK, CASBEE in Japan, LEED through the USGBC in the USA, Green Star in Australia, are proving useful criteria and instrumental tools. There is also the Green Globe certification, an specific system providing standards to support sustainability in travel and tourism, evaluating a company’s performance and impacts.

These standards provide a number of criteria and indicators as well as policies and procedures in line with sustainability certification programmes, established worldwide. In Argentina, a significant body of knowledge is building up and developing evaluation programmes related to policy studies and human behavour particularly relevant to provide support for these initiatives (Evans, J., 2010). These standards, originally focused primarily on urban areas, include studies and analysis seeking for the improvement of habitats built with minimum use of resources and low environment impact though achieving adequate confort, mainly by intelligent design and bioclimatic strategies. Sustainability requires a change of mentality, a shift in values towards new lifestyles. These changes may be able to enhance global interaction, environmental management, social responsibility and economic viability.

The new approach to sustainable design must recognize the consequences of each design option favouring natural and cultural resources at local, regional and global levels. According to the Declaration of Interdependence for a Sustainable Future “Sustainable by Design”, of the International Union of Architects (UIA), Chicago (1993): *"sustainable design integrates consideration of resource and energy efficiency, healthy buildings and materials, land use ecologically and socially sensitive and an aesthetic sensitivity that inspires, affirms and allows".* The UIA has also expressed in the Copenhagen Declaration (2009) that *"architecture must develop holistic methods, from the smallest scale to urban planning, not to mention the buildings, landscapes, natural environment and infrastructure elements essential to the continued creation of sustainable and livable future. An attentive and respectful design of forms, geometry and space strategy, associated materials, equipment and adequate functional distribution can reduce resource use, emissions of greenhouse gases and global environmental impact of 50 to 80 %".* This statement puts the value of responsible architectural design as a source of identity, diversity and pluralism, in accordance with UNESCO's declaration on cultural diversity, where it is declared a common heritage of humanity, source of exchange, innovation and creativity " assuming it is as necessary for humanity as biodiversity is for nature". (2001, Art.1)

Background of certifications

The qualifications and certifications add value to the sustainable building in the market. The objective of the certification systems is to provide an independent mechanism to verify the progress of sustainability in architecture. For this purpose, it is necessary to have the guidance of the designer during the design process, always considering transparency and reliability in the evaluation.

In the last few years, there have been concerns in the Latin American region related to the application of Sustainable Building qualification and certification systems, calling into question the criteria and methods used in systems developed and implemented in highly industrialized and highly developed countries. RESET model (Sustainable Building Requirements in the Tropics), a basic document developed in Costa Rica by the Institute of Tropical Architecture (IAT), designed to extend sustainability requirements to a wide range of buildings, prioritizing the Design and the sustainability potential of architecture. As stated in the Manual: *"Enhancing the design of architecture and engineering as a tool to achieve sustainability, will bring savings, independence and adaptation to the place. Adapting to the climate by recovering its attributes and renewable resources, strengthening the local economy, favoring the use of local labor and materials, and strengthening the culture that is updated and enriched with contemporary architecture that emerges from the traditions"* (2012:7).

This standard becomes a pragmatic tool that facilitates and revises project decisions, serving as an indicator and guideline, to incorporate responsible criteria with the environment and was designed for the evaluation of a building in its design, construction and / or operation stage. The results of the evaluation are determined in a percentage of achievement, that does not quantify emissions, nor savings of consumption in numbers; but reflects efforts made in the design and construction of the building.

Several documents analyze the current state of the situation and the evaluation of the advances, limitations and possibilities of sustainability certification of sustainable construction in the Latin American region. At regional level in Latin America, it is necessary to advance a series of considerations that allow the development of regional criteria and local instruments of implementation (de Schiller et al., 2003)

Environmentally Responsible Design Methodology

The use of sustainable criteria in National Parks implies less impact on natural sites to preserve in the most pristine way possible for present and future generations, through the translation of these strategies into effective measures of implementation. The effects of determining the degree of sustainability in architecture, has been designed a Environmentally Responsible Design Methodology (ERD), a product that is constituted as a qualification and certification system. Applying this Methodology, also collaborates in decision making at the moment of design, thinking about sustainability in architecture, with more design strategies than with technologies, deepening the potential of design, before adding technologies, only using them as a complement. This contributes to the conservation of the natural heritage, located inside and outside the National Parks of Argentina.

For their design, different qualities have been analyzed to consider specifically and locally the desirable attributes that make a construction project sustainable. This determination of attributes, not unique or exclusive, is oriented to an environmental responsibility of the interventions and propitiates actions that aim at a minimization of negative impacts. Ten key points are established which, in turn, have ten items to consider, through which the actions to be fulfilled are quantified. Through this analysis the percentage of the interventions can be calculated in percentage terms, while the desirable parameters for buildings are proposed within a space where the main objective is the conservation of nature. With these indicators, the sustainability actions of the project are measured, according to the following set of items that contribute to minimizing impacts. To the items indicated above, it is proposed to associate each of them with a quality attribute, which can be quantified (Table 1).

	ITEMS	ATTRIBUTE
1	Implementation and site.	Adaption to the site
2	Efficiency in the use of water.	Water, care and efficiency
3	Efficiency in the use of energy.	Energy, care and efficiency
4	Envelopes and materials.	Materiality, and enclosoures
5	Universal accessibility.	Universal accesibility in design
6	Natural conditioning, lighting and ventilation.	Naturality, lighting and natural ventilation
7	GHG emissions (greenhouse gases).	Emissions, Impact of GHG, Green-house Gases
8	Equipment	Capacity, with equipment
9	Usability	Operability, in the efficient use of buildings
10	Construction and deconstruction	Rationality of the construction processes

Table 1 – Attributes

In order to carry out the analysis and qualification of each project, characteristics are established, which configure each attribute, as detailed below:

- The **adaptation to the site**, it is considered of paramount importance to avoid the alteration of ecologically sensitive areas, maintaining the natural drainage systems, respecting the topography, making minimum interventions in the movement of soils, as well as the conservation of the existing arboreal species, adapting the Architecture to the site and not the site to the architecture.
- In the case of **water, care and efficiency**, it is considered the implementation of measures for the use and reuse of gray water for cisterns and toilets, with toilets with the option of half load. Consideration is given to design decisions that propose the recycling of gray water and its use in risk, as well as the reduction of the use of drinking water, collecting waste water, use of sanitary parts, faucets and accessories for consumption (with automatic wáter closing systems) and incorporation of elements that value water as a vital resource.
- In relation to **energy, care and efficiency**, the maximization of bioclimatic design strategies according to the Bioenvironmental Zoning of the Argentine Republic, IRAM Standard 11,603, prioritizing the local construction and material traditions, as well as the implementation of the project considering orientation, Sunning and wind protection or catching breeze. Actions that tend to use renewable energies and actions that minimize energy dependence, isolation of the soil to isolate it from the cold and / or snow are weighted.
- In the case of **materials and envelopes**, the use of local materials and the use of building materials with low energy demand for manufacturing, transport and

maintenance is preferred, considering the total or partial reuse of existing buildings. The use of toxic materials used in the treatment of timber should be avoided, using those certified throughout the chain of custody, not only from certified forests. The use of local and non-toxic materials, which can nobly return to the earth, and actions aimed at avoiding the use of solvent-based paints, favor the reuse and recycling of existing constructions.

- Through actions aimed at implementing **universal accessibility** measures in projects, it is considered mandatory to apply Decree 914 / of Law 22,431 modified by Law 24.314, National Accessibility Law. In public works, a universal accessibility design should be included, including the Use of Spaces and Services for All, and the Design for All Manual, incorporating adapted toilets, ramps, entrance doors with adequate measures, texts in Braille, Sound signals, and accessible parking, design decisions that effectively contribute to the story of sustainability within the framework of social equity.
- The attribute of N**atural, conditioning lighting and ventilation**, is related to actions that favor design strategies to enhance lighting and natural ventilation, considering the incorporation of the concept "access to the sun", sun protection in summer, thermal comfort of buildings and Visual to the outside. The application of vernacular criteria and the generation of intermediate spaces between the interior and exterior are evaluated, reducing the direct impact of the external climate.
- The item on **GHG emissions (Gases Greenhouse Effect)**, is related to designs that reduce these emissions. Measures are taken to promote energy efficiency measures for conserving heat in winter, sun protection in summer (avoiding overheating and consequent energy demand for cooling), adequate thermal insulation in walls and ceilings, and integration of passive and active systems.
- In relation to the saving **Capacity** in construction processes, the efficiency in the operation of the facilities is evaluated, reducing the demand for maintenance, including an efficient waste management and recycling.
- With respect to **Operativity** and its link to the efficient use of buildings, it is considered valuable that the buildings have use manuals and training programs for users and personnel operating the building. It possible to visualize the operation, management and use of the facilities, incorporating thermostats, sensors, meters, dimmers and other control devices, as well as the control of electricity and water consumption by premises or sectors.
- The attribute of **Rationality** is related to efficiency in construction processes, considering the measures that mitigate noise and dust, as well as unnecessary movement of materials. Likewise, they describe constructive procedures that assure the mitigation, control and elimination of pollutants to the soil and the conservation of existing organic land, establishing their management during the construction process, through their recovery, storage and reuse.

Universe of analysis, Nahuel Huapi National Park

The creation of the Park dated from 1903, when Perito Francisco Moreno donated the land to the Nation, an area of three square miles, located on the border of the Neuquen and Río Negro territories, on the west end of the arm Blest of the Nahuel Huapi Lake. The area became the heart of Argentina's first National Park, declared in 1922 as “National Park of the South”. In 1934 the National Congress passed the law creating the Nahuel Huapi National Park, incorporating a larger territory. Thus, Argentina became the third country in the Americas, after the United States and Canada, to have a National Park.

Located on the southern foothills of The Andes, in the Argentinean side of the northwestern Patagonia, the pioneering history of the Park soon become a heritage feature. Since the creation of the Nahuel Huapi National Park, a project was born with the aim of “urbanising” the region. A team of architects, Bustillo, Estrada and Césari, designed and built a series of buildings, including several within the site to establish a settlement which is now the City of Bariloche, along the lines of a general plan supporting local development. The architecture develops as a cultural expressions producing, according to the ideas of the time. Samples of varied cultural heritage from rural buildings made by local people who settled in the area before the creation of the Park, were covered with tiles, with little ornamentation and strong trans-Andean influences with intuitive bioclimatic features.

Study Cases

The proposed Environmentally Responsible Design Methodology was applied to representative buildings providing case studies from the four stages of the National Park development process, to qualify and quantify sustainability issues relating buildings and environments, and analyzing evolution over time.

For example, The Las Flores Lodge (Figure 1), a representative example of the architecture of the first pioneers in the region. Is analized with the Environmentally Responsible Design Methodology (Table 2 and 3).

ADAPTA-BILITY	WATER	ENERGY	MATERIALITY	ACCESIBILITY	NATURALLY TY	EMISSIVITY	CAPACITY	OPERATIVITY	RACIONALITY
	Care and efficiency	Care and efficiency	and enclosoures	universal in design	conditioning, lighting and ventilation	GHG emissions	with the equipment	in the efficient use	in construction processes
10 0	7 3	3 7	8 2	0 10	6 4	3 7	4 6	2 8	7 3

Table 2 - Values Environmentally Responsible Design Methodology
Lodge Las Flores

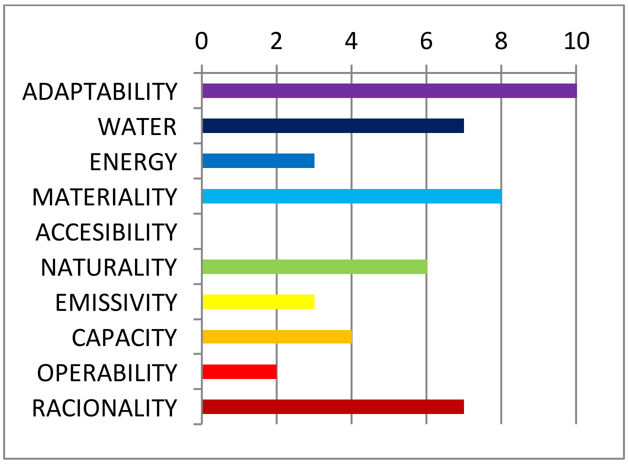

Table 3. Values of Environmentally Responsible Design Methodoloy for the Lodge Las Flores, Nahuel Huapi National Park.

Figure 1. Lodge las Flores, Nahuel Huapi National Park

Other example is the Building of the Park Headquarters (Figure 2) of the National Park (1936). Through the new architecture of National Parks was looked for a mountain image with strong central European influences, defined by the formal and the use of stone and wood. Often listed as picturesque, they have provided local features and regional character to the image of the National Parks Administration. Is analized with the Environmentally Responsible Design Methodology (Table 4 and 5).

ADAPTA-BILITY	WATER	ENERGY	MATERIALITY	ACCESIBILITY	NATURALLYTY	EMISSIVITY	CAPACITY	OPERATIVITY	RACIONALITY
	Care and efficiency	Care and efficiency	and enclosoures	universal in design	conditioning, lighting and ventilation	GHG emissions	with the equipment	in the efficient use	in construction processes

Figure 2. Headquarters Nahuel Huapi National Park

Conclusions

This paper emphasises the importance of incorporating innovative approaches to promote the protection of natural environments, providing effective enforcement measures within the development of built environments located in sensitive natural hábitats. This methodology allows incorporating effective measures to achieve designs that impact responsibly on the environment. From its application through the detailed analysis of buildings, a percentage value will emerge, because there are ten attributes with ten items each. The points Naturality and Materiality include the analysis and assessment of authenticity, the use of traditional constructive traditions and their materials.

As an original contribution to this context, the paper proposes bases to establish sustainable construction requirements in environmentally sensitive sites, prioritizing the design capacity and feasibility of potential implementation within the institutional framework of the National Park Administration, providing configurations and actions for the construction Of environmentally responsible project-architectonic narrative in extremely sensitive natural environments. This promotes the development of new designs with strategies that minimize the impact of construction, to enhance the heritage of natural and cultural heritage for current and future generations.

PLEA 2017 EDINBURGH
Design to Thrive

The wealth of a house lives in its empty space. Vacuum appropriation strategies between traditions, innovation, flexibility and use

Simone Solinas[1]

[1] University of Cagliari, Dipartimento di Ingegneria Civile Ambientale e Architettura, Cagliari, Italy, Via P.ssa Maria 74, 07100 Sassari, Italy.

Abstract: The quality of the vacuum-space is a parameter of sustainability understood as potential adaptability of a project to its interpretations and modifications implemented over time by users. The appropriation of vacuum is an architectural design strategy which aims to enclose a formless void portion. Vacuum finds its most immediate representation in Nature and, placed in relation to the full, reach a balance in the final built system. 26 social houses built near Seville develop sustainability research through the vacuum-space, reinterpreting local typology consisting of deep courts, modulated by patios sequences that alternate solids and voids, lights and shadows. Weaving the full-space with the empty one, suggesting a close relationship between interior-exterior, it is possible to get a flexible spatial mesh susceptible to modification, studied as unit's expansion program, according to the needs that may arise in time by users. Sustainable housing quality is guaranteed by cross ventilation and intensity lighting controlled by the openings membranes, covering elements, vegetation, that contribute to energy efficiency and degrees of privacy between the different constituent parts of the house, and these and the relationship with the public space of the street.
Keywords: space, void, patio, tradition, flexibility.

Keywords: space, void, patio, tradition, flexibility.

Introduction

“Surely the architect possesses thoughts and interests, passions on the patio and the void. These ideas have certainly engraved in the design and implementation of its houses next to the River. Perhaps he thought, while building them, that he would like to live there. As he could not occupy all, or at least not all together, it was clear that other people would lived in those houses. Someone now is living there and perhaps also the architect. We do not know whether they live in his own way, or in their own way. Curiously we can ask us.” (Unknown, 0000)

Determine which are the parameters to be used to build and analyze a work is not easy. The quality of a project, out of certain types of prejudice especially in social housing, is a first theme complex and intriguing. The quality of a project is achieved by offering users spaces that can be adapted and modified according to their diversity. Environments included in a context of continuity with the past, which look to the future recognizing the importance of sustainability in design that opens to a broad concept of this term, which includes the use of ecological materials and energy-saving, but it goes further.

A second theme, the "use" of space, especially in its component vacuum-space, acquires an extreme importance to reach the main goals that the architecture is proposed. Void-space and full-space should not necessarily be read in an apparent contrast between spatial and geometric mass. The opposition of the two terms should be seen, rather than in a abolition of the two parts, as a dialectical relationship between these extremes. Their relationship is essential and necessary in the construction of space, constituting the two fundamental elements that enhance the meaning.

The homes of the case study are like tubes placed on the table in a scientific laboratory. A brief description, let's say objective, of the project highlights some key aspects and some reflections that will be discussed in this essay: the continuity of contemporary project with tradition and history; the relationship with sustainability understood as energy savings essentially based on passive systems that affect the shape of space; the flexibility of use in the post-built.

Case study

The 26 social houses built in Umbrete near Seville develop sustainability research through the vacuum-space reinterpreting the local typology consisting of deep courts that penetrate in the block, modulated by patios sequences that alternate solids and voids, lights and shadows.

Figure 1. View of the intervention.

The project strategy chosen is the internal porosity which is opposed to the apparent compact exterior of the block, model that interprets the local ways of life that "occupy" the spaces of the road as much as those of the house. The project therefore aims to define at the same time some key issues: on one side the house type, and on the other the global image of the intervention, as well as the relationship of both with the urban context.

The first strategic and conceptual act resolves the project by occupying the entire surface available of the block, without leaving to chance any residual space, with an alternation of volumes, solids and voids, which establish a close relationship between them, thus drawing the entire project.

A first reading of the principal elevation provides a compact image, almost two-dimensional, with the presence of measured windows on the first floor and large openings on the ground floor, veiled with a wire mesh that protects from the gaze of passers.

The overall image gives form to a project where the outside just shows slightly the different cells of which it consists, and proposes a vision of unity and global image, establishing a dialogue with the urban fabric, and coexisting harmoniously with the examples of traditional domestic architecture. Inside the house a succession of full and empty volumes occurs. Spaces that are at the same time internal and external, that are surrounded and in turn surrounded, allowing to play with the lights and shadows that glide on the walls.

The access to each house, from the street, is produced under a covered space which can be used as a car park, open to the street on one side, and on a first patio on the other. This first sequence between "full and empty" generates the threshold between public and private which continues, within the home, with the living room. The sequence is completed by a second patio, intimate and hidden -the lemon patio, which overlooks the kitchen. In the interior, the stair climbs up in a double-height volume joining the two floors vertically, bringing on a catwalk that connects horizontally the bedrooms and a terrace-solarium, located above the living room. The "voids" of the house, internal or external, are essential in the overall reading of the project, along with the "full" generate the living spaces of the house itself.

The intervention proposed is therefore a route between full and empty spaces that alternate constantly at various levels, both in a longitudinal as well as in the transversal reading, creating a sequence of rooms and environments some of which open to the sky. This is a reinterpretation of the succession of spaces typical of the Andalusian Baroque patio house, hybridization itself from the Arabic and Roman typology.

Continuity and tradition

The comparison of a typical house of Seville and those in analysis highlights some features of similarity that concern two aspects: the elementary pieces that make up the project and their concatenation and composition.

Figure 2. Plan of a typical patio house in Seville (left) compared with case study (right).

The spatial sequence between entrance hall, first patio, living room and second patio/garden is evident in the two examples exposed (the historical and the contemporary one) regardless of scale issues or building systems used. This sequence is found in numerous examples of contemporary architecture and it opens to multiple reflections which can only be mentioned in this brief essay.

This alternation of light and shadow, of indoor and outdoor spaces, covered or open, it is also verifiable in the association between the sketch of Le Corbusier, realized during the journey to Pompeii in 1911, and the internal perspective of the Villa Savoye of 1929. It is possible to argue and support that will ultimately be (in all 3 projects) the same spatiality, or classical spatial configuration, composed by *fauces*, *atrium*, *tablinium* and *peristylium*. The description given of the phenomenological experience in Towards an architecture of the House of the Silver Wedding by LC it is perfectly transferable to the Villa Savoye.

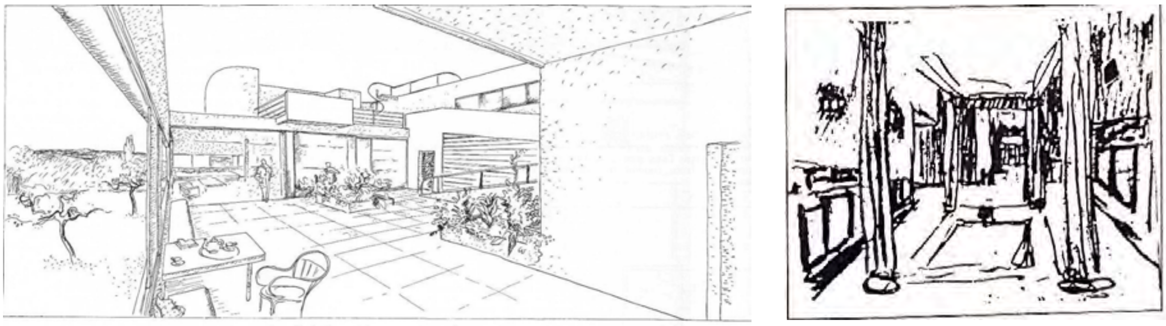

Figure 3. Drawings of Le Corbusier: Villa Savoye and Pompeii house of Nozze d'Argento.

The sequence of elementary components of the Pompeii's houses can be found in the structural organization of the houses in Umbrete.

Figure 4. Sequence of penetration following *fauces, atrium, tablinium and peristilium* composition

Not only this; it is possible to document that, as proposed by Richard Padovan, "the Villa Savoy in Poissy is a courtyard inside a pavilion" (Padovan, 1995). This aspect is even clearer if we associate and visualize the spatial sequence of the elements of the Villa in Poissy plan with the plan of the House of the Silver Wedding near Naples. This aspect highlights the importance of the sequence of empty spaces particularly in the use of the "patio as an archetype polyvalent, able to collect beneath itself a large amount of uses, shapes, sizes, styles and different characteristics" (Capitel, 2005)

Sustainability aspects

Starting from the data of the project program and a careful analysis of the context, introducing sustainability data as necessary elements but in itself not sufficient (materials, longevity, energy balance, passive environmental use of energy, natural lighting, natural ventilation, orientation, volume, etc), you will get the best possible welfare housing conditions, reducing consumption and waste. Architecture is a great amalgam of elements that must work together (space, structure, systems, economy, active systems, passive, etc.) in a global constructive act, not to mention an aesthetic and formal richness, which is critical in our work.

The main effort in Umbrete design was directed to a passive energy operation of buildings, whereas the cost of the construction of only 526.22 euro/m2 and a selling price of 68,355 euro for each house (year 2007), has made impossible to install systems with active technologies. The simple construction and the use of readily available materials and known by local workers have been the dominant choices: large thermal mass in the thick audience of foundations, walls and vaulted roofs, allow us to isolate ourselves from the heat in summer and cold in winter.

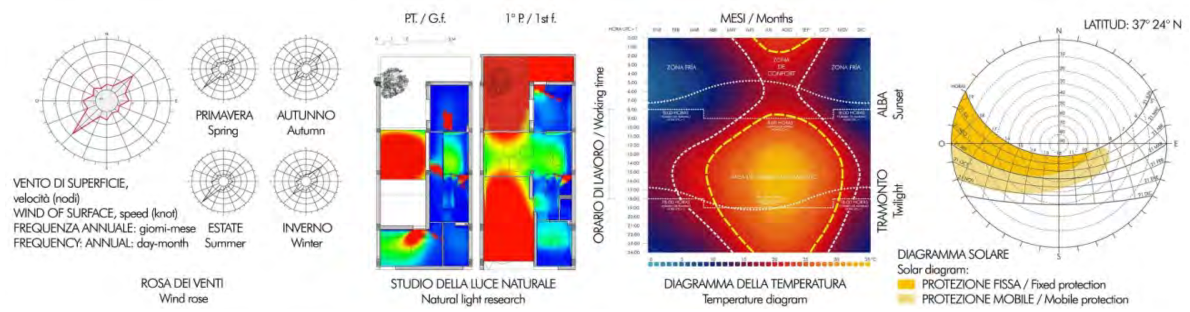

Figure 5. Sustainable scheme.

The proposal distribution in the block was a result of the conditioning initially perceived as negative, such as solar orientation, which had the longest prospects on the northern and southern facade. This imposition has led to the search of the proposed solution, which is considered climatically optimal. The living rooms and master bedrooms, assigned on either side of the lot, but symmetrically distributed, have been designed to always have views simultaneously on both exposures.

The sustainable housing quality is also guaranteed by cross ventilation and intensity lighting controlled by the openings membranes, covering elements, vegetation, leaving the possibility to the sun to penetrate when appropriate, taking advantage of the seasonal variation of its angle of incidence on the ground. These are key issues in the climate of southern Spain, that contribute to energy efficiency and a good degrees of privacy between the different constituent parts of the house, and also between these and the relationship with the public space of the street.

Flexibility

Each interior space is linked to its own external reference space that is studied as the unit's expansion program.

The minimum surface of 70m2 useful provided by the Andalusian legislation, distributed in three bedrooms, living room, kitchen, bathroom and circulation have been designed as "hopefully modifiable” or extensible by some suggestions/consideration proposed in the design phase, to improve the user adaptability to the project. The house would not change its essence and nor its relationship and its overall look with the outdoor spaces of the road, if you extend the kitchen to the garden at the end of the lot. (Figure 6. Option b). This would result in more room to eat and keeping the close relationship with the open space of the lemon patio.

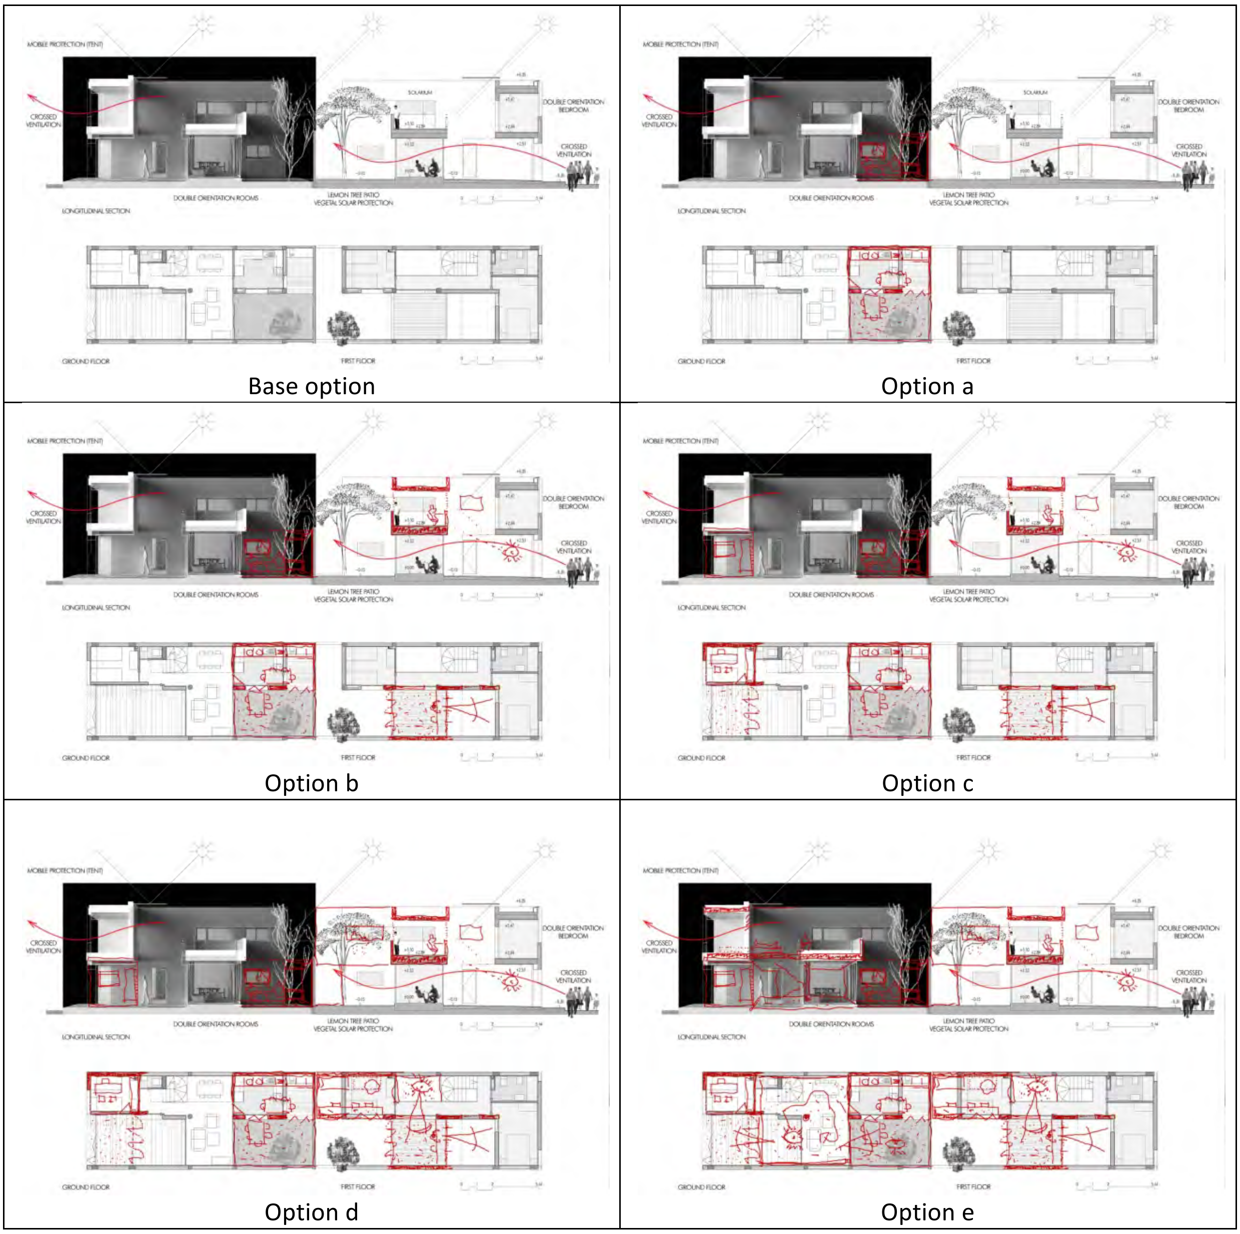

Figure 6. Scheme of extension and modification of the base plan. Flexibility.

Upstairs, the room in the kitchen correspondence has been studied for a possible extension (Figure 6. Option e.). Also on the first floor, you could build an additional room in the solarium, with the simple addition of a roof between the existing walls, thus creating a new bedroom. This would be useful in the case of the arrival of a new family member, giving also the possibility of an extra space for a study area, maintaining, without substantial changes the sequence of the patios existing in the original project (Figure 6. Option c). The room on the ground floor, which is the only enclosed space in direct contact with the outside, can be made independent from the rest of the house, to respond to the changes required by the job, and open directly onto the adjacent access space (Figure 6. Option d). The latter could also be close and attached to the "inner" part of the house. Possibilities that may be needed to accommodate a ever-changing society.

Conclusion

In designing new works it seems to be important the relationship with the past. It is clear that our physical position in time and space can only be the one that occupies the present. It remains significant however the way we look at the past -depending on the problems that we have in the present- and how we use it to generate future solutions. Many are the possible pasts. We can observe them with the eyes of the Angelus Novus, a painting of Paul Klee, without being able to know the future towards which we travel.

The picture has long been owned by Walter Benjamin who has developed a complex philosophical point of view about history and its relationship with the present and the idea of progress. At the same time we must realize that every time we design we are going to take a leap into the void. We do not know exactly what we will find. This launch is yet to be done.

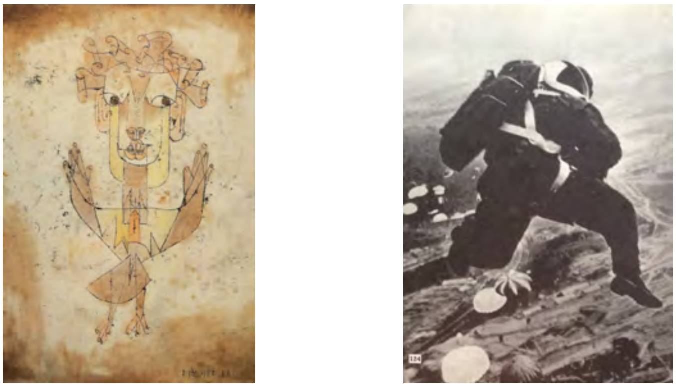

Figure 7. Paul Klee, Angelus Novus. Le Corbusier, Aircraft.

This jump is not simply about and towards the construction of new buildings, but also involves an analysis of our works once constructed and used, after a prudential time period defined as post-built, in which users have taken possession of the designed spaces.

If the work just completed and built can tell some of his stories, the work inhabited reveals its true essence and its potentials. The following images tell us a fraction of this reflection.

The first picture was done by an architectural photographer. It shows the purity of forms, the depth of space, and the electrical blue of the sky. The second one is a lucky camera shot, from the same spatial point of the other picture but with coloured human figures that are moving, playing and living in the penumbra of the inner space. Same space, different space!

Figure 8. Same point, different space.

10 years after the construction of the 26 social houses in Umbrete is carried out an analysis that "detect" and “reveal” the changes introduced by the use of housing units to find the matching of the adaptability assumed in the project, as if it were an experiment in test tubes, in order to detect whether exist or not the adaptability and flexibility think time ago. It is necessary to consider about the past/present through the views of users involved building a new sustainable quality.

Figure 8. Inhabitants.

The observations that arise from the process of post-built verification, lead to further reflections on how collocate ourselves in front of next projects, giving a deeper meaning to this profession. Reflecting on the past, to dream another future.

Statistical and Spatial Analysis of Climate Data for Updating Passive Design Strategies in Brazil

Iraci Stensjö[1] and Camila Ferreira[2]

[1] Environmental Comfort Lab, School of Architecture, Federal University of Minas Gerais, Belo Horizonte, Brazil, iracistensjo@gmail.com;
[2] Environmental Comfort Lab, School of Architecture, Federal University of Minas Gerais, Belo Horizonte, Brazil, camilaccferreira@yahoo.com.br;

Abstract: In Brazil, the standards for thermal performance of buildings, and the certifications to evaluate building energy efficiency are based on thermal comfort indexes, whose recommendations are obtained from climatic data of the Climatological Normals of the period 1961-1990. Between 1990 until today, the country underwent major transformations in its territory, such as the reduction of forest area, advancement of the agricultural area, expansion and densification of urban centres. All these factors may have affected the macro, meso and microclimate. Thus, data for the period 1961-90 may not reflect the current climate and the condition of acclimatization of populations. The purpose of this research is to analyse the most current climatic data, aiming to assess whether or not there are changes in the climate that affect comfort, as well as verify the pertinence of the current recommendations for thermal performance. The selected data for analysis are air temperature and humidity for the period 1985-2015, provided by the National Institute of Meteorology. The methodology uses descriptive statistics to determine the trends and variability for behavioural assessment of climate change. Subsequently, building design strategies of different comfort indexes, such as Givoni, Mahoney are revised regarding the new climate data, as well as, the changes in neutral temperature and degree-days. Then, spatial distribution of the results is present in thematic maps, thus one can assess the regional trends inside Brazilian areas. As a result, the mean temperature of cities had increased all over Brazil, which causes changes in the recommendations for thermal performance

Keywords: climatic data, climate changes, thermal comfort, adaptive comfort, project strategies

Introduction

The indices of human thermal comfort are widely used in Brazil for evaluation of thermal comfort and building energy efficiency. Frequently, they are used to analyse the climatic characteristics of a given location from the viewpoint of human comfort and specify building design guidelines to maximize the comfort conditions for passive buildings, the most common type of building in Brazil. For these reasons, the indices are used in the definition of parameters of performance and comfort of different Brazilian norms and regulations, such as (ABNT, 2005), (ABNT, 2008), (INMETRO, 2010), (INMETRO, 2012).

These documents were developed using the Climatological Normals of 1961-1990 (Ramos, et al., 2009) as database for climate analysis, since it is one last Normals published in Brazil. Between 1990 until today, the country underwent major transformations in its territory, such as the reduction of forest area, advancement of the agricultural area, expansion and densification of urban centres. All these factors may have affected the macro, meso and microclimate. Thus, data for the period 1961-90 may not reflect the current climate and the condition of acclimatization of populations.

This work evaluates two climatic databases with different temporal cut-offs, for the Brazilian territory, to verify local climate changes, and to assess if the changes impact on the building design strategies. The climatic databases chosen are the Climatological Normals of 1961-1990 (Ramos, et al., 2009), and digital data from 1983-2013 retrieved from the Brazilian Institute of Meteorology website (INMET, 2016). They were chosen because they have a large number of stations and because their data are collected with the methodological rigor established by the WMO. In addition, the time range between the bases allows to study if the urban transformations that the country has undergone have affected the local climate in some way.

The analysis of the comfort conditions uses the adaptive model proposed by Dear and Brager (2002) as an alternative to the method of ASHRAE Standard 55 of 1998. In addition, the study of the changes in design strategies is carried out by the Mahoney's Tables (United Nations, 1971) and the Building Bioclimatic Chart (Givoni, 1992), because they are simple methods of climate analysis that incorporate comfort indexes, they are widely used in Brazil, and they provide guidelines in early stages of the architectural design.

The database

In this work, the data of the Climatological Normals (Ramos et al., 2009) are used as the reference, which correspond to the monthly averages from January 1961 to December 1990. Specifically, sine curve of temperature and humidity data to evaluate human thermal comfort, because this is also the method used in the norms to define Brazilian bioclimatic zoning. Since there is not another Normals series published after, raw data was downloaded from the national digital database (INMET, 2016), then the arithmetic average calculated. The selected period is 1983-2013, 20 years of data, because there are just a few cities with 30 years of data. The variables retrieved are: mean monthly hourly temperature, T; mean monthly maximum temperature, T_x; Mean monthly minimum temperature, T_n ; Atmospheric pressure at the barometer level, P (in Pa); and, mean relative humidity, RH (%)

The definition of a typical day

The database provides average values that may not be representative of the comfort conditions. So, hourly values for typical days are calculated. The average hourly air temperature data can be obtained by adjusting the local data to sine curve of the World Meteorological Organization (WMO) (Assis, 2001), as described in Equation 1:

$$T = T_{\mathrm{x}} - (T_{\mathrm{x}} - T_{\mathrm{n}}) \cdot j \qquad 1$$

where

j is the setting value of the hourly temperature curve, from 0 h a.m. to 11 h p.m.: 0,75; 0,78; 0,82; 0,87; 0,89; 0,96; 1,00; 0,93; 0,76; 0,57; 0,41; 0,28; 0,15; 0,11; 0,02; 0,00; 0,04; 0,08; 0,15; 0,46; 0,56; 0,64; 0,73; 0,70.

The daily range of relative air humidity is estimated according to the Brazilian Standard NBR 15.220 (ABNT, 2005). This standard presumes the average daily variation of absolute air humidity equal to 3 grams of water vapor per kilogram of dry air. The hourly value of the humidity was determined from the hourly vapor pressure as a function of the air temperature.

Thermal comfort models

The adaptive comfort temperature

Adaptive comfort models are based on fieldwork that measures the environmental conditions and the simultaneous response of thermal sensation of individuals involved in their usual tasks, with the least possible intervention of the researchers, in an attempt to reproduce the real conditions. This work uses the model presented by Dear and Brager (2002), which is the model used in the review of ASHRAE 55 in 2004 and it is widely used in Brazil. This regression model calculates the optimal comfort temperature, T_{conf}, based on the external climatic conditions, characterized in terms of mean outdoor air temperature (T) (Equation 4) (Dear & Brager, 2002, p. 553). They also define zones of comfort: for acceptability of 90% the range is 5 °C, and for 80%, 7 °C, both zones are centred on the optimal temperature of comfort.

$$T_{conf} = 0{,}31 \cdot \mathrm{T} + 17{,}8 \qquad (4)$$

Mahoney Tables

Carl Mahoney, John M. Evans and Otto Königsberger. (United Nations, 1971) elaborated a series of Tables that offer recommendations to the architectural project from the analysis of climatic data, useful in the initial stages of the project. The thermal comfort zones proposed in the tables vary according to the annual mean monthly temperature, period of the day (daytime or night-time) and monthly average relative humidity. The Mahoney Tables are often used in bioclimatic design in tropical climates, so it is considered unnecessary to reproduce all of its methodology in this text.

Building Bioclimatic Chart

The Building Bioclimatic Chart (BBCC) was developed by Givoni (1976) and it was later expanded by Milne and Givoni (1979). It is a method of graphical climate data analysis, as well as, building design guidelines, especially for hot climates. The chart of human thermal comfort zone is drawn in a psychrometric chart. The BBCC differs from others comfort charts because it presents partial charts of the climatic conditions within which various building design strategies and natural cooling systems can provide indoor comfort.

Statistical treatment of climatic data

The behavior of T, T_n and T_x data, in both database, is evaluated by data dispersion plots as well as linear regression models. A linear regression model is given by Equation 5, where β_0 represents the intercept of the trend line with the y-axis and β_1 the slope of the line. The value of β_1 will indicate whether there is a tendency for temperature values to increase or decrease.

$$y = \beta_0 + \beta_1 x \qquad (5)$$

The linear regression models allow evaluating the slope of the trend line, which indicates whether there is an increase or decrease in the value of air temperatures in the data 1983-2013 compared to the 1961-1990 data. In addition, the standard deviation values between the databases are calculated for T, T_n and T_x. The standard deviation (s) is given by Equation 6, it measures the dispersion of the individual (y_i) values around the arithmetic mean ($\bar{y}$), where n is the number of observations.

$$s = \sqrt{\frac{\sum(y_i - \bar{y})^2}{n-1}} \qquad (6)$$

Results

The results of this work are presented in two modes: graphs and maps. The graphs present the statistical trend of minimum, average and maximum temperature data. The maps present the data spatially distributed, allowing the spatial comparison between the two databases adopted. The maps of population are also presented, in order to identify possible relations of growth of the cities and the identified climatic changes.

Statistical trend of the data

The scatter plots for T_n (in blue), T (in green) and T_x (in orange) of both databases are presented in Figure 1, as well as linear regression models. They indicate the increase of the three temperatures in 1983-2013 compared to 1961-1990 database. The standard deviation also shows the trend of increasing temperatures in the most recent data. However, the standard deviation calculated for the T_n (5.8 °C) is higher than T (1.7 °C) and T_x (2.7 °C). Thus, it can be concluded that the increase of T_n is more significant than the general increase in temperature.

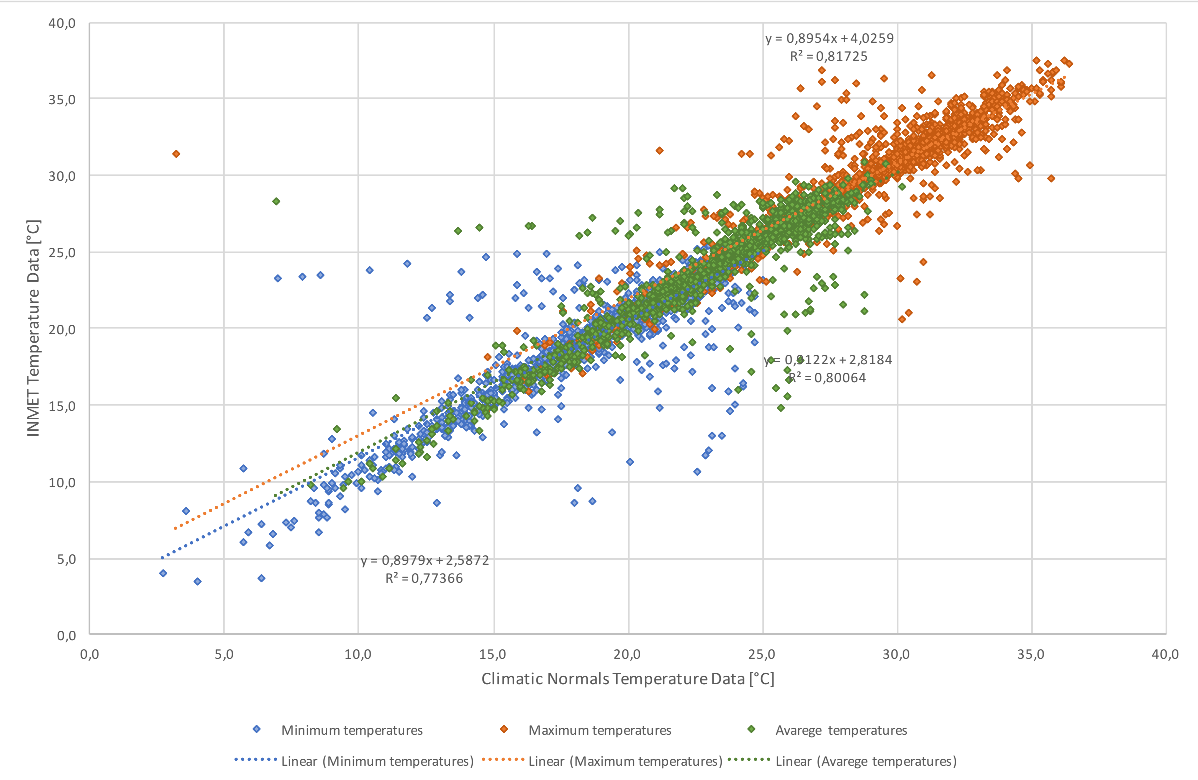

Figure 1. Scatter plots for T_n (blue), T (green) and T_x (orange)

Maps

Weather stations are not always the same in databases. Many were disabled, several were created. In addition, the 2013-1993 database does not contain stations that are still analogic, so there are fewer stations. Thus, the spatial analysis is relevant because maps allow to evaluate the trends by region, by comparing nearby stations, even if they are not exactly the same.

The first set of maps presents the population changes. Figure 2 compare the population of municipalities where the weather stations are, in 1992[1] and in 2012. The maps are divides by administrative regions: North, Northeast, West, Southeast and South. In the last 50 years, there was a demographic explosion in Brazil and the country had an increase of approximately 130 million people. But this growth occurred mainly in the capitals and their metropolitan areas. The Southeastern region received the largest migratory flow in Brazil, during the period of study. It is the region with the greatest growth in the number of large towns and cities (yellow and orange dots in Figure 2), besides contemplate the 3 largest Brazilian metropolises.

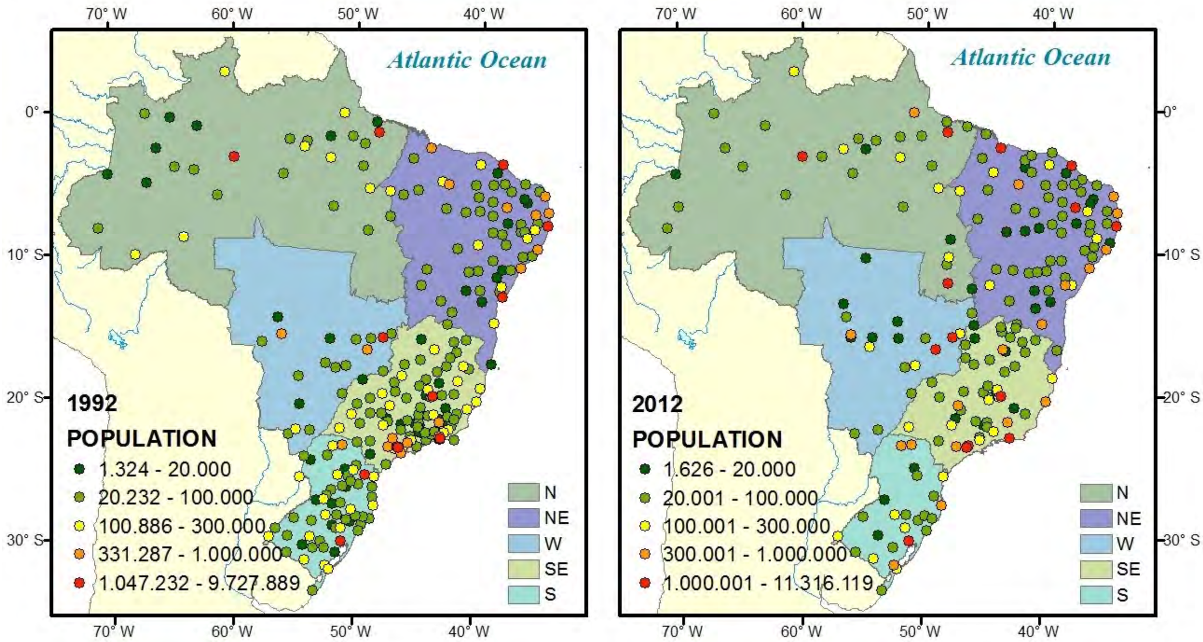

Figure 2. Population of municipalities

The second map (Figure 3) represents the percentage of hours of thermal comfort, considering the Bioclimatic Chart developed by Givoni (1992). There are almost no changes in North. In Northeast, the number of hours in comfort is reduced (~10%) in the stations near coast. There are fewer stations in the South and Southeast, but there seems to be a reduction in comfort hours of about 10% in some stations. The increase of discomfort is higher in West (20%) and more frequent.

Figure 4 shows the comfort hours using the adaptive model of (Dear & Brager, 2002) and a range of temperatures around the comfort temperature of 3,5 °C, corresponding with 80% thermal acceptability. In 2013, there is a common increase of comfort hours of 10% in the North Region, but comparing the numerical values, there was a reduction of 2% in the average number of hours of comfort. The same trend happens in some stations of the NE, particularly those near the north coast. On average, there is a reduction in the number of hours in comfort of 4% in NE. In the West Region, there seems to be no significant change in the maps, but the average number of comfort hours has reduced 7%. However, the hours of comfort are reduced in some stations inside the SE Region. This is the region of the greatest reduction in average hours in comfort, 9%. In South, the comfort hours have increased in many stations. In average, considering all stations in S, them have reduced 1%.

[1] 1992 is the first year of digital data available for all Brazilian cities in the Brazilian Institute of Geography and Statistics (IBGE, 2015).

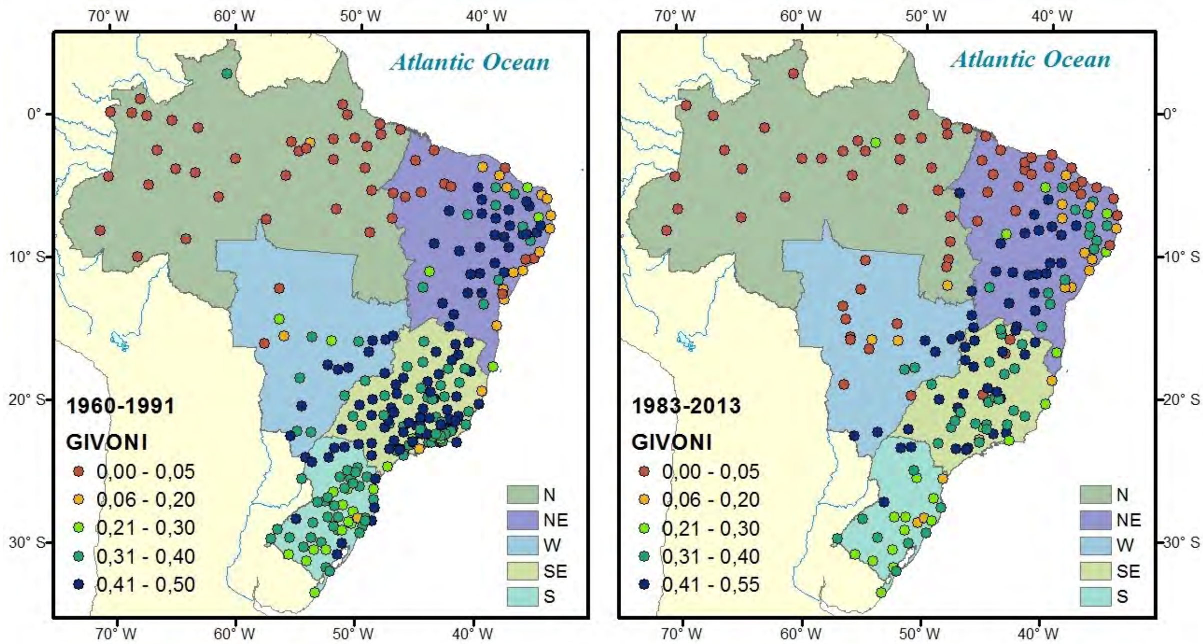

Figure 3. Comfort hours in the year (%) according to Givoni's bioclimatic diagram (Givoni, 1992)

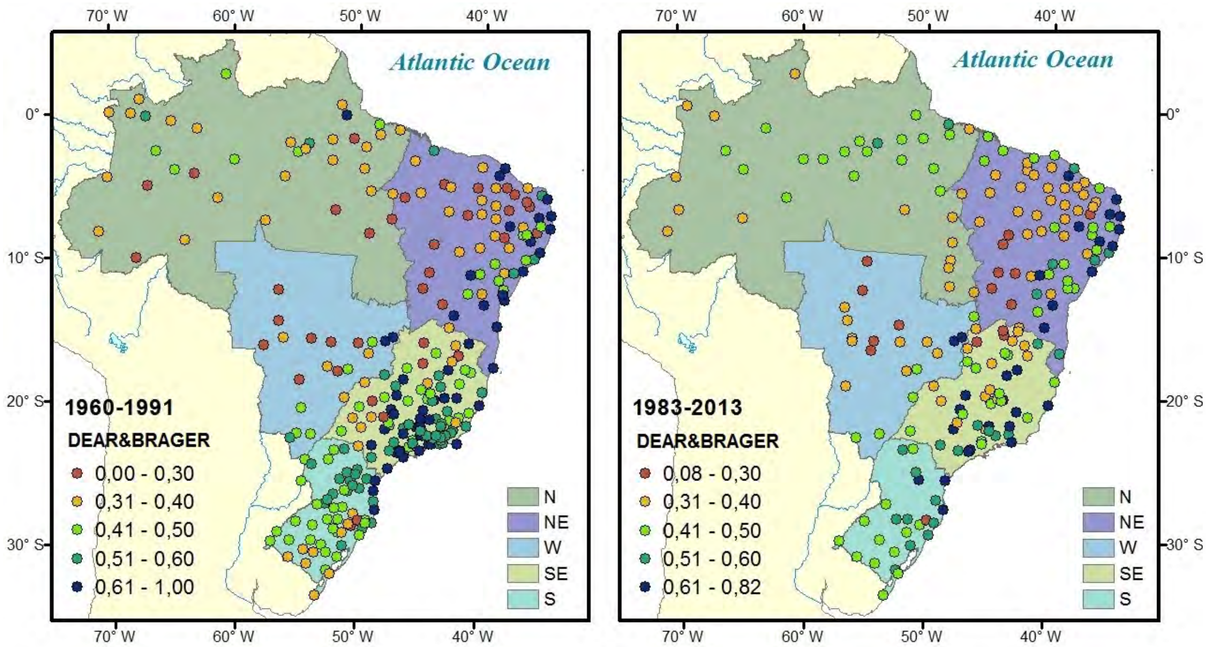

Figure 4. Comfort hours in the year (%) according to Dear and Brager (2002) (80% acceptability)

Comparing Figure 2 with Figure 4, one can see that the cities with the greatest changes in the hours of comfort were the big cities, pointing out that there is a relation between the population growth and the increase of the discomfort due to the increase of the temperature.

In all regions, there is a reduction of comfort hours regarding Givoni and the adaptive model. The next maps show the Mahoney indicators, so we can evaluate the impacts of the changes of the humidity. H1 is applied when high temperature and humidity are combined or high temperature, moderate humidity and small diurnal range. The arid indicator A1 is applied in months when a large diurnal range coincides with moderate or low humidity. Figure 5 shows the maps of H1 indicator, and Figure 6, the maps of A1. The only region with significant changes is the Southeast, where there is a reduction of the number of months in H1 and the increase of A1 in several places.

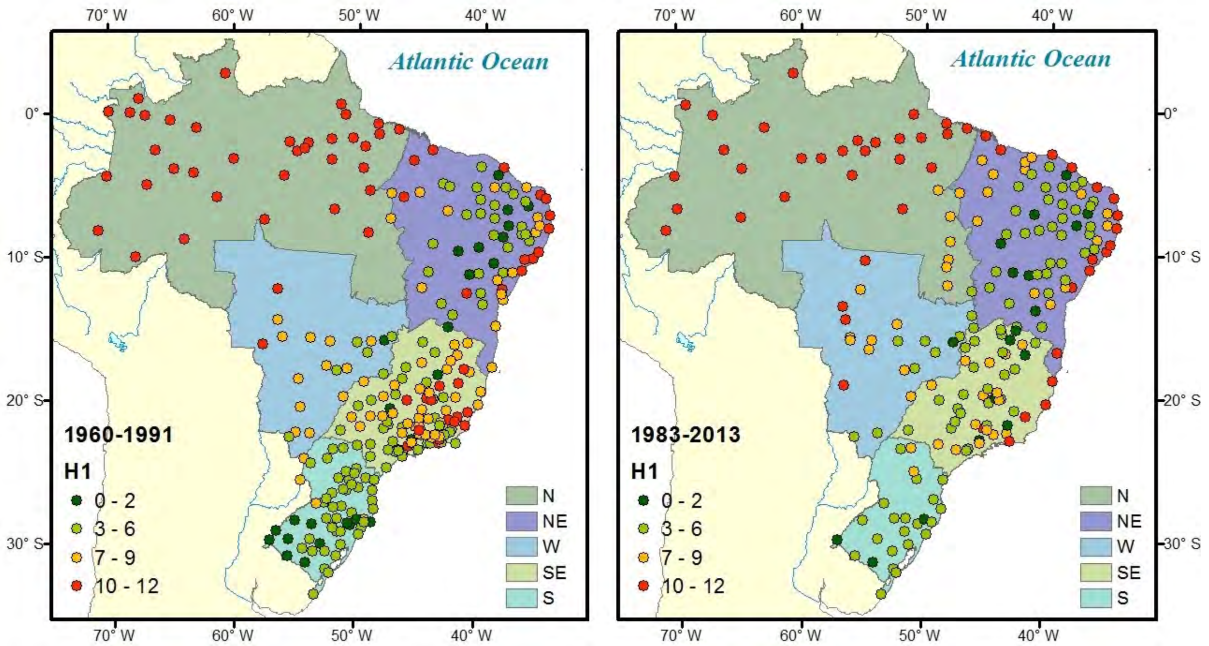

Figure 5. Total of humid indicators H1 per year, according to the Mahoney Tables. (United Nations, 1971)

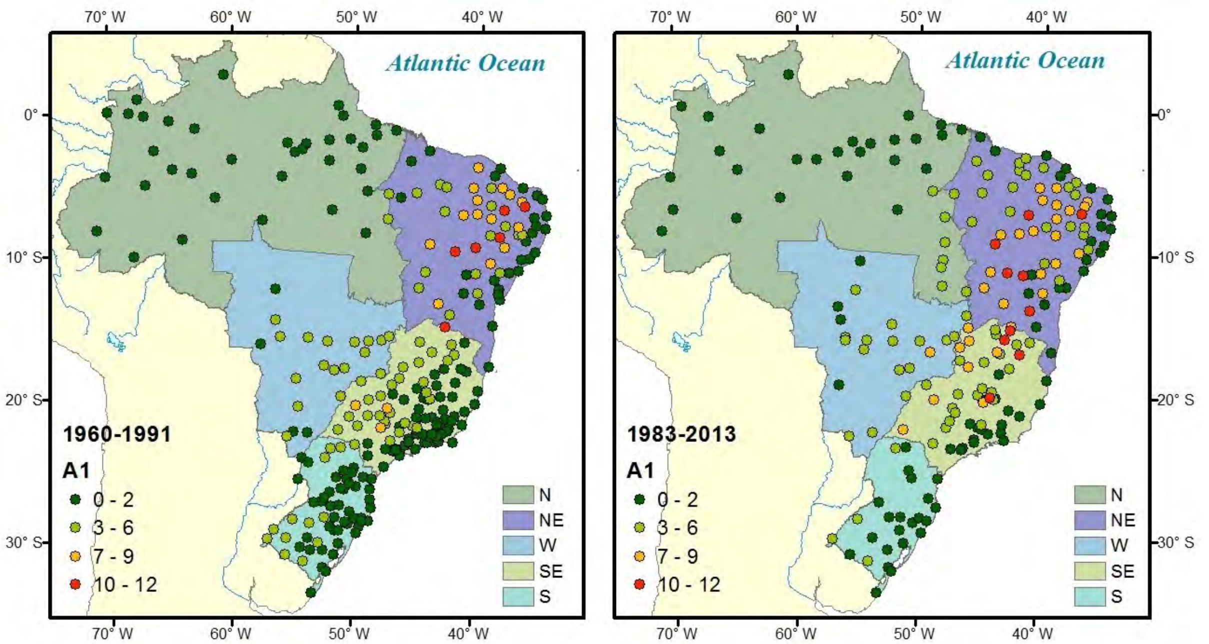

Figure 6. Total of arid indicators A1 per year, according to the Mahoney Tables. (United Nations, 1971)

Final Comments and conclusions

The indices of human thermal comfort are widely used in Brazil for different functions, however there is no standard in the country that establishes comfort conditions according to acclimatization of the Brazilian population. Thus, the present work proposed to perform a more updated climate data analysis to evaluate the changes in the human comfort response, as well as, to verify the relevance of the current design recommendations for building thermal performance.

The results show an increase in the minimum, average and maximum temperatures, which causes a reduction of comfort hours regarding the adaptive model, in all regions. The stations that experienced the greatest reductions in comfort are in North and Northeast regions, the hottest climates in Brazil. The South Region has the least change in comfort hours, because the increase in temperature resulted more hours of comfort in some cities of cold climate.

The Southeast Region experienced the highest reduction in the sensation of comfort considering the adaptive model; and considering the Givoni model, the Western Region. The Southeast Region also has become drier and has less problems of cold, according to Mahoney. These climatic changes are probably due to the growth of cities in this region, both metropolises and intermediate-sized cities.

In general, it can be noticed that there have been changes in comfort and recommendations caused by the elevation of temperature. Therefore, the growth of cities appears to be an active factor, but not the only one, demonstrating the need for further studies.

Abstract: The external envelope of a building has a significant effect on its energy consumption. Windows are a weak component of the outer envelope. Appropriate window design can take advantage of solar radiation and daylighting to improve a building's thermal performance. In this paper, the characteristics of windows (orientation and window-wall ratio) and office building geometry are investigated to study the energy consumption characteristics of individual office rooms. DAYSIM and DesignBuilder software are used to simulate the energy consumption and daylighting performance of offices in the city of Xi'an, located in a cold climate region in China. We analyse the relationship between spatial office parameters and energy consumption and the relationship between spatial office parameters and the quality of the lighting environment. The evaluation indexes are total annual energy consumption, DAcon and UDI. The results show that as the room index increases, the energy consumption of lighting increases, and the decline of heating and cooling energy consumption gradually slows. When an office is approximately square-shaped, the optimal window orientation is south and 15 degrees west of south, and energy consumption is lowest when the window-wall ratio is 50%-70%.

Keywords: room index, window-wall ratio, energy consumption, useful daylight illuminance

Introduction

Buildings rely on windows for lighting and heat transfer, and the use of daylighting helps to reduce power consumption from lighting devices and to improve indoor environmental quality. However, the absorption of sun radiation through windows introduces heat load and affects the energy consumption of cooling or heating systems, so fenestration design is a critical step in energy-saving design. For multi-storey buildings, heat dissipation through doors and windows accounts for approximately 30% of the building's total heat dissipation. A common method of energy saving using fenestration design is the introduction of appropriate amounts of natural light.

Orientation is known to have a significant impact on building energy consumption. In building energy-saving design standards, it has been noted that building design should select the optimal local orientation or most suitable orientation, and south-facing is the optimal building orientation in Xi'an. "Design Standard for Energy Efficiency of Public Buildings" GB50189-2015 recommends that the orientation of buildings should be south-facing, ranging from 30° west of south to 30° east of south. Different orientations will lead to differences in building performance and energy consumption.

Irina Susorova et al. analysed the total annual energy consumption of office buildings in terms of window-wall ratio, window orientation, and room width/depth ratio. They found that it is most efficient to install south-facing windows in cold regions in the United States; the installation of large windows helps south-facing rooms achieve optimal energy-saving performance, and the installation of small and medium windows is most appropriate for rooms with small depth and large depth, respectively.

Carlos E et al. studied the performance, comfort, and dynamic evaluation of a 3.5m * 5.3m * 2.7m office and applied the chart optimization method to avoid multi-objective conflict and compromised to meet the multi-objective requirements. Ultimately, they obtained optimal window-wall ratios for different orientations and proposed that window optimization is conducive to reducing building energy consumption and providing a higher level of visual comfort.

Steinar Grynning et al. explored window energy balance based on the window thermal performance index (heat transfer coefficient K and solar heat gain coefficient SHGC values). They suggested that even in cold regions where demand for heating is high, office buildings should be designed based on cooling demand. They evaluated the energy saving potential of different combinations of K and SHGC.

Enedir Ghisi et al. simulated rooms using 5 different room ratios and 10 different dimensions in two different regions and used windows to balance daylighting and artificial lighting. They suggested that a large window-wall ratio is most energy-efficient with regard to small rooms and that a low thermal load from solar radiation is conducive to reducing building energy consumption.

Quality of lighting environment and evaluation criteria for energy efficiency

If parameter settings (orientation and window-wall ratio) of windows and office building geometry are different, the indoor lighting environment and energy consumption are different. This paper seeks to determine the optimal window dimensions for offices of different scales to balance energy consumption and daylighting performance.

Energy efficiency indicators include heating, cooling, lighting, and other energy consumption (kWh/m²), and the goal of energy saving is to minimize total energy consumption. China's architectural lighting design standards use static evaluation indicators for lighting environments, such as daylight factor and illumination. This paper uses continuous daylight autonomy (DAcon), useful daylight illuminance (UDI), and other dynamic evaluation indicators of the lighting environment to more accurately and comprehensively study the annual daylighting performance of buildings.

UDI is based on the illumination value on an indoor work surface. This indicator is based on hourly climate data to describe whether indoor daylighting is effective; it is highly accurate and can take into account user comfort. If work surface illumination is less than 100lx, indoor lighting conditions are insufficient; if work surface illumination is greater than 2000lx, indoor lighting conditions are superabundant, and the probability of users experiencing glare greatly increases; the work surface illumination that meets human requirements is 100lx <UDI<2000lx. This range was proposed by Azza Nabil in assessing office space lighting in 2005, and it was confirmed by John Mardaljevic in 2012.

Method

The research content is divided into two parts. The first part examines the influence of office geometry and window-wall ratio on energy consumption and the lighting environment. The second part selects a fixed-size office to analyse its photothermal performance based on its orientation and window-to-wall ratio.

Xi'an (34.3N, 108.93W) is a city representative of a cold region of China. It has a warm, temperate, and semi-humid continental monsoon climate. Its winter monthly average temperature is typically below 0 °C, and its lowest temperature in winter can fall below -16 °C. Its summer monthly average temperature is approximately 26 °C, and its highest temperature reaches 40 °C or above. The climate difference between winter and summer in Xi'an is very large, resulting in high numbers of heating days or air-conditioning days. A north-easterly wind is prevalent throughout the year, annual sunshine hours range between 2,200-3,000, total annual solar radiation is greater than 5,000 MJ/m², and there are characteristics of light and heat over the same period. In using natural light, necessary measures must be adopted to avoid the absorption of excess heat, that is, design must focus on balancing lighting, heating, and sun-shading.

An ideal office model is established. Its roof, floor, and inner wall are built of thermal-insulating materials, and the external wall is constructed following common construction practices in Xi'an, i.e., 20mm-thick cement mortar, 60mm-thick glass wool, 20mm-thick cement mortar, 200mm-thick aerated concrete blocks, and 20mm-thick cement mortar, with a heat transfer coefficient of 0.5 W/m² · K. The g-value， U-value and LT- value of glass is 0.33, 1.4, 0.37.

Heating, ventilation, and air conditioning equipment consist of a fan-coil air conditioning system. Heating uses natural gas as the energy source with an energy efficiency ratio of 0.85. Cooling uses electricity as the energy source with an energy efficiency ratio of 1.19. The indoor temperature is set at 20 °C in winter and 26 °C in summer. Use time is 7am to 6pm, Monday to Friday. The light climate zone of Xi'an belongs to class IV, and the outdoor daylight illumination value is 13,500 lx. According to current building lighting design standards, a 0.75-m-high horizontal plane is chosen as the work surface for lighting; the standard value of lateral daylighting in the office is 500 lx. The windows are double-layer low-E glass. The illumination intensity is 9 W/m², and per capita fresh airflow is 30 m ³/h · people.

Methodology of Part One

The offices mentioned in this article are rectangular and oriented towards the south. The room index (RI) represents the value of the office building geometry, which is calculated as:

$$\mathrm{RI} = 2 \times \mathrm{S}/(\mathrm{h} * \mathrm{l})$$

where S is the room area, l is the room horizontal circumference, and h is the calculated lamp height from the work surface.

For rectangular offices, the expression of RI can be written as:

$$\mathrm{RI} = \mathrm{WD}/(\mathrm{W} + \mathrm{D})\mathrm{h}$$

where W is room width, and D is room depth.

Common values of RI are 0.8, 1, 1.5, 2, and 3; common values of room width/depth ratio (W: D) are 1, 1.5, and 2 (see Table 1). When D: W = 1, W = 2RIh; when D: W = 1.5: 1, W = 2.5/1.5RIh; when D: W = 1: 1.5, D = 2.5/1.5RIh; when D: W= 2: 1, W = 3/2RIh; and when D: W = 1: 2, D = 3/2RIh(see table 1). The height of the room is 3.6 m, the height of the office work surface is 0.75 m, and the height of the lamp from the work surface is 2.85 m. The windows are located in the centre of the external walls, with window-wall ratios varying from 20% to 80%, in increments of 10%.

Table 1. Room index and room dimensions

RI	2 : 1		1.5:1		1:1		1:1.5		1:2	
	W	D	W	D	W	D	W	D	W	D
0.8	6.8m	3.4 m	5.7 m	3.8 m	4.6 m	4.6 m	3.8 m	5.7 m	3.4 m	6.8 m
1	8.6 m	4.3 m	7.1 m	4.8 m	5.7 m	5.7 m	4.8 m	7.1 m	4.3 m	8.6 m
1.5	12.8 m	6.4 m	10.7 m	7.1 m	8.6 m	8.6 m	7.1 m	10.7 m	6.4 m	12.8 m
2	17.2 m	8.6 m	14.3 m	9.5 m	11.4 m	11.4 m	9.5 m	14.3 m	8.6 m	17.2 m
3	25.6 m	12.8 m	21.3 m	14.2 m	17.1 m	17.1 m	14.2 m	21.3 m	12.8 m	25.6 m

Methodology of Part Two

Width/depth ratio analysis was performed on 13 office rooms in multi-storey and high-rise office buildings in Xi'an. The proportion of office rooms with a width/depth ratio between 1: 1 and 1: 1.4 accounted for 86% of all the offices in multi-storey buildings, of which office rooms with a width/depth ratio of 1: 1.1 accounted for the highest proportion. The proportion of office rooms with a width/depth ratio between 1: 04 and 1: 1.08 accounted for 83% of all the offices in high-rise buildings, of which office rooms with a height of 3.6 m accounted for 54%. Office rooms in high-rise office buildings are thus mostly large-width rooms, and office rooms in multi-storey office buildings are mostly large-depth rooms. The differences between the width and the depth of offices in high-rise buildings and multi-storey buildings are mainly due to the structural and auxiliary space layout.

The simulated office has a width/depth ratio of 1: 1.1, width of 7.8 m, depth of 7 m, height of 3.6 m, surface area of 54.6 m^2, and volume of 196.56 m^3. According to standard, the per capita occupation of the building is 10 m^2/person, so the office can accommodate 5-6 people.

Orientation variables are 30° west of south, 15°west of south, south, 15° east of south, and 30° east of south. The windows are located in the centre of the external walls, with window-wall ratios varying from 20% to 80% in intervals of 10% (see Figure 1).

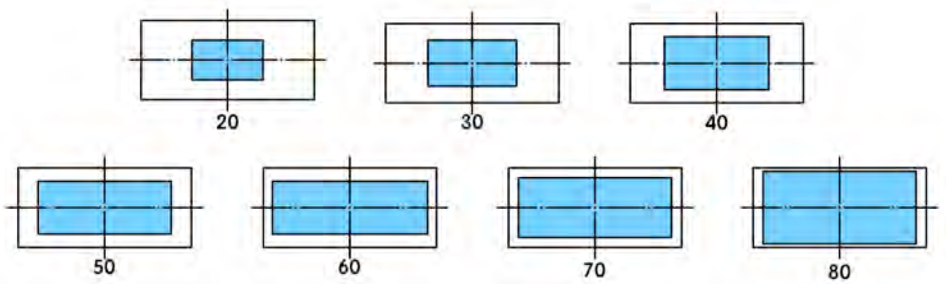

Figure 1. Examined window size variations. Amounts expressed in percentage Window-wall ratio(WWR)

Simulation tools – DesignBuilder and DAYSIM

DesignBuilder software is a tool for predicting and investigating building energy consumption. The computing engine is EnergyPlus, which provides information regarding climate, building, and thermophysical properties of construction, operational systems, and HVAC equipment. The simulation results are output as visual graphs, tables, and data.

DAYSIM is an analysis tool for lighting and illumination developed by the National Laboratory of Canada and the Fraunhofer Institute for Solar Energy Systems in Germany, which can be used to analyse the annual dynamic lighting level of buildings. It uses the Perez all-weather model for sky luminance and can comprehensively compute the impact of direct light, diffuse light, and ground-reflected light on indoor daylighting throughout the year under overcast, sunny, cloudy, and other sky conditions.

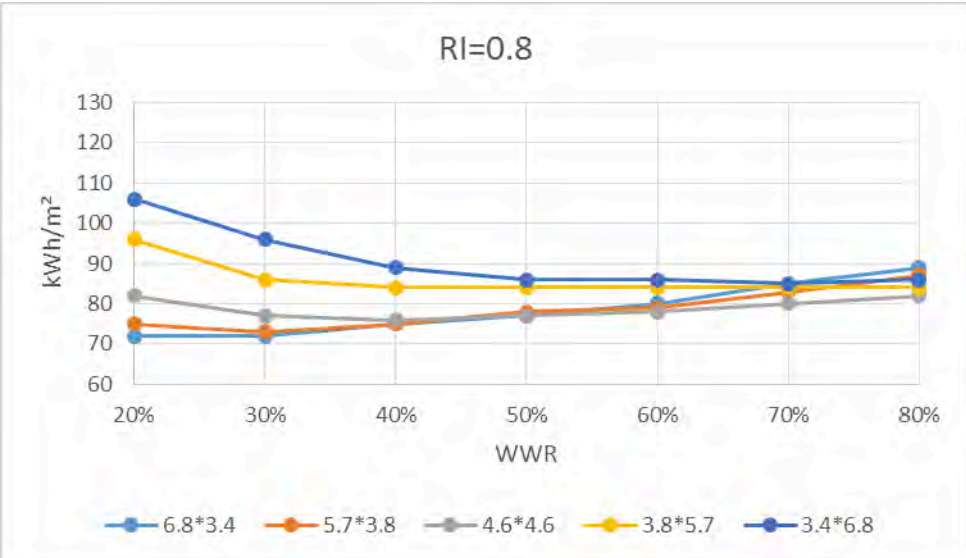
Simulation results

Results of Part One: the impact of room index and window-wall ratio on the photothermal performance of office rooms

The average brightness of the sky is clearly most intense in the south, so the UDI>2000 and DAmax of a south-facing office room are both 0, with no glare in the south. As the window-wall ratio increases, the introduction of solar radiation and natural light increases, heating energy consumption and lighting energy consumption demonstrates a decreasing trend, and cooling energy consumption shows an increasing trend(see Figure 2).

When the RI is 0.8 or 1, the total energy consumption of large-depth office rooms and large-width office rooms is inversely proportional to the window-wall ratio. In other words, the total energy consumption of large-depth office rooms decreases as the window-wall ratio increases, and energy consumption is lowest for a window-wall ratio of 60%-80%; the total energy consumption of large-width office rooms increases as the window-wall ratio increases, and energy consumption is highest for a window-wall ratio of 30% -50%. Large-depth rooms require a large fenestration area to introduce more natural light to lower energy consumption. Large-width rooms are more suitable to a smaller fenestration area to control the introduction of natural light to avoid overheating the room.

When the RI is 1.5, 2, or 3, energy consumption is lowest when the window-wall ratio is 50%-70%. This type of office fits the scope of a large-scale open space, and the increased introduction of natural light will reduce energy consumption, so total energy consumption increases as the window-wall ratio increases. The decrease in energy consumption is most significant in large-depth office rooms with a W: D ratio of 1: 2, and total energy consumption decreases by 7%, 9%, 13%, 16%, and 23%, respectively, when the RI increases from 0.8 to 3.



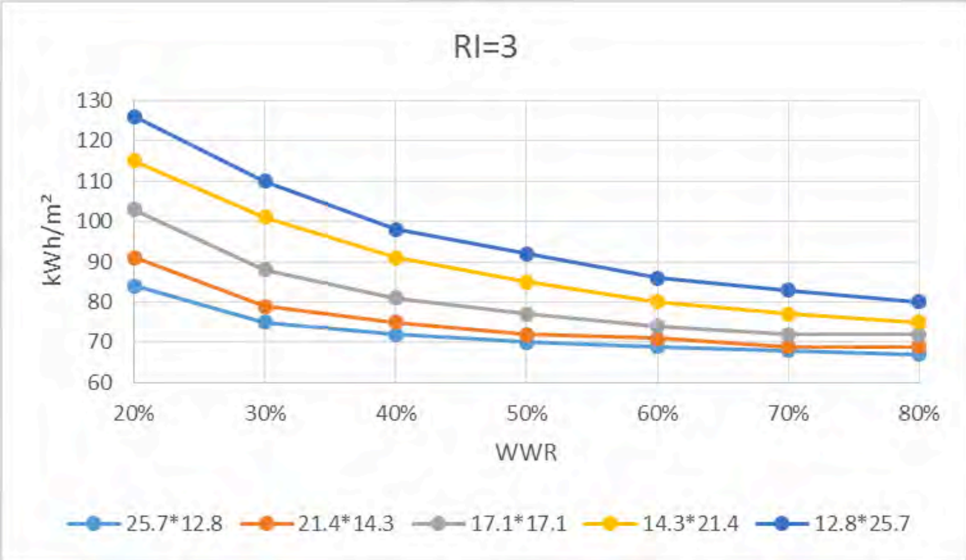


Figure 2. the impact of room index and window-wall ratio on the total energy consumption

The heating energy consumption of office rooms tends to decrease as the window-wall ratio increases, regardless of the magnitude of RI values. When the RI is 0.8, heating energy consumption is as high as 52kWh/m²; and when the RI is 3, heating energy is as low as 21 kWh/m². As RI values increase, the decline in heating energy consumption gradually slows. When the RI is 0.8, heating energy consumption can be reduced by 32%; however, when the RI is 3, heating energy consumption can only be reduced by 8%.

The cooling energy consumption of large-width office rooms and square office rooms increases as the window-wall ratio increases. When the RI is 0.8, 1, or 1.5, the cooling energy consumption of large-depth office rooms increases as the window-wall ratio increases. When the RI increases to 2 and 3, the cooling energy consumption of large-depth office rooms decreases as the window-wall ratio increases. As RI values increase, the decline in cooling energy consumption gradually slows. When the RI is 0.8, maximum cooling energy can be reduced by 48%; however, when the RI is 3, maximum cooling energy can be reduced only by 21%.

RI is proportional to lighting energy consumption. An increase in RI values means that the room scale increases, so lighting energy consumption gradually increases. As the window-wall ratio increases, more natural light is introduced into the office rooms, and their UDI100-2000 and DAcon increase.

Results of Part Two: the impact of window orientation and window-wall ratio on the energy consumption and lighting environment of a nearly square office

Using 5 different orientations and 7 different window-wall ratios as variables, we conducted a total of 35 energy consumption and lighting simulations, including DAcon and UDI simulations for each individual office room, a simulation of the average total annual energy consumption per square metre, and a simulation of average annual energy consumption per square metre for heating, cooling, and lighting, respectively.

According to the simulation results, the orientation corresponding to the lowest level of energy consumption is south and 15° east of south, followed by 15° west of south and 30° east of south. The orientation corresponding to the highest level of energy consumption is 30° west of south. The reason is that the western orientation has the longest daily duration of solar radiation, resulting in the highest level of cooling energy consumption. Solar radiation is most intense at 30° west of south, resulting in an increase in cooling energy consumption. The optimal window orientation in the Xi'an area is south and 15° east of south, and corresponding energy consumption is lowest for a window-wall ratio of 50%-70%(see Figure 3).

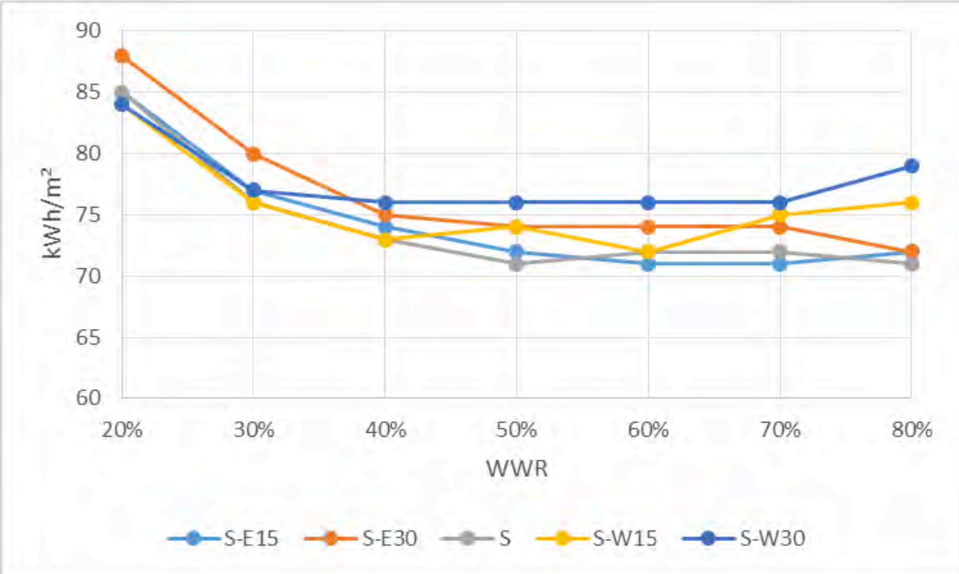

Figure 3. Energy consumption corresponding to the five different orientations

Table 2. Useful daylight illuminance UDI $_{2000}$ corresponding to the five different orientations

UDI>2000 / WWR	S	S-E15	S-E30	S-W15	S-W30

50%	0%	41%	30%	71%	72%
60%	0%	51%	44%	72%	72%
70%	0%	54%	46%	72%	72%
80%	0%	55%	49%	72%	72%

The heating energy consumption of offices with east-trending orientations is higher than that of those with west-trending orientations. The UDI>2000 of south-facing office rooms is 0, while the UDI >2000 of office rooms facing 15° or 30° east of south is up to 55%, and the UDI2000 of office rooms facing 15° or 30° west of south is 71%(see table 2). The orientation corresponding to the lowest frequency of glare occurrence is thus south, followed by east of south. The orientation corresponding to the most severe glare is west of south, so external shading for office rooms facing this direction must be installed in order to block direct light. In summary, the optimal orientation is south, which corresponds to optimal daylighting quality, least glare occurrence, and lowest energy consumption.

Conclusion

The simulation results show that differences in energy consumption are caused by differences in window-wall ratios, office room geometry, and window orientation. The energy consumption of office rooms varies based on room geometry, and a suitable window-wall ratio should be selected to reduce total energy consumption. A southern orientation is optimal in terms of daylighting and energy consumption, followed by 15° east of south, although glare has to be avoided in this orientation.

The energy consumption of mall-scale large-depth office rooms in the Xi'an area decreases as the window-wall ratio increases, and their optimal window-wall ratio is 60%-80%; the energy consumption of small-scale large-width office rooms increases as the window-wall ratio increases, and their optimal window-wall ratio is 30%-50%. The energy consumption of large-scale offices and square offices decreases as the window-wall ratio increases, and their optimal window-wall ratio is 50%-70%. The total energy consumption of large-depth office rooms decreases more rapidly than that of large-width office rooms as the window-wall ratio increases. In other words, the rate of decreases of total energy consumption as the window-wall ratio increases follows the order of large-depth rooms>square rooms>large-width rooms from high to low. As RI values increase, that is, as room scale increases, heating and cooling energy consumption decline gradually slows. The RI is proportional to lighting energy consumption, as lighting energy consumption is likely to increase as room scale increases.

Abstract: The project is mainly concentrated to create a wide Strategic Plan and Pilot Project for the small island in Sardinia, Italy. In the two last centuries the Island hosted several prisons but now it becomes a Natural Park, famous for environmental quality and biodiversity. Its few built-up areas represent an enormous potential and the administration is oriented to explore the impact of an eco-tourism attractive model, thinking out a Strategic Plan for a self-sufficient island, implementing energy efficiency and architectural integration of renewables, suggesting new activities and functions but with extreme care towards their cohesion with the environment and the biodiversity. The integrated approach will generate more effective architectural design strategies, green infrastructures and technological solutions: building integrated PV and mini-wind turbines, a broad water-harvesting network, waste management and mobility plan, for a deep reduction of CO2. The retrofitting building concept focused on naturalistic experience, offering beautiful and wellness luxuries, exclusive green suites and agri-therapy for children. It concentrates primarily to improve the efficiency of 3 buildings blocks, with high attention to envelopes performance, integrating green space, green roof and facade, as well as some passive bioclimatic technologies to reach a full-scale of comfort inside.

The challenges of Mediterranean Islands

In the Mediterranean area you can identify at least three different types of smaller islands, characterized by ecosystems and environmental heritage of great value, with a long and troubled process of historical sedimentation settlement. Today almost all of these islands are considered protected natural areas, such as Montecristo, the former penal colony of Pianosa and Asinara and traditional tourist islands as Giglio, Capraia and Maddalena. Small islands are still full of stories of treasures, memories and symbols that have undergone a process of transformation in recent years, often uncontrolled and characterized by fragmented management. In a perspective of sustainable development, it becomes necessary to stimulate the regenerative capacity of territories and natural resources, for local identity development in a spirit of cooperation and community involvement. In this process it is necessary to involve actors other than the public administration and SMEs playing a key role in the implementation and activation of local development.

The Asinara Island, located in the north-west of Sardinia, which includes the National Park of Asinara, has a surface of 51,9 square kilometres, formed by four minor mountain systems that are surrounded and linked by a narrow and flat coastal belt. The marine island environment represents an unicum in the Mediterranean area from a geological point of view, as well as its flora and fauna, both on land and sea, given the state of its territorial naturalness and outstanding presence. The island of Asinara in different centuries underwent alternation of cultural influences, creating a succession of different social dynamics of communities and settlements: from Cala Oliva as the village of Ligurian fishermen to various hospitals in the first and second period, as well as Cala Reale and the agricultural structures of Campu Perdu and Santa Maria, and the prison sectors of Trabuccatu, Fornelli, Tumbarino.

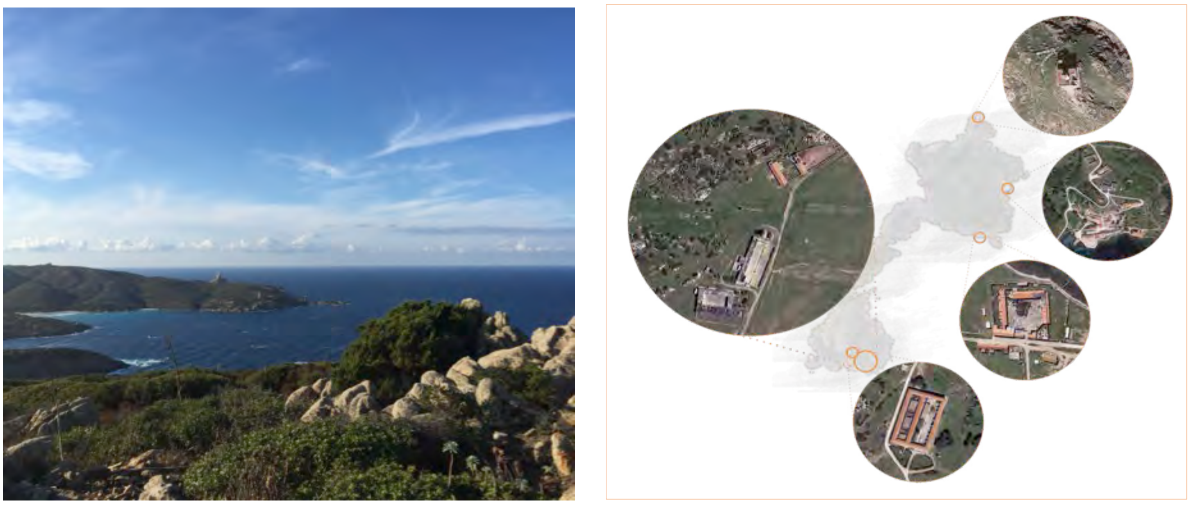

Figure 1-2. General view of the Asinara Island and 4 main prison structures

Despite the diversity of the social structure the islanders have allowed us to maintain a dynamic balance between nature and man, being able to manage the entropy of the system in all its complexity, ensuring at the same time the development of agricultural activities as economic and functional aspects of the island and the island life.

The establishment of the Asinara National Park has fortunately slowed down the phenomenon of massive tourism and led to a reversal of the trend, aiming at stimulating a growing demand for high environmental quality services, more aware of the rural and natural resource ecosystems, with a scientific approach and an international feel.

The Asinara territory can be an ideal and real testing ground for the international sharing and the promotion of a sustainable use pattern of low density territories and man-made high concentration of natural and cultural resources. A laboratory in which to test both systems of governance is the creation of ecological networks for smart resource management, integrated with business and Km0 agricultural model (local production of food and beverage). In this way it could trigger a virtuous process that brings the revitalization of the area, improving the competitiveness of local SMEs operating levels in the chain of tourist use. Thanks to the experimentation of a governance strategy and a participatory model of innovation and inclusive development, it becomes possible to enhance the system resources as well as the economic structure towards a model of eco-tourism and responsible tourism, which will produce in the short and medium term an increased green growth in a sustainable development perspective.

Figure 3. Flow chart of main drivers to stimulate regeneration process

The island in the island: Network of Cluster to stimulate the regeneration process.

The strategic plan designed to initiate a rebirth and Asinara island regeneration process, through the development of functions compatible with the fragile ecosystem, is based on the introduction of new activities, eco-compatible and integrated with the environment. However, to predict and to best design the arrangement and management of these new activities, it has developed an additional level of planning: blending various activities into Clusters and Networks. The term cluster is redefined in this case and applied to the particular natural and cultural context in which we find ourselves. It is to divide the island into several parts, which are considered self-sufficient but closely connected and collaborating. This brings us to the concept of the island in the island: a complex of buildings, structures, agricultural and natural areas full of all types of services and activities related to its function. This self-sufficiency is related to one (or more) particular activity, well defined, with a series of facilities dedicated to it. These structures are usually obtained from the pre-existing buildings. Each cluster has a main theme, and in some cases we have an additional division, as some activities are located in various parts of the island.

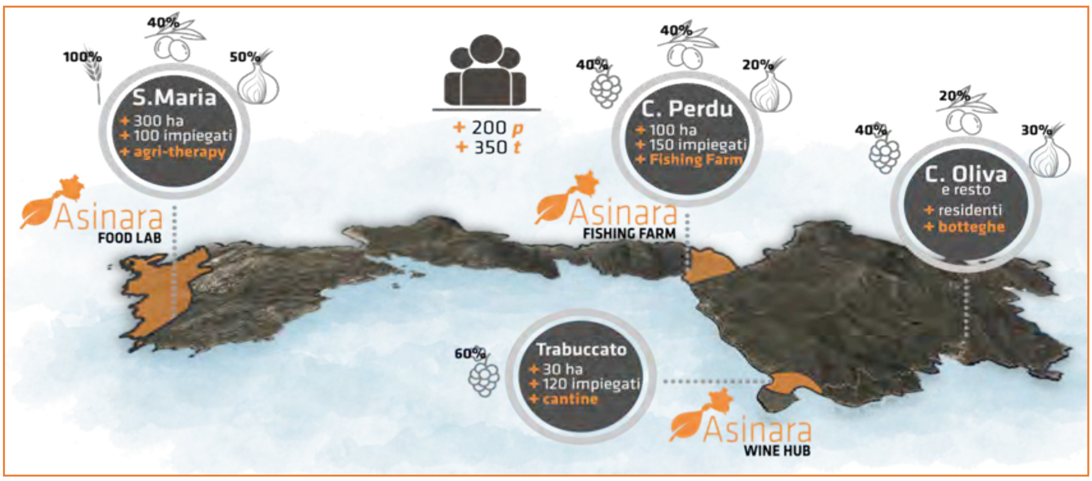

Fig. 4 Cluster distribution, related activities and personal involvement

The project concentrated mainly towards creating a wide Strategic Plan for the island regeneration: its main goal was creating completely new activities and functions that are compatible both with its touristic potential and especially with its natural fragility. These functions have been planned in order to give life and continuous activity to the island, but with extreme attention towards its cohesion with nature and biodiversity. 4 Pilot Projects as Food Lab, Fishing Farm, Wine hub, Wellness centre.

These various activities have been supported by a complex network of structure and services, dedicated to maintaining the island's ecosystem intact, and improving its offer and abilities to create both natural and commercial environment. The Strategic Plan has been developed with various strategies for reaching a sustainable and self-sufficient island, and has included various technological solutions. For example, there is an extensive use of building integrated PV and wind turbines which are inserted in architectural and urban environments in a non-invasive way. Other strategies include a broad water-harvesting network that includes harvesting rain water from roofing, in urban areas, and especially in agricultural areas, given its high need and waste of water used for irrigation. Other strategies include a revised mobility plan that points towards complete elimination of CO_2 emissions, giving priority to use of electric cars, as well as encouraging cycling and walking, given various beautiful natural areas on the island.

Fig. 5 The location and activities of the Cluster in the Master Plan

Food Lab - Santa Maria Pilot Project

The focus of the pilot project was the revitalization of the former prison sector Santa Maria as an international laboratory for ecotourism. This complex, located in the south of the area, has been used in the past as a farm for a particular group of inmates, and is situated near a field of nearly 200 hectares that can be turned into an agricultural farm complex. The concept behind the project was about creating a structure that is both productive and commercial, that offers a unique and naturalistic way of approaching and learning processes of agriculture, but that also offers beautiful and relaxing luxuries such as a slow food restaurant, exclusive green suites, a kitchen laboratory and an agri-therapy for children. It has been conceived as multifunctional set of buildings with green public spaces in-between, perfectly connected and able to offer a full set of activities and leisure for tourists as well as researchers. The building is a prison structure that has been revitalized and refreshed to house a slow-food restaurant and various suites for visitors. The project leaves internal disposition practically intact, but intervenes on buildings facades, making it much more open and illuminated, creating almost semi-open spaces that collaborate perfectly with the green surrounding them. These facades have been elaborated with some air and light-treating technologies, in order to reach a full-scale comfort inside the suites and restaurants. These technologies include:

- ***EvaCool***, a separated façade system built with tube structure that envelopes plants and hygroscopic materials that help cool air via evaporation, and channel it inside the building with specially designed cross-ventilation systems;
- A special ***in-suite greenhouse*** that uses a ***skylight for water harvesting*** and for better illumination, increasing the climatic comfort in the suite as well as indirect and diffused illumination;
- Inside and outside ***gardens*** that house a terrace-based water harvesting system.
- ***CanoPV+,*** a modular, tree-like canopy structure, with integrated photovoltaic cells that serves both as energy efficient element as well as for creating shaded spaces in outside gardens.

Fig. 6 -7 General view of the location and activities of the Cluster in the Master Plan

GreenRoom

It can be considered a nucleus of various technological solutions, with the scope of bringing perfect comfort and ideal thermal state inside the suites of the A Block. As suggested by its name, GreenRoom is characterized by a special in-suite greenhouse that uses a skylight for water harvesting and for better illumination, increasing the climatic comfort in the suite as well as indirect and diffused illumination.
Standing between the in-suite bathroom and the bedroom, it has a wide array of functions:

- The greenhouse serves as a water harvesting system, with rainwater being collected from the roof, through the skylight, and to the vegetation. The humidity of the plants helps cool down the ambient and provides a unique experience with the bathtub in-between the high vegetation;
- All the excess water that is not absorbed by vegetation is brought down to the general water harvesting system;
- The skylight at the top of the structure helps bring more natural light to the interior.

- With its glass structure and precisely inclined roof section, the GreenRoom helps diffuse natural light into the bedroom, giving more light in the morning period but maintaining low exposure during warm hours;
- The exterior of these suites has been enriched with a shading structure made primarily of wood and steel. It has a mobile front element that helps direct light throughout the day, contributing to the general comfort of the interior.

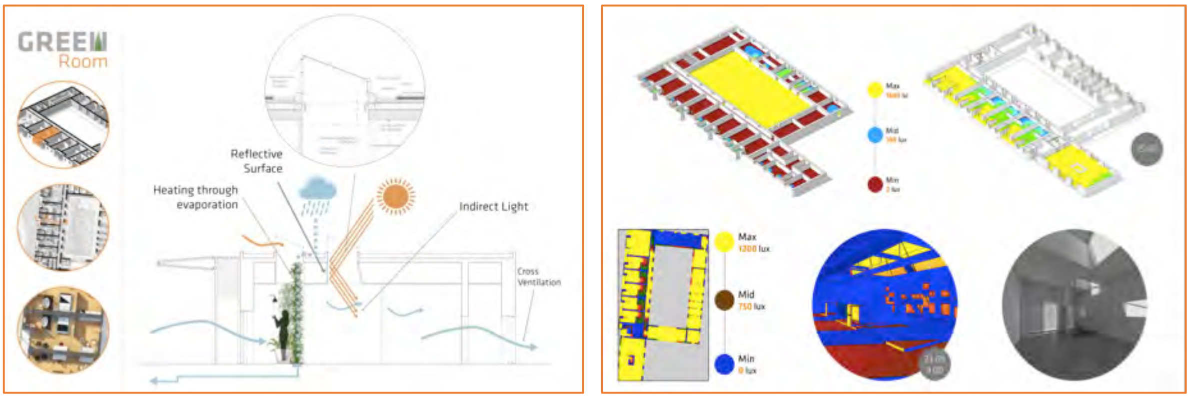

Fig. 8-9 Strategies of Green Room and Daylight evaluation

EvaCool

A separated facade system built with tube structure that envelopes plants and hygroscopic materials. These materials help cool the air via evaporation, and channel it towards the interior of the building with specially designed cross-ventilation systems.

The idea behind the creation of EvaCool is based on the need to create a new solution for the main facade of A Block, along with the intent of giving thermal comfort to the interiors. It is characterized by a tubular 3D structure with vegetation between the tubes. The tube system is connected to the green roof that collects rainwater, then channels it to the tubes. From there, part of the water is sprayed on the vegetation and the rest continues to the main harvesting system. This way, hygroscopic materials in-between the vegetation and tubular structure make contact with water, enabling them to instigate evaporation. The warm air gets colder and subsequently enters the interior via specifically-designed openings above the doors. This system, combined with the cross-ventilation provided by aligned openings, assures thermal comfort inside the right wing of the building.

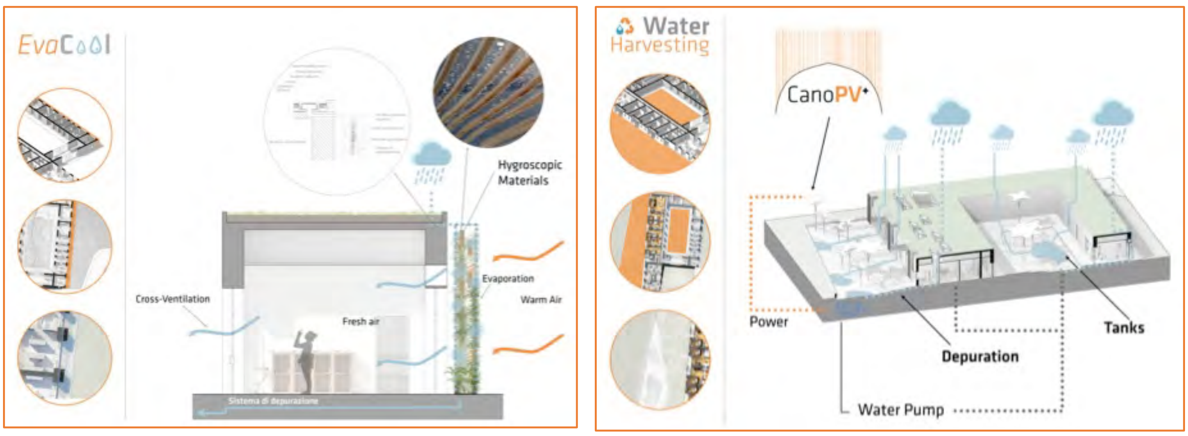

Fig. 10 -11 Strategies of Evaporative Cooling and Water Harvesting

ComfortRoom

The B Block houses another set of suites that have been designed with an effort to provide a complete thermal comfort. The ComfortRoom is characterized by an external shading structure with mobile elements that provide shading as well as rain protection and ventilation. Steel elements of this external structure is a part of general water harvesting structure that helps provide water for irrigation of nearby vegetable gardens. The original openings on the back side have been modified in order to provide more daylight and also to improve the cross-ventilation system, guaranteeing major comfort inside the suites.

Fig. 12 The location and activities of the Cluster in the Master Plan

General Water Harvesting System

All the above-mentioned technologies are a part of a wider system for collection, depuration and subsequent re-use of rainwater. This water-harvesting system interacts directly with the two main gardens (one inside and one on the outer side) that house a terrace-based water filtration system. The rainwater is collected both from the roof structure and from the gardens themselves. The green roof helps cleaning the rainwater with its filter layers. The water continues and is conveyed through the EvaCool and GreenRoom systems, where it has an important function for thermal comfort regulation. The excess water then continues and is attached to the underground system and conveyed through terraces inside small tanks that are integrated in the gardens. Water is then pumped from the tanks back to the building using energy provided by the CanoPV+ structure positioned in and around the gardens, contributing to the optimal eco-sustainable result, taking into account both water harvesting and energy efficiency.

Hybrid Heating System

Heating and warm water system is also designed to contribute to energy saving goals of the project. It consist of a hybrid solution that minimises the electric energy consumption, uses energy-efficient heat pump, but also includes a special solar thermal system to help contain energy usage. The solar-thermal modules are positioned on the left wing of the green roof, and interact with the ceiling system that houses all the installations.

This system should contribution to minimizing electric energy consumption, and can go as far as making it completely unnecessary during main summer months. Combined with the energy provided from CanoPV+ modules, this system further develops the eco-sustainable nature of the project.

Solar control design by matching criteria between its shading mask and the shadow desirability schedule to improve natural daylighting in an office building in the tropic

Jorge Hernán Salazar Trujillo

Profesor Titular, Grupo de Investigación EMAT, Facultad de Arquitectura, Universidad Nacional de Colombia, Medellín. jhsalaza@unal.edu.co

Abstract: Natural daylighting issues now are included in the design goals of shading devices, but the meteorological data needed to simulate its daylighting performance are hardly included during the early stages of the architectural design process. When a shadow device is perfectly sized and placed, it does not mask more sky than needed, nor does it allow unwanted solar entrance. To keep undesirable masks at their minimum while keeping desirable masks at their maximum, a perfect coupling is needed, something rarely achieved intuitively. An optimization method starting from minimum input was developed, useful when many of the project's energy efficiency decisions are still to be made. The Solar Coupling index here defined and applied, assess the deviation of an architectural alternative from the "perfect match": the best possible correspondence between the masked region and the shade desirability schedule. The methodology was applied in a 65.000 m2 office tower in Medellín Colombia, applying for LEED GOLD Core & Shell v3. The paper shows the evolution of the facade design process, illustrating the counterbalance between shading, natural daylighting exploitation and required aluminium expenses, illustrating the possibilities of the Solar Coupling method as an early design tool.

Keywords: Shadow efficiency, Shading device, Solar control, Daylighting, Sky visibility

Introduction

To avoid direct solar radiation income during the periods when solar gain will be unwanted is a basic premise of energy efficient buildings. If solar control is handled with high shading coefficient glass, the thermal load reduction will be a transmission-conduction issue. Optionally, when the envelope design includes shading devices, the search for energy efficiency becomes essentially a geometric issue. In this second case, the aim will be to prevent visibility towards the sectors of the sky dome where solar trajectories happen during time periods the shadow will be desirable. If visibility restriction towards those "unsuitable" sectors of the sky dome is not complete, the solar control device will mask a smaller portion of the sky dome than needed, providing insufficient solar control. Shade shortcoming will evolve in higher cooling power needs, higher initial investment in equipment, higher energy consumption of the mechanical cooling system and unwanted solar intrusion. In this situation, it is almost sure that users will try to block annoying solar intrusion by closing curtains or blinds, preventing daylighting and visual contact with the surroundings (William et al, 2012). The opposite situation could also happen: if the shading device masks a broader part of the sky dome than needed, it will include regions where there will not happen unwanted solar trajectories, precisely where the possibilities of taking advantage of diffuse light are the highest (Lan, 1986) (Bodart et al., 2002). Unnecessary sky masking will reduce the possibilities for natural light exploitation and greater use of daytime artificial lighting will be necessary (Reinhart et al, 2006).

Because excess or insufficiency in sky masking has a negative impact on energy efficiency and environmental quality of a building, the ideal situation is to design openings that maximize diffuse lighting while guaranteeing the absence of solar intrusion into the building. Interdependence relationship between diffuse lighting exploitation and shading depends on the geometrical configuration of solar control devices but it is strongly modified by changes in the facade's orientation, opening's shape, latitude and site skyline, making the task little intuitive during the preliminary drawings stage. High level of realism is needed for modelling natural lighting from climatic information (Mardaljevic et al, 2009) and that is also the case for thermal modelling (Monteoliva et al, 2012) (Rogers, 2006). Once the design team is finally prepared to provide the architectural information needed for carrying out the dynamic simulations of energy performance and conjugated lighting, the design flexibility is not as high as it was during the early design stages because the project has already gathered enough decisions that limit design choices.

Close correspondence between needed and provided shadow, only depends on the similarity between the masking originated by a shading device and the shade desirability schedule. This compromise relationship reaches an optimal point when a solar control device prevents any solar intrusion without limiting visibility towards any other sector of the sky dome (Figure 1). Reached the maximum level of coupling, mobile shading devices, selective glazing or automated systems would be the ways to continue increasing energy efficiency of an optimized shade (Nielsen et al, 2011). Because such perfect match is rarely perfect, it is important to calculate the bias from this ideal situation and define a metric of the situation since in any of the two scenarios: deficiency or excess, the result will be an increase in the energy needs. Once the design process reaches enough detail such condition is detected easily, but now the adjustment needs will be expensive in time and team effort.

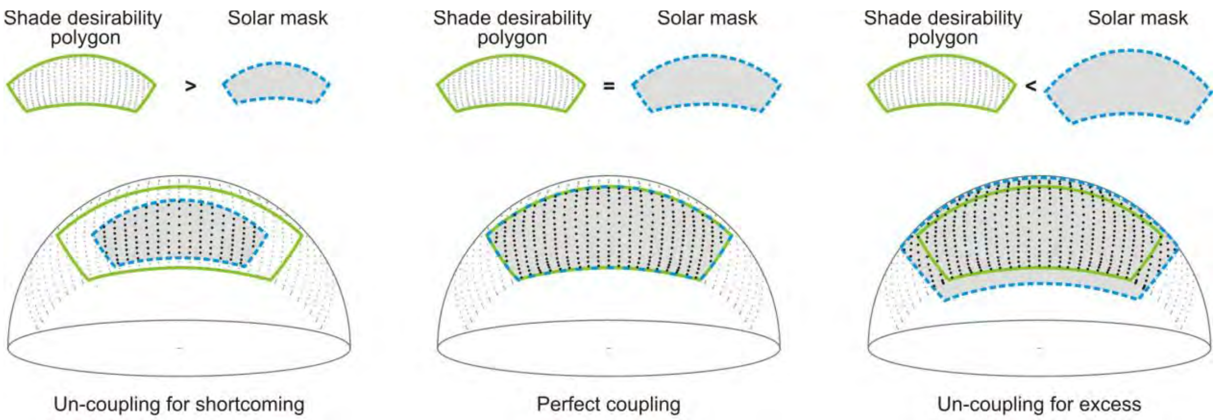

Figure 1 – Relationships between lighting exploitation possibilities and shade. Left: Un-coupling by shortcoming, when the shade desirability polygon is greater than shadow device´s solar mask. The room will be luminous but overheated. Centre: Perfect match. Right: Un-coupling by excess: the shading mask exceeds the desirability schedule. The room will be over-shadowed. Source: Author (2017).

Objective

Early decisions have the strongest impact on design. If the initial drawings provided to start energy detailed studies guarantee the Solar Coupling of every opening is close to its optimal, the starting point of HVAC designers would be better tuned and a solution could be reached in a less expensive way. Taking advantage of the fact that Solar Coupling is just a geometric property and that its calculation requires little input information, an analysis method allowing an early diagnosis of the relationship between natural lighting and shading was developed. The aim was to create and test a tool useful during the facade conception, promoting decisions that favour daylighting and solar protection. The results obtained help the architecture design team to identify the most advisable alternative and find equivalent solutions from the perspective of the natural lighting-shading relationship, quantifying the shade improvement margin of any opening, no matter the geometrical complexity involved.

Methodology

Shading masks are a classic tool of solar design. Basic shapes collections are included in a great deal of Bioclimatic literature (Olgyay, 1963) (Lippsmeier, 1969) (Baruch, 1976) (Szokolay, 1977) (Yáñez, 1988). Superposing a shading mask over a solar chart and count masked solar positions is a simple way to estimate the efficiency a solar control device will have. Additionally, the counting of non-blocked positions is the simplest method to know its optimization margin. Solar Coupling calculations and the computer code that allows its practical application are based on the relationships between spherical polygons obtained from the shadow desirability schedule and the opaque elements surrounding every studied opening. In order to make the calculations, initial 3D polygons must be transformed in 2D shading masks. Transform three-dimensional opaque elements representing a shading device into their corresponding spherical polygons, required to divide every one of their sides into short segments. Once those segments were drawn, every vertex was transferred towards a spherical surface representing the sky dome using size relations between similar triangles from a point operating as the polar coordinate system origin (Figure 2). Using geometric transformations applied on individual points instead of deriving trigonometric functions for specific shapes, is what allowed calculating the shading mask for any opening, regardless of its geometric complexity.

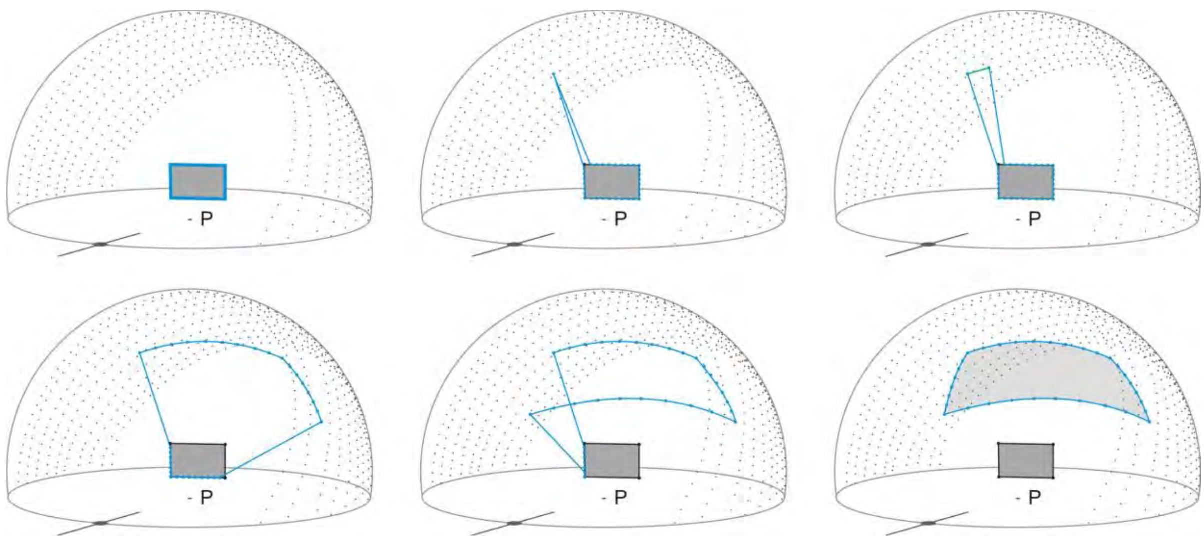

Figure 2. Drawing of a spherical shading mask. Transformation of any opaque element into its corresponding masking polygon from point P. Source: Author (2017).

To calculate masked sky regions, thousands of randomly distributed points on a spherical surface representing the sky dome were counted. Applying an algorithm previously developed that allows to determine whether or not a point is included in a closed polygon (Salazar, 2009), the belonging condition of every point to every group of spherical polygons was verified to classify them into four sets: Shaded (points included in the masked region and belonging to a shadow desirability polygon). Not Shaded (not included in the masked region and belonging to a shadow desirability polygon). Visible (not included in any masked region) and Not Visible (included in the masked region but not belonging to any shadow desirability polygon). This last set of points corresponds to the part of the sky unnecessarily masked. The counting of points belonging to those four sets allowed to calculate the proportions among the different regions in which the sky dome is divided by an opening, its shading elements and the neighbour objects. The addition of those four percentages is always equal to the unit (Figure 3, left).

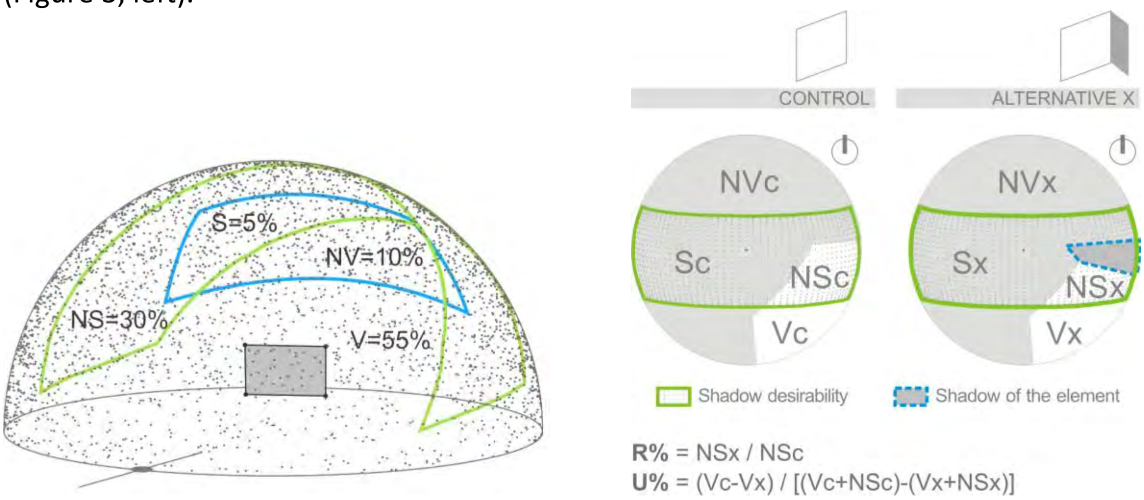

Figure 3: Left: Points classification depending on whether or not are included in the shading desirability polygon (green) and/or the shading mask (blue). Four groups were defined: Shaded (S), Not-Shaded (NS) corresponding to the shade shortcoming, Visible (V) and Not-Visible (NV) corresponding to the unnecessarily masked sky. Right: Remanence (R%) and Un-coupling (U%) of a shading element by means of the comparison between the studied alternative and a control opening used as a reference. Source: Author (2017).

Solar Coupling depends on masking polygons size and position. When shade sizing is done, the masked region at least should be as wide as the shading desirability polygon. This first condition is verified when the Not Shaded value (NS) is equal to zero. Besides, the masked region should not include portions of the visible sky dome, situation reached when the Not-Visible value (NV) is equal to zero. As can be noticed, the best possible condition happens when the masking polygons and the shading desirability polygons meet point by point. To define the Solar Coupling as a property of comparative nature, a reference case is necessary. The obtained values (Vc and NSc) from a control opening used as a reference and the subsequent values (Vx and NSx) from any opening, allowed calculating the Un-coupling U% and Remanence R% using equations 1 and 2. The former is defined as the percentage of the sky dome that has been masked even though it is not part of the shading desirability polygon. The last defined as the percentage of solar positions that should be blocked but have not been masked yet (Figure 3, right). Both values expressed as a percentage of the control opening.

$$U\% = (Vc-Vx) / [(Vc+NSc)-(Vx+NSx)] \quad \text{Eq. 1}$$

$$R\% = NSx / NSc \quad \text{Eq. 2}$$

Minimizing the un-coupling (U% close or equal to zero) while guaranteeing the shading conditions previously established (R%=0) is the path to design shading devices causing a minimal restriction to natural light exploitation. A maximal un-coupling (U%=100) means that the shading device does not block any additional part of the shading desirability polygon compared to the reference opening. A maximal remanence (R%=100) means that the alternative being evaluated does not offer any additional masking compared to the reference opening.

Results and discussion

To test the method three shade alternatives on a prototype square opening located in latitude 6.25°N were evaluated. The calculations considered three shade sizes in a progressive width of 0.50m, 1.0m and 1.50m and the Solar Coupling diagrams (Figure 4) show the obtained results. The reference opening: same size and orientation without any shadow element in front of it, is always located at the upper right side of every diagram, while the best possible value corresponds to the origin. The Un-coupling (U%) lies on the abscissas: as a point moves away from the origin, it will unnecessarily mask a greater part of the sky dome. The remanence (R%) is on the ordinates: as a point moves away from the origin, it will leave unmasked a greater part of the shading desirability zone.

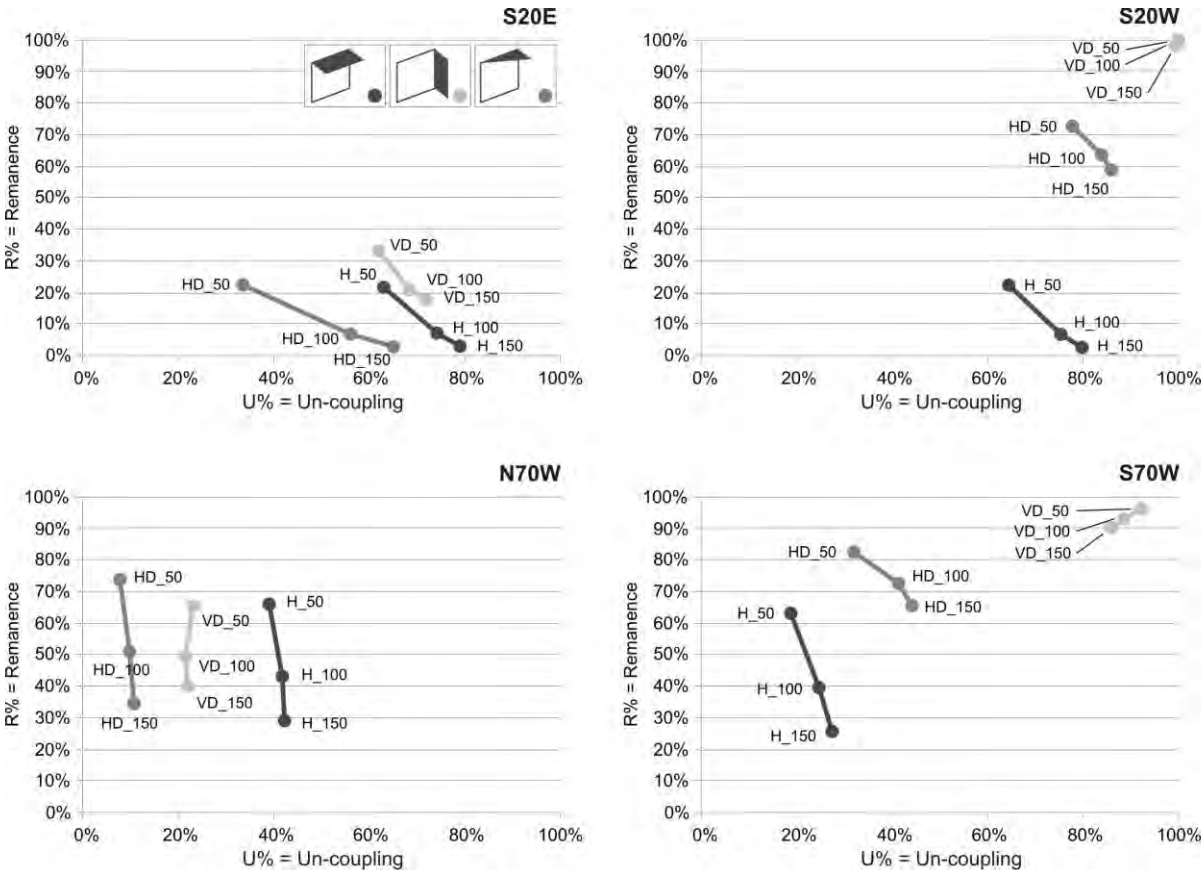

Figure 4. Solar Coupling Diagrams of a square opening facing different orientations in latitude 6.25°N. Three shading alternatives of increased width in cm were used: Horizontal overhang (H), Vertical fin (VD), and Triangular shade (HD). The control opening used as reference maintains size and orientation but lacks of any shadow element and its obtained value is always located at the upper right side of every diagram. The best possible Solar Coupling attainable corresponds to the origin. Source: Author (2017).

Points vertically lined up will generate equivalent unnecessary sky dome obstructions, but the one placed the lowest will have a better solar performance since it leaves fewer solar trajectories unprotected and, therefore, will generate less solar direct gains. Points horizontally lined up leave equivalent portions of the shading desirability polygon unmasked, but the one located farthest to the left will be preferable, since it will allow visibility towards a greater part of the sky dome and, therefore, will favour a higher level of daylight exploitation.

The prototype window test revealed significant differences between the shade alternatives evaluated. As can be noticed in figure 4, for a S20W square opening changing from 0.50m vertical elements to horizontal ones would reduce up to a fifth the solar income without important changes in its level of light exploitation. The situation is totally different in S20E openings, because same change would halve the natural lighting possibilities without any significant reduction in the solar gains. It is possible to make other comparisons, e.g. shape changes are more favourable than shading device enlargement in some orientations.

Figure 5. Left: Business Centre “Milla de Oro” designed by AIA in 2012 and located in Medellín, Colombia. Right: Built façade, corresponding to the alternative number 15 in figure 6. Photo: Valentina Zuluaga (2017).

Finished the test, the method was applied in the facade design of a 65.000 m^2 Business Centre located in Medellín Colombia (6.25°N, 75.6°W and 1550m above sea level). The “Milla de Oro” project, designed by AIA Architects and actually applying for LEED GOLD Core & Shell v3, proposed since the first sketches a high level of shadowing instead of the high reflectance glazing, the standard look of an office building in the city. A single 0.70m overhang at 2.70m height is the starting point of the analysis. The office towers have two west facing facades maintaining a single shade design in both orientations in order to have rounded corners. The South West façade has the highest solar exposure and the shading devices were designed under SW considerations. It explains why the obtained results are better than the North West results, where the façade is slightly overprotected and gets less natural lighting than the maximum for its orientation would allow (Figure 6).

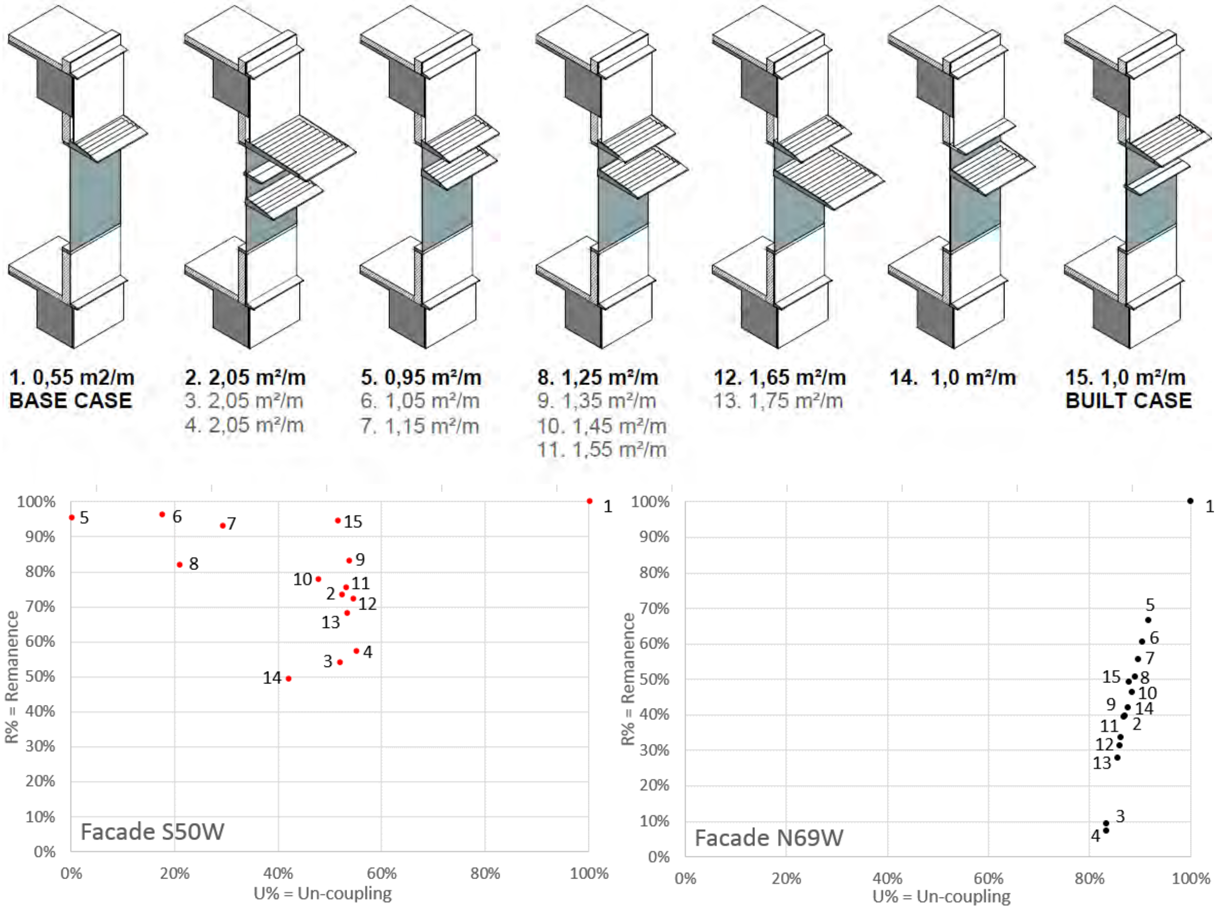

Figure 6. Sketches evaluated during the first design stages and its aluminium needs. Below, the corresponding Solar Coupling Diagrams in South West and North West facades. Source: Author (2017).

The 15 evaluated alternatives and the aluminium needs expressed in m^2 of aluminium per typical floor facade metre, reveal the explorations made during the early stages of the architectural design. In the beginning (alternatives 2, 3, 4) the aluminium needs were high, testing the possibilities of use clear glazing. The corresponding results (points 2, 3 and 4 in both diagrams) reveal the performance of design choices equally expensive. Once the aluminium investment needed to counterbalance the wind loads was included as a design variable, sketch number 5 show an aluminium cut off. Several choices considering two shelves and glazing as clear as possible (alternatives 6 to 11) were evaluated. Sketches number 14 and 15 show the final choices under consideration. From this point detailed thermal load calculation started, orientated to HVAC design and to define the final glazing specifications.

Conclusions

Show the Solar Coupling in an intuitive diagram, easy to understand even for people with basic knowledge on energy efficiency, allows that Architectural design teams interested in energy conservation promote lower energy demands from the early design stages. Starting from basic geometric information make possible to compare between similar façade sketches, identify the optimization margin and visualize the effectiveness of decisions oriented to minimize solar intrusion, maximizing the natural light exploitation possibilities and improving indoor environment conditions.

The method used to calculate the Solar Coupling in the Business Centre allowed to define numerically a minimal coupling threshold and to work to reach it from the early design stages. The typical un-coupling values in built facades frequently will surpass the ideal value, but the distancing from this theoretical situation constitutes an unbiased method to quantify the mismatch between the solar performance of any shading device and the best attainable condition.

To give opportune information according to design team agenda, a homogenous sky model was used to reduce computing time. Further improvements can be included (e.g. solar data, cloud coverage and ground reflections), but including climate data and materials optical properties would take out the method from the domain of the standard team that produce architectural sketches, leading the research to the natural lightning prediction area.

Abstract: The need for more low-income housing accounts for 89.6% of the national Brazilian housing deficit, currently estimated at approximately 5.5 million units. New houses built in response to this demand should seek to deliver thermal comfort and energy efficiency to their occupants. In this paper, the authors use a low-income housing typology designed for the climate of Porto Alegre in southern Brazil as a vehicle to explore ways of optimising the building envelope to improve thermal performance passively. The concept of fabric first approach is explored, varying the levels of insulation and airtightness of the envelope as means of improving indoor environmental conditions and energy savings. The method used was dynamic building simulations, underpinned by empirical data and assessed for its thermal/energy efficiency and construction cost. The findings suggested that an optimised envelope can achieve an increase of the thermal comfort of up to 130%, and a reduction of the energy demand to negligible levels. The results demonstrated, however, that the envelope optimisation increased costs considerably. The results also suggested that there is a need for further investigation of infiltration levels in residential buildings in Brazil and their implications on the delivery of thermal comfort.

Keywords: thermal comfort, energy efficiency, low-income housing, building envelope optimisation.

Introduction

Brazil has a housing shortfall of 5.546 million housing units (Fundação João Pinheiro, 2011). The most affected by this shortage of housing is the low-income population, which represents up to 90% of the national deficit (UN-Habitat, 2013, Angélil and Hehl, 2014).

The housing deficit varies across the country and it is more expressive in the northeast of the country, where the poorest population are mostly found. However, it is in the southern part of the country where the delivery of the thermal comfort is a greater challenge due a more extreme climate. There, the housing deficit ranks 3rd and represents 10% of the national deficit (Fundação João Pinheiro, 2011). The great concern in the provision of these new low-income housing typologies in south of Brazil is related to the lack of adaptability to the climate and use of culturally accepted materials. In the city of Porto Alegre (lat. 30.05°S, long. 51.23°W, alt. 47m) the climate is characterised by both the existence of warm to hot summers that are also humid, and cold winters, and buildings are characterised by often conflicting solutions for dealing with heating and cooling demands.

The concept of the fabric first approach, which mostly considers an insulated and airtight building envelope, is used in this paper to support the argument for higher energy efficiency in Brazilian dwellings, despite these concepts are not vastly employed in Brazilian buildings yet, as shown in Tubelo et al. (2014).

Low-income Housing in Brazil

The main characteristics of low-income housing typology in Brazil when delivered or financed by housing programmes are its standardised nature, which is adopted in terms of typology and materials indistinctly across the country without minding climate and cultural differences.

In this context, the most common low-income housing typology consists of a 2-bedroom 1-floor detached building of an area larger than 36m^2 (Tubelo, 2016). The fenestrations of these low-income houses mostly do not exceed 2m^2 and are commercialised in standardised dimension due to the costs (Tubelo et al., 2016). The house eaves are built out of a minimum eaves requirement of 50cm length as suggested by Ministério das Cidades (2014), which allow the delivery of a certain degree of shading when combined to the typical small windows (Tubelo et al., 2016). However, this does not consider the house's orientation. These houses are mostly built with a layer of load-bearing hollow block wall of 14cm thickness with a layer of plastering of about 2cm of thickness each; windows are mostly made out of aluminium or steel with a 3mm single glass (Tubelo et al., 2016).

Data from low-income housing research suggests that these buildings have a high occupancy rate. Data from 2010 Census states that the average household in Brazil have 3.3 people (IBGE, 2010), but low-income housing have a much higher density. Previous research on low-income housing shows a occupancy rate of 1 person per 13m^2 (Cruz and Ornstein, 1995) but common practices in low-income housing could be 1 person per 9m^2 so it is not unusual to find a house of 36 m^2 with 4 people living in.

The case study: the Alvorada House

This research adopted a case study representative of a low-income housing typology, built in Porto Alegre, southern Brazil, which complies with most of those typical characteristics of a low-income Brazilian housing such as reduced area, rectangular shape on the plan, medium-sized windows, pitched roof and eaves. The case study is a north-south oriented one-storey detached house of a useful area of 38.67m^2 (Figure 1). The house accommodates externally two porches, used as a space of transition for the house access apart from its shading function.

However, differently from the other typical low-income housing typologies, this house was designed using passive design strategies with the aim of providing better environmental quality to its occupants at affordable costs. It was designed to be a place for investigation of passive design solutions applied to the context of compact affordable houses (Sattler, 2007). The house design considered a set of design strategies for increasing thermal comfort for both winter and summer periods. The strategies are described in Figure 1. Previous works on the Alvorada House can be found in Morello (2005), Grigoletti (2007) and Sattler (2007).

Furthermore, the house represents a degree of improvement in the current state-of-art of low-income housing typologies built in Brazil as it considers culturally accepted and high quality materials combined with the use of local and affordable techniques, instead of adopting a standardised strategy of the low-income buildings (Sattler, 2007, Tubelo, 2016).

The Alvorada House was constructed using uninsulated materials as traditionally found in southern Brazil. The walls were built out of a non-load-bearing masonry, mostly built out of a layer of solid bricks of 11 cm of thickness; small deviations of this pattern were considered for other wall facades and these are shown in Table 1. Windows were made out timber frame and single glazing (U-value: 5.78W/m^{2}K). Roof was designed mostly facing south to reduce the incidence of sun and was built out of ceramic roof tiles with a reflective aluminium foil inside to reduce the indoor heat transmission.

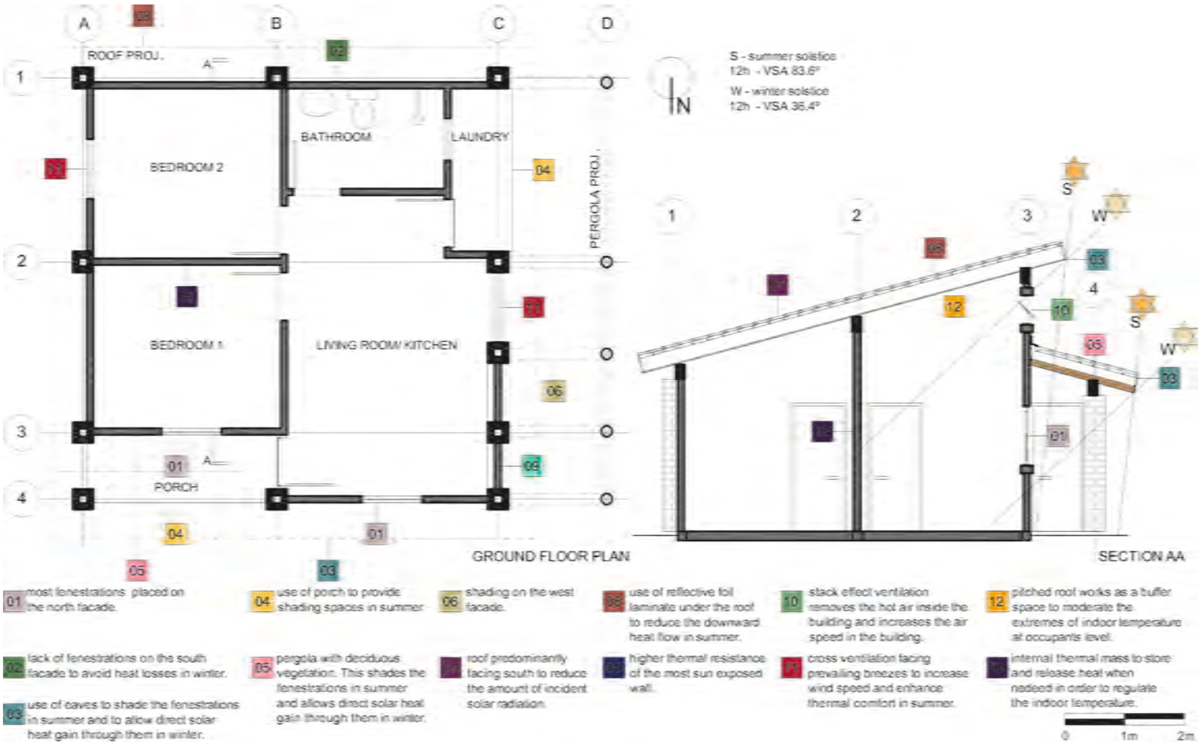

Figure 1. The Alvorada housing plan and section and the passive design strategies.

Table 1: The Alvorada fabric, as detailed in Sattler (2007) Morello (2005) and Grigoletti (2007)

Unfortunately, the infiltration of the house is unknown as this type of test is not currently performed in Brazil. High infiltration impairs the thermal performance of the house and the delivery of the thermal comfort mainly in winter period as it allows uncontrollable air movement coming into the house mostly through its joints and leaky windows.

Porto Alegre Climate

Porto Alegre has a humid subtropical climate with a great seasonal and daily variation (Cfa according to Köppen climatic classification); the summers are hot with high levels of thermal humidity, while the winters frequently have colds and rainy days of a moderate amplitude but also have cold and sunny days of great temperature variation when under influence of polar waves (Tubelo, 2011). Average monthly temperatures and relative humidity are showed in Table 2. Annual average temperature is between 18 and 20°C (Alvares et al., 2014). Winter winds are mostly from south and southeast direction and are of low speed.

Table 2: Porto Alegre average monthly temperature (T) and relative humidity (RH), based on Roriz (2012)

Methodology & Calibration

Envelope combinations were investigated using as reference the fabric first approach, replacing the current building envelope specification with an envelope with low thermal transmittance and infiltration values.

It should be noted that this house was chosen because a set of passive design strategies were already implemented. However, the concept of super-insulated envelopes was not considered and the authors saw it as one of the potential solutions to increase energy efficiency and comfort. Other potential design strategies were considered elsewhere (Tubelo, 2016) but were outside the scope of this paper.

The methodology consisted of the use of dynamic thermal building simulations using TAS (Thermal Analysis) software (EDSL, 2013), underpinned by 1-year of monitoring data collection obtained by Morello (2005). The use of empirical data helped to establish a realistic representation of the house. The monitored data did not include occupancy and so, the simulations allow for an estimate the house's potential post occupancy functioning.

Temperature data from monitoring was used to calibrate the simulation model. Literature to support the establishment of a good agreement between simulated and monitored data is not easily found. This research made use of ASHRAE (ASHRAE Guideline, 2002), that provides two different indexes. The mean bias error statistically measures how consistent the simulated data is related to the measured data and root mean square error statistically measures the magnitude of the varying quantity. The results corresponded to 0.7% and 5.6%, which were lower than the acceptable limits established by ASHRAE (ASHRAE Guideline, 2002) of 10% and 30% for hourly calibration data of the mean bias and root mean square errors, respectively. The referential used for calibration is showed in **Error! Not a valid bookmark self-reference.**.

The simulations analyses consisted of testing the house at different aspects: under the current condition that the house was built; under a degree of improvement compatible with highly insulated envelope, as those suggested by the fabric-first-approach-based regulations; and then, with a reduced infiltration rate.

Table 3: Calibration referential

Measured mean indoor temperature	20.86°C
Simulated mean indoor temperature	20.76°C
Standard deviation of measured indoor temperature	4.30
Standard deviation of simulated indoor temperature	3.85
Correlation coefficient	0.93
Mean Bias Error (< 10%)	0.7%
Root Mean Square Error (< 30%)	5.6%

The envelope optimisation was based on typical envelope construction elements adopted where saving-energy approaches have been used, as shown in IBO - Austrian Institute for Healthy and Ecological Building (2009) and in line with the Passivhaus standard referential of thermal transmittance of no more than $0.15W/m^2K$ for opaque elements (Passive House Institute, 2015). The selection of the optimised envelope was also based on a further study that investigated different envelope combinations varying each construction element at a time and this can be found in Tubelo (2016). The optimised envelope and its thermal property are shown in Table 4. The use of traditional materials was kept and high levels of insulation material were adopted. Windows of $1.42W/m^2K$ with low-e double glazing were used.

Standard infiltration referential for simulating Brazilian constructions is suggested to be 1 ach at atmospheric pressure, according to the NBR 15575 (ABNT, 2013). In the case of the reduction of the infiltration, as buildings in Brazil are mostly naturally ventilated, especially those used for low-income householders, minimum requirement of infiltration for maintaining the use of natural ventilation was adopted. The referential used in the United Kingdom regulation of $3m^3/hr/m^2$ at 50 Pa in which no additional mechanical ventilation system is required was adopted (Cotterel and Dadeby, 2012, NHBC Foundation, 2009). This is calculated to be roughly equivalent to 0.15ach.

Each room of the house was considered as a thermal zone and specific patterns of use were adopted accordingly. The occupancy pattern aimed to simulate as close as possible the real condition of use (Table 5). Household appliances considered the most typical ones found in Brazilian residential buildings. Lighting power and usage were based on INMETRO (2012).

The results obtained from the dynamic thermal simulation were compared in terms of thermal comfort and energy expenditure. Internal doors were kept opened in the simulations and because the results for the rooms were quite similar due to the small size of the house, data from the living room were used as representative.

As for the energy calculations, the building can operate in mixed mode, a more conservative criterion of thermal comfort was adopted to be between 20-25°C. However, the occupants of residential buildings can tolerate a wider range of temperatures (Nicol et al., 2012) and because of this adaptation, a wide thermal comfort interval of 18-29°C was also considered in the analyses. The choice for the wide comfort limit considered the adaptive approach in which the temperature intervals were calculated according to ANSI/ASHRAE Standard 55 (2010). The calculated comfort limits for Porto Alegre corroborate with the referential suggested by Givoni (1992) of 18-29°C of temperature to be used in Brazil.

The cost analyses explored the viability of the envelope optimisation and they were undertaken using the TCPO database (PINI, 2015b), which is a Brazilian database with more than 5 thousand typical construction composition prices (PINI, 2015a). The cost analyses compared the costs of the main house envelope elements as built against the costs of the optimised envelope.

Table 5: Simulation assumptions

Occupancy	2 people per bedroom at rest for a use schedule of 10 hours in weekdays and 12 hours in weekend; all occupants in the living room at sedentary work with an occupancy of 5 hours in weekdays and 10 hours in weekends.
Lighting	5W/m^2 for bedrooms, usage 3 hours per day; 6W/m^2 for the living room; usage 5 hours per day in weekdays and 6 hours per day in weekends.
Household appliances	TV of 30W used 4 hours per day; Fridge, microwave, iron and washer were assumed at a typical usage, totalling a daily energy consumption of 1.9kWh.

Results

Thermal comfort analyses

Externally, the temperatures were mostly within the thermal comfort; 36.7% of the time they were below 18°C and 6% of the time they were above 29°C. The occupied areas were within the thermal comfort of 20-25 °C and 18-29 °C for 42% and for more than 81% for the current envelope condition, respectively (Table 6).

The adoption of the insulated envelope increased the thermal comfort in the occupied areas by 73% and 21% for the narrow and wide thermal comfort interval when compared to the current envelope, respectively. The occupied areas were within the thermal comfort of 20-25 °C and 18-29 °C for more than 72.5% and for 98% of the time, respectively. The main change was related to the reduction of thermal discomfort for temperatures below 20°C and above 25°C.

The adoption of an insulated and airtight envelope diminished the thermal discomfort to negligible levels. The occupied areas were within the thermal comfort of 20-25°C and 18-29°C for 96.8% and 100% of the time, respectively. This meant an increase of the narrow and the wide thermal comfort by more than 33% and 2% when compared to the case of only the change of the envelope but at a standard infiltration rate; and it represented an improvement of the thermal comfort of 130% and 23% related to the current envelope, respectively.

The occupied areas of the Alvorada House had a peak temperature of 32.82°C in the living room/kitchen in the current envelope use. Adopting the insulated envelope at a standard infiltration rate, the indoor peak temperature was reduced by about 5.5 K relative to the current condition. Using the insulated and airtight envelope, the indoor peak temperature was 1.5 K lower than in the insulated envelope at a standard infiltration rate and about 7K lower than the current envelope use.

Table 6: Thermal comfort levels

°C	Ext.	As built	insulated envelope + 1ach	insulated envelope + 0.15ach
20-25	30.8%	42.0%	72.5%; 73% more related to as built.	96.8%; 130% more related to as built.
18-29	57.2%	81.0%	98.0%; 21% more related to as built.	100%; 23% more related to as built.

Energy efficiency analyses

The Alvorada House envelope as built had its annual energy demand estimated to be 45.39kWh/m^2. With the adoption of the insulated envelope at a standard infiltration rate, the energy demand would be reduced to 5.35kWh/m^2. Then, with the reduction of infiltration, the energy demand would be smaller than 1kWh/m^2. This meant that the optimisation of the envelope and later the reduction of infiltration levels would be able to achieve annual energy savings of 88.21% and 99.3% compared to the Alvorada House envelope as built, respectively.

For a 50-year lifespan period and considering the average Brazilian inflation on the energy tariffs, the costs for running the Alvorada House as built would be 8.5 times bigger than the situation with an optimised envelope at standard infiltration and 151.3 times bigger with the scenario of the optimised and airtight envelope if a mixed mode scenario would be adopted to maintain the temperatures within the thermal comfort interval of 20-25°C.

However, the costs of the optimised envelope showed to be 4.1 times more than the costs of the Alvorada House envelope as built. A cross-analysis of the costs of the envelope and costs for running the housing (for a standard infiltration rate of 1 ach) revealed that the payback period would be estimated to be approximately 19 years. The envelope optimisation would add 65% to the overall typical Alvorada House cost. The analysis could not estimate the cost for building an airtight envelope as it might require a great effort of all construction actors in both design and construction stages (Pacheco, 2013, Tubelo, 2016).

Final considerations

This paper looked at increasing the thermal performance of a low-income housing, built in southern Brazil, by acting on its envelope. The work adopted insulated and airtight building envelope as response for the delivery of energy efficient and thermally comfortable houses.

The results showed that the optimised envelope adopted would be able to deliver up to 130% more thermal comfort and up to 99% more energy savings in comparison to the envelope as built. However, the findings demonstrated that the overall housing costs would be exceeded in more than 65% compared with its typical costs, which makes the optimisation unfeasible for these income range households and house typology.

It remains a scope for investigation the accurate quantification of the levels of infiltration adopted in Brazil and its potential thermal comfort benefits in case of reduction. It is also important to investigate the potential cost increase of the reduction of infiltration in order to explore its feasibility in the Brazilian housing construction.

Acknowledgements

The first author would like to acknowledge the Coordination for the Improvement of Higher Education Personnel (CAPES) and the University of Nottingham for their support. Our gratitude also goes to the NORIE of the Federal University of Rio Grande do Sul (UFRGS) for providing the researchers with the Alvorada House empirical data.

Abstract: Humans and most organisms require varying degrees of porosity in their natural way of life, and traditional designs exemplify porosity as essential parameter to comfort and functionality. Based on the theory of affordance, complementarity of climate and lifestyles, the paper highlights the pertinence of passive design: adaptive shading, ventilation (summer) and air-tightness with glazing (winter). Adaptive wooden louvers on the West (vertical) and South (horizontal), and shading protects the indoor environment from overheating in summer while allowing solar heat gain in winter. Low thermal conductivity materials and natural ventilation through space syntax integration between private, semi-private, public zones or indoor and outdoor could be conducive for comfort. The objective is to highlight low-energy passive design strategies through the analysis of passive climate charts and parametric simulations and further respond to local needs: vernacular reinterpretation, economic, and environmental symbiosis. Comfort parameters are temperature (℃), relative humidity (%), and air-velocity (m/s). PMV's range of -1 to +1, comfortable, is possible on most days through affordance: complementarity of climate and lifestyles in passive architectural niche which are expected to be novel strategic principles towards designing to thrive in an increasingly energy intensive built environment.

Keywords: Affordance, passive design, climate, parametric, comfort.

Introduction

Humans and most organisms require varying degrees of porosity to thrive and grow in their natural way of life, and traditional designs that have been an integral part of Manipur's environment and daily way of life also exemplify porosity as essential parameter to comfort and efficient function. E.g., Matted split bamboo baskets, wood or bamboo and thatch houses, etc. As concomitants to eccentric development and lifestyle changes, energy consumption in the form of electricity or gas increases since traditional passive ideas were substituted by active cooling or heating and comfort is often limited to high energy heat sources in winter or fans and air-conditions in summer. The design of this propose porosity house envelope and planning affords possibilities for low-energy comfort through various degrees of porosity: natural ventilation (summer) and air-tightness (winter) in combination with adaptive shading and other passive design techniques. As a theoretical basis, 'affordance' (Gibson, 1979) connotes the complementarity of the architectural niche ingenuity, climate and proactive lifestyles responsive to diurnal or seasonal changes while paying homage to the vulnerable vernacular habitats. In the last few decades, the lifestyle of most families in Churachandpur have changed due to interstate or international travel or habitation, employment, merchandising, and access to internet and print media, etc. Concrete and steel materials, auto-centric and high-energy developments without appropriate passive design principles radically changes the traditional means to affording comfort associated with vernacular dwellings. Often, local resources: materials, energy, infrastructures, and local architectural paradigms are at odds with the new paradigm shifts. The basic traditional tenets of proactive lifestyles, natural ventilations with envelopes' porosity, low thermal conductivity material paradigms have been sacrifice to development.

Hypothesis, Objectives and Methodology

Architectural reinterpretation of novel traditional ideas and revival of proactive lifestyles proposed in this modern porosity house aims to highlight the pertinence of porosity: natural ventilation, and adaptive shading in cool-humid areas of Manipur. The hypothesis is base on the theory of affordance: complementarity of the building's adaptive envelope with the users' lifestyles, and connectivity of indoor and outdoor for good ventilation, appropriate air change rates (ACR). These could afford comfort in indoor thermal environment. Space syntax layout of kitchen, dining, living, stairs, bedrooms, lounge, attic space, etc., facilitates natural ventilation. The primary objective is to established novel passive design principles and strategies for comfort with low-energy through vernacular reinterpretations, computer simulations, and responsive lifestyles. Qualitative site survey was done and quantitative systematic computer simulations for various grades of ventilation, air change rate (ACR), and adaptive shading were perform in combination with other optimal passive design techniques in Solar Designer Ver.6.0. Pertinent findings in summer and winter are expected to highlight a more resilient low-energy built environment possibilities. Predicted indoor temperature and relative humidity were analyzed with CBE's thermal comfort tool and indoor thermal comfort possibilities were studied under various adaptive activities, air change rate (ACR), and clothing.

Survey and Analysis

Macro Climate Analysis

Hill-town Churachandpur is located near Imphal at coordinates: 24°20’N 93°41’E at an elevation of 914m above MSL. Spring and autumn are pleasant while winter can be damp and cold without adequate sun penetration; summer is hot without appropriate shading and ventilations. Figure 1 shows the mean temperature fluctuation ranges: 14-18°C in winter and 6°C in summer. The mean diurnal temperature high is about 20°C or more through the year. Diurnal maximum is 28°C or more but drops to about 20°C at night in summer, and minimum is 6°C or less in winter nights. Maximum solar radiation is 500W/m² or more throughout the year. The nights’ humidity ranges 80-95% or more and diurnal humidity is 70% or less through the year. Wind speed is 0.4-3.4m/s in the day, and the nights are calm, 0-0.2m/s through the year. Prevailing wind direction is from West in February-May, and S-East in June-December. Figure 2 shows the project site location near the foothill of a mountain in a mid density residential area with detached houses, mixed used shops, and cultural buildings. In summer, the temperature variations between the hills and the residential areas could modify micro-climate due to cool breeze from the hills to the relatively hotter residential areas.

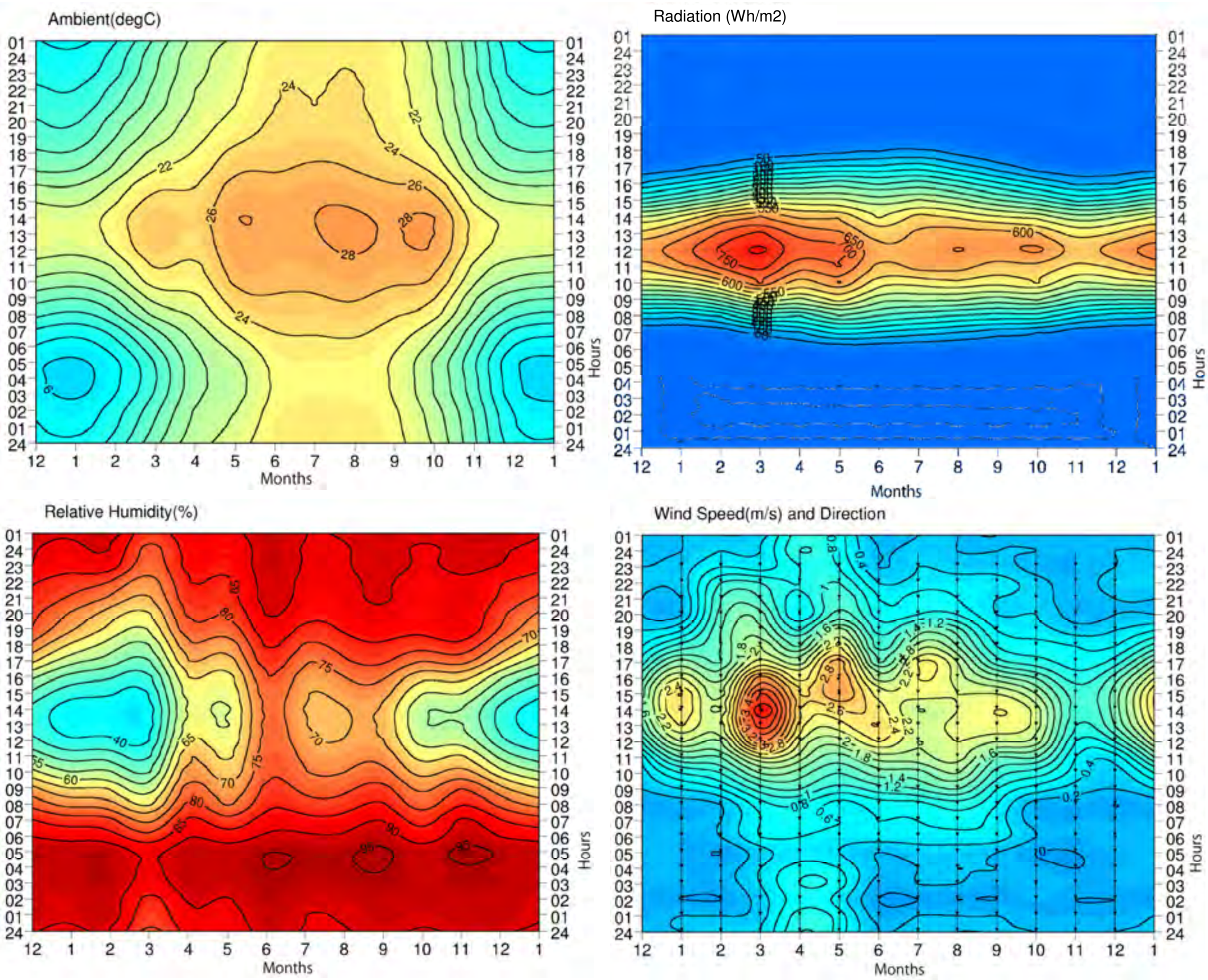

Figure 1: Passive climate charts' climate parameters fluctuation in cool-humid Imphal, near Churachandpur.

Space and Function

Space and Function in Vernacular Architecture

Figure 2: Site view showing mid density detached houses from surrounding hills, in Churachandpur.

Figure 3: Vernacular habitats extroverted space functions, and porosity of envelopes with deep thatch eaves.

Generally, a house functions as an evening and night-time occupancy in traditional dwellings due to agricultural occupation for working members, except for children and the elderly who stays home. While the absence of high industrial development is noted in the vernacular habitats, it doesn't necessarily mean low technical soundness or inadaptability for modern reinterpretation towards climatic responsiveness and proactive low-energy lifestyles. "As concomitants to the cool-humid climatic parameters, resources and socio-cultural praxis, the vernacular habitats are one-room typologies that afforded inherent flexibility to fulfil multiple functions: dining or living, bed or lounge, social gatherings, and workspaces for cooking, weaving traditional shawls or bamboo. The front veranda performs a versatile function of workspace, rainwater harvesting from thatch roof, and social space or enjoy fresh air. People's culture and lifestyles has made adaptations as a response to basic human body's comfort needs by wearing warmth clothes in winter and lighter porous cotton clothes in summer." (Tungnung, 2015). Figure 3 shows possible passive design lessons: space syntax of the vernacular habitats indoor and outdoor, envelope's porosity, and deep thatch eaves that afforded ventilation and shading, as well as complementarity of lifestyles in the use of indoor and outdoor, depending on the time and seasons.

Selection of Appropriate Passive Design Techniques and Paradigms

Manipur's cool-humid climate necessitates heating in winter and cooling in summer. In vernacular habitats, "porosity: air-flow, light and shade due to low thermal conductivity porous envelope and void like interiors with attic space afforded protection to the living-dining hall from the sun while ensuring seamless connectivity of the interior and exterior for airflow and the same attribute allows control radiation of heat or glare-free diffuse light from the sun or fire-place, evenly, to all parts of the house." (Tungnung et al, 2015). Modern reinterpretation possibilities and appropriate passive design paradigm were selected by simulating a module with different envelope materials: 'A', adaptive wooden louver and glazing on four walls; 'B', light weight wood on the East and West and louvers with glazing on north and south; and 'C' is a high mass 230 brick wall with openings on North and South. Figure 4a shows maximum temperature ranges for module 'A' in winter due to air-tightness, indoor heat sources, earth contact plinth, night curtains, etc. Module 'B' shows high fluctuation while 'C' is stable but low. In figure 4b, 'B' and 'C' under night-ventilation shows higher diurnal temperature due to small temperature fluctuation on cloudy & sunny days. Low nighttimes' ACR and indoor heat can increase diurnal temperature in low mass 'B' and high mass 'C'. Higher ACR may not be possible in 'B' and 'C' due to small openings and low wind speed. But 'A' has adaptive porosity and higher ACR is probable and shows low temperature ranges due to higher ACR and low ambient temperature except on peak very sunny days. Given the novelty concerns of reinterpreting vernacular passive techniques, 'A' was chosen as a possible appropriate architecture with adaptation for winter comfort needs using glazing. Some peak summer days are hot, but when it's cloudy or rainy the weather can be pleasant. The indoor temperature can be modify by opening or closing glazing.

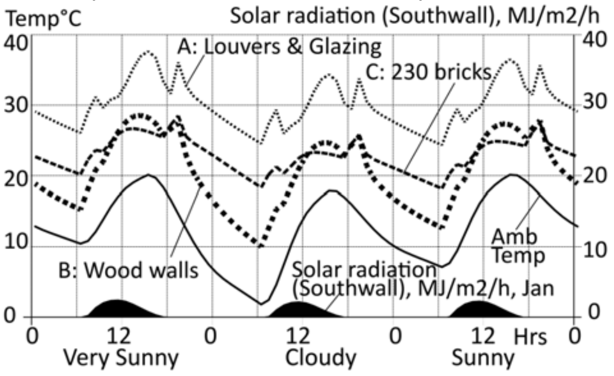

Figure 4a: Temperature fluctuation in Modules A, B, C under low ACR of 0.5, day & night, January.

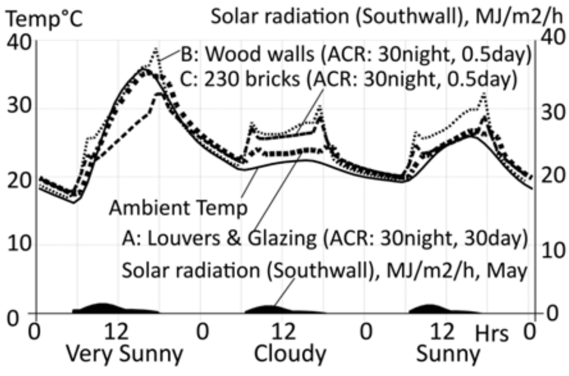

Figure 4b: Temperature fluctuation in Modules A, B, C under probable air change rates (ACR), May.

Space and Function in Re-interpreted Modern Architecture

The paper investigates reinterpretation possibilities of traditional porosity design in the form of adaptive envelope elements: wood louver walls and glazing windows, and adaptive shading to respond to seasonal changes in the context of an increasingly energy intensive housing and lifestyle paradigms. Figure 5 shows image of high porosity envelope with cool-air inlet at the ground while the stairs, porous wood floor, and attic space serves as hot-air outlet and buffer. The semi-public living-dining, kitchen, and verandas have good horizontal spatial syntax integration, while the stairway ensure good vertical space syntax integration for air-flow and connectivity. Adaptive porous louvers and glazing on the hill facing facades: West and South allows natural ventilation and cool hill breeze due to micro-climate effects of cooler hills and hotter residential areas in summer and green-house effect in winter. The front courtyard could serve as heat sink to the building. The *verandas* reminisce traditional space syntax integration of indoor and outdoor functionally for working as well as social space. The use of corrugated metal sheets without insulation on the roof resulted in hot attic-like spaces for the top floor due to high thermal conductivity and high emissivity, but the same thermal principles could afford for a cool space in the evening and nights. As a response to such pragmatic issues: thermal environment in the day and night and social privacy needs, the bedrooms and private lounge are propose at the top floor and the semi-public living-dining-kitchen room in the ground floor for daytime use. The living-dining room in the ground floor affords an appropriate thermal environment for occupants comfort in the daytime with shade, buffer space of the attic-like first floor, and porosity of the walls that allows space syntax integration with the outdoors. These passive design techniques are expected to be pertinent to thermal comfort without air-conditioning or with minimal use of fans. Verandas on the mountainside serve as thermal buffer and semi-outdoor spaces to enjoy cool breeze and view sunsets.

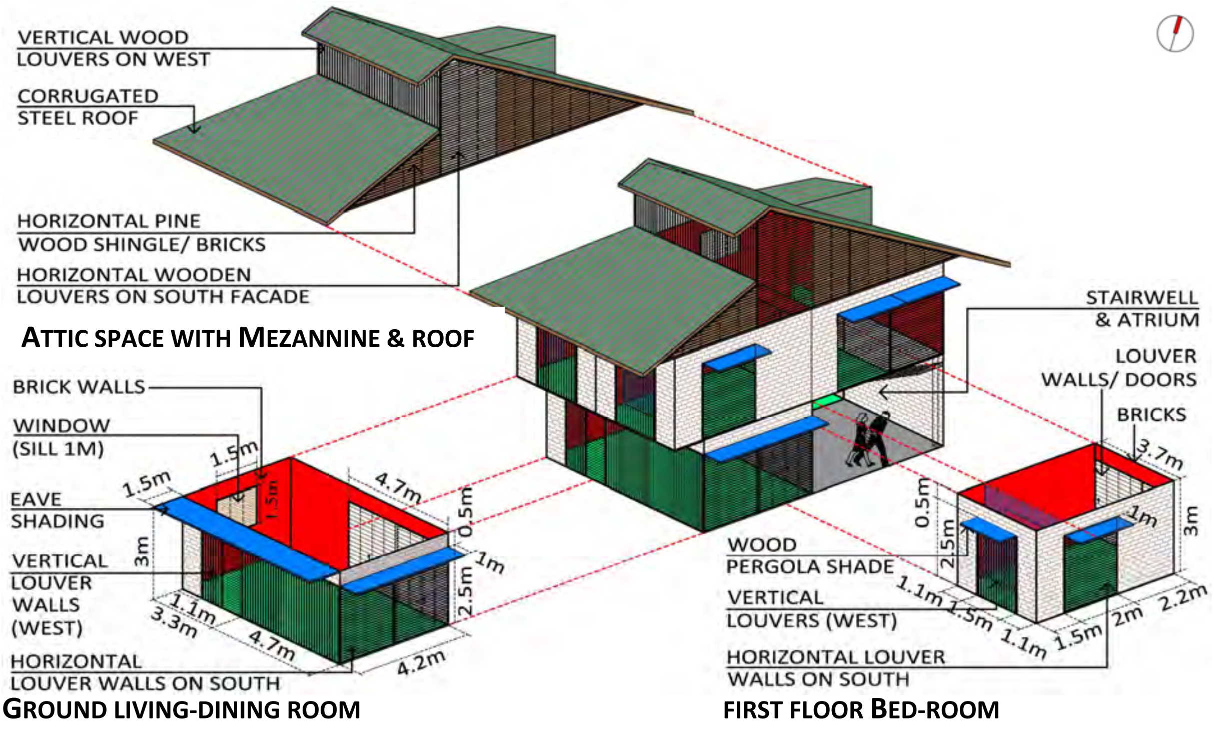

Figure 5: Modern reinterpretation of vernacular indoor-outdoor space syntax integration to account for ventilation in the private (bedroom, attic), semi-private (living-dining) and public spaces (stairs and veranda).

Parametric Simulations for Selection of Optimal Passive Design Techniques

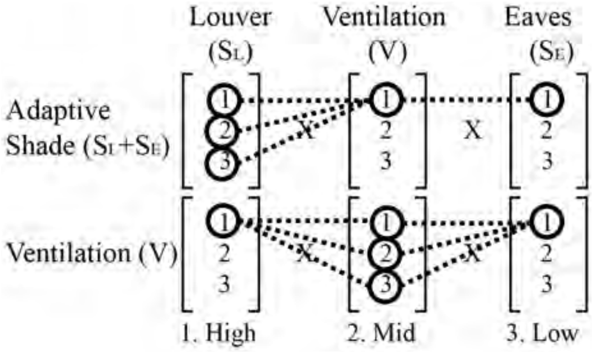

Figure 6a: Simulation combinations for selection of optimal passive design techniques in summer.

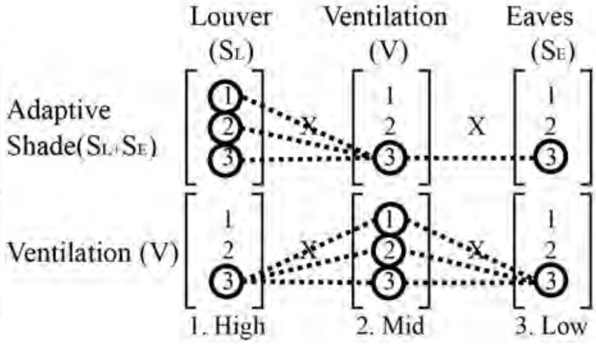

Figure 6b: Simulation combinations for selection of optimal passive design techniques in winter.

Spaces thermal performance is affected by various parameters: ventilation, thermal mass, shading, etc. Figure 5 shows the module analyze, ground living-dining with wood louvers and minimal brick walls, earth contact plinth, and insulating buffer first floor. The lifestyles of the 6 family members and room occupancies, internal heat generations, etc., are simulated in the best representative way for summer and winter. Adaptive shading can be achieved by controlling solar transmittance, sash ratio, with operable louvers (S_L) and awnings or eaves (S_E). For simulation of passive design's optimal combination, the optimal grades were selected and only the parameters of the passive technique analyze is systematically varied. To analyze the effects of shading with louvers (S_L), the other invariant combinations of Ventilation (V) and shading with eaves (S_E) are: 1, high grade in summer and 3, low grade in winter. The same system is applied for shading with eaves (S_E), and ventilation (V). Louver (S_L) grades: 1). 85%, 2). 50%, 3). 15% were systematically varied by changing the window sash ratio. For ventilation, the grades are: 1). V1, All-day-ventilation (30acr, day & night), 2). V2, night-ventilation (30acr night, 0.5acr day) in summer, and day-ventilation (0.5acr night, 30acr day) in winter, 3). V3, air-tightness (0.5acr, day and night). The grades of shading with eaves (S_E) are: 1). High (Adaptive), 2). Mid, 3). Low.

Ground Floor Living-dining

Churachandpur has moderate temperature fluctuation ranges in winter, but low in summer. So, thermal storage and the effect of stabilizing the room temperature fluctuation is not envisaged in summer and low mass module is selected. In winter, solar heat gain through large glazing areas and air-tightness can be beneficial.

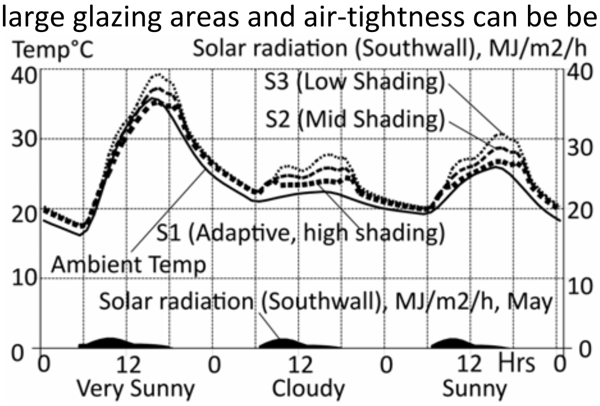

Figure 7a: Temperature fluctuation due to the effects of various shading grades on 3 typical summer days.

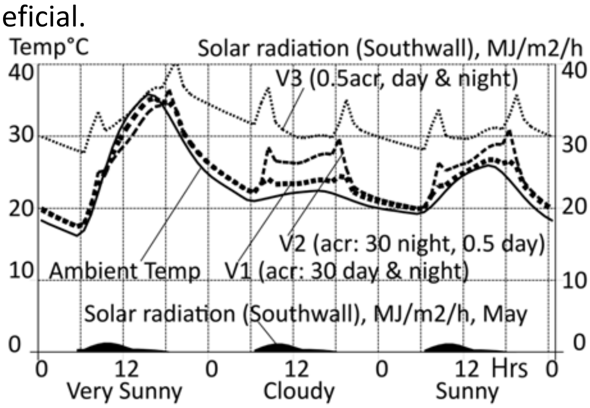

Figure 7b: Temperature fluctuation due to the effects of ventilation modes on 3 typical summer days.

Figure 7a shows the effects of shading (S): eaves (S_E) and louver (S_L) walls on the indoor thermal environment in the ground living-dining room under all-day ventilation with

30ACR, day and night, for May. The effects due to various shading (S) grades: S1). Adaptive (high); S2). Mid; S3). Low shows significant diurnal temperature fluctuation ranges. Since the module is under all-day ventilation with low mass and low thermal conductivity, the effects of materials cool storage are negligible. The outdoor temperature and RH (%) are relatively lower than inside, so the idea is to dissipate indoor heat gain and humidity from equipments, people, and wet areas such as, kitchen, toilets, etc. On peak summer days, when the temperature is above comfort ranges (30°C) adaptive comfort is expected to be possible through natural ventilation, adaptive lifestyles, and fans. Figure 7b shows predictions for the same living-dining room under different ventilation modes: V1, high; V2, mid; and V3, low. The use of high heat generating equipments, in the morning and evening, increases indoor temperature. In spite of the low mass, direct solar heat gain through the large glazing areas resulted in high indoor temperature ranges due to air-tightness for V3. Night-ventilation (V2) and all-day ventilation (V1) shows comfortable indoor temperature ranges except on very sunny peak summer days. Figure 8a shows the effects of shading (S) with eaves (S_E) and louver (S_L) for the ground floor living-dining room under air-tight ventilation with 0.5ACR, day and night, for winter. The effects on the room temperature fluctuations due to the difference of various shading grades: S1, S2, and S3 show significant temperature fluctuations. Even though the module has low thermal mass, air-tightness (0.5ACR) affords comfortable temperature ranges even in the night. S2 and S3 are lower than S1, and the ambient temperature is much lower, since adaptive shading (S1) affords direct heat gain and indoor heat sources also increases temperature. The ambient temperature is cold, so the idea is to reduce heat transfer from indoor to outdoor at night and retain solar heat gain and indoor heat with air-tightness. When the temperature is above comfort ranges, >30°C, natural ventilation can dissipate heat. Figure 8b shows prediction results of the room under different ventilation modes: V1, V2, V3. In spite of low thermal mass, temperature ranges are high for V3 throughout day and night due to air-tightness, solar heat gain from large glazing areas, and indoor heat generation. All-day ventilation shows low temperature ranges in cold nights. Unlike regions with high diurnal winter temperature, day ventilation with high ACR in the daytime and low ACR in the night shows low temperature ranges in the morning due to low ambient temperature ranges.

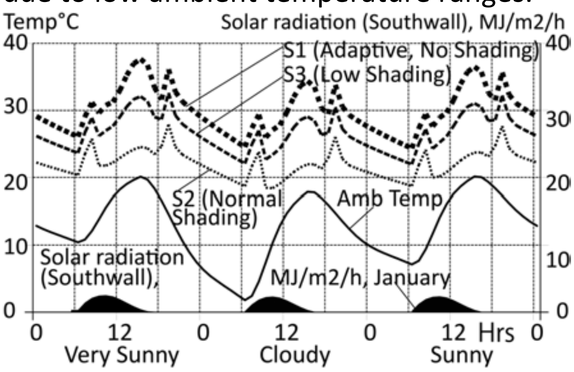

Figure 8a: Temperature fluctuation due to the effects of shading grades on 3 typical winter days.

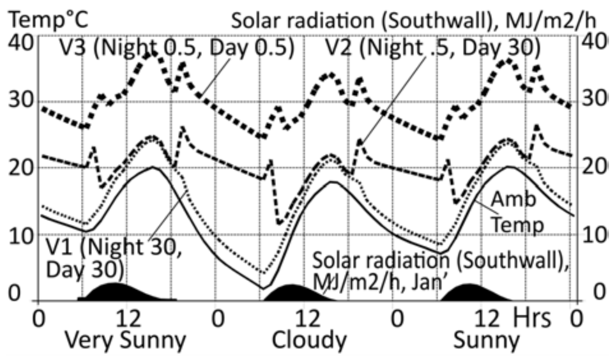

Figure 8b: Temperature fluctuation due to the effects of various ventilation modes on 3 typical winter days.

Indoor Comfort Analysis

Analysis on thermal comfort accounts for the effects of radiation from the envelopes and indoor air temperature by considering operative temperature, OT. Relative humidity was calculated with psychrometric chart and CBE thermal comfort tool was used to calculate PMV for normal as well as adaptive clothing, air-velocity, and activity (Met rate).

Without adaptive comfort, PMV (Predicted Mean Vote) fluctuation under calm air-velocity (0.2m/s) and summer clothing (0.5clo) for 3 typical days of May shows thermal sensation of > +2 (hot) to -3 (vey cold) depending on the time of the day. However, with adaptive comfort through adaptive air-velocity, activity, and clothing, PMV shows thermal sensations of -1 (Slightly Cool) to +1 (Slightly Warm) except on peak hot and sunny days.

Conclusions

Low-energy passive design base on the theory of affordances: complementarity of climate, lifestyle and ingenuity of architecture was attempted through reinterpretation of traditional design principles', porosity with low mass and low thermal conductivity materials, in modern context for natural ventilation (summer), and adaptive shading and glazing were added for heating and cooling synergy needs. Low thermal conductivity porous envelopes, space syntax integration between indoor and outdoor were essential to natural ventilation needs, and parametric simulations shows appropriate ventilation, adaptive shading and glazing complements the needs of vernacular reinterpretation, economic, and environmental symbiosis. As a passive design principle based on the theory of affordance: complementarity of lifestyle and climate, adaptive clothing, activities and air-velocity shows PMV's range of -1 to +1, comfortable, except on peak summer days with explicit links to low-energy possibilities. The porosity proposal is expected to serve as cue to reduce energy consumptions, proactive lifestyles, user-initiated incremental adaptations towards comfort, freshness and enhance quality of life. The paper, through the analysis of design tools: passive climate charts and parametric simulations, validates the applicability of local affordances: complementarity of climate and lifestyles, vernacular reinterpretations and shows novel principles towards designing to thrive in a rapidly changing built environment in cool-humid Manipur.

Abstract: In humid tropical climates, the passive behaviour of residents contributes to the reduction in energy consumption in the same way as passive designs contribute to energy saving. We measured the thermal environment in Surabaya, Indonesia, and conducted interviews with its residents to determine which rooms and terraces they freely select as their ideal environment. The results showed that the residents change locations on the basis of what they think are comfortable environments in the house at different times of the day; for example, they stay on the 1st-floor northern terrace in the morning and the 2nd-floor southern terrace in the evening. On the 1st-floor northern terrace, the temperature does not increase in the morning because of the shade and large thermal mass of its concrete floors and increases at noon because of the reflection of solar radiation. In the evening, the temperature of the 2nd-floor southern terrace drops more quickly and below that of the 1st-floor northern terrace because of higher winds. Thus, the thermal environments in selected locations in the house are more comfortable than in other locations. Choosing a comfortable location in the house reduces residents' use of air conditioning and contributes to energy saving.

Keywords: Selection of ideal environment, resident's behaviour, field survey, hot and humid climate

Introduction

In Indonesia, population increase along with the recent economic growth has led to the expansion of cramped houses, which lead to no spaces between buildings or houses or in houses, in urban areas. The semi-open spaces that Indonesians used as common spaces are decreasing in these houses, which tend to be cramped and closed to the outside (Alfata et al., 2015). These houses are easily affected by outdoor conditions, and residents of such houses control the indoor thermal environment using air conditioners. Nowadays, household energy consumption is rapidly increasing in Indonesia (BPS, 2014), along with the increasing use of air conditioners to achieve comfortable thermal conditions.

According to the results of the field surveys conducted on the thermal environment in houses with air conditioners, people prefer using air conditioners for longer hours at lower temperature settings especially while sleeping (Ekasiwi et al., 2014; Uno et al., 2003a). Furthermore, houses with a very low thermal performance are not effective for air conditioning (Uno et al., 2012). The way in which the air conditioner is used can cause serious problems for both energy consumption and resident's health.

Passive design, which is an architectural design to realize low energy without air conditioners, contributes further to these problems. However, in cramped houses in crowded cities, these passive designs tend to be ignored for economic efficiency. It is actually vital to consider passive designs appropriate for the local climate. Additionally, residents' behaviour in moving around the house to choose the ideal thermal locations is also important (Gusti & Ekasiwi, 2006). Using field surveys on and measurements of thermal environments, this study evaluated this behaviour of residents from the viewpoint of their thermal preferences.

Survey area and measurement season

The surveyed area is in Surabaya (7°S 133°E), which is located in the eastern part of Java Island in Indonesia. It is located in a hot and humid climate, with 2 predominant seasons: dry and wet. There is little precipitation during the dry season from May to October. The annual mean temperature is 28°C, and the monthly average temperatures vary from 27.2°C to 29°C (Figure 1). The average monthly relative humidity is between 65% and 80%.

The measurements and field surveys were conducted between August 31 and September 2, 2016, during the dry and slightly hot season. Figure 2 shows the results of the outdoor temperature, relative humidity and solar radiation measured in the courtyard of the target house. The outdoor temperature rose to 35.5°C. The surrounding wall shades the house from solar radiation before 09:30 and after 15:30. The estimated solar radiation shown in Figure 2 is the integrated value of the direct and diffused solar radiation estimated through Berlage's and Bouguer's equations (Hokoi et al., 2002), respectively, at an atmospheric transmissivity of 0.7 [−].

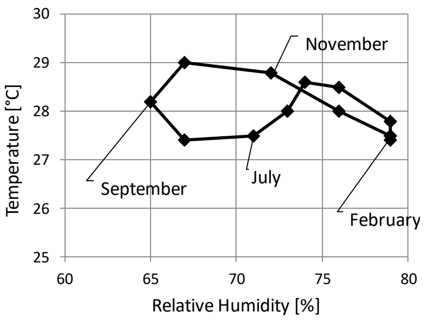

Figure 1. Temperature and relative humidity in Surabaya.

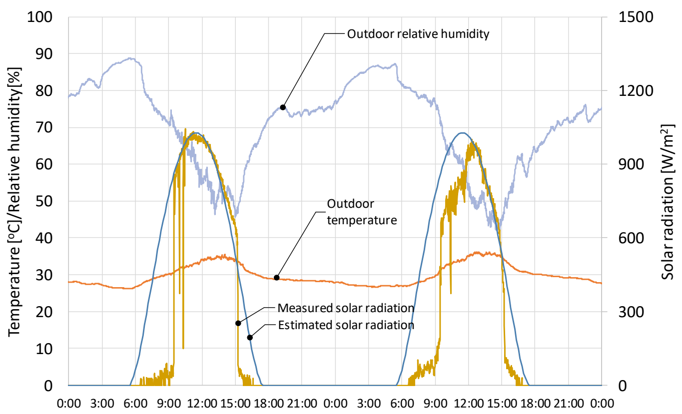

Figure 2. Measured outdoor temperature, outdoor relative humidity, and solar radiation.

Plan of measured house

The target house is located in the urban area of Surabaya City. Two people (80-year old man and 77-year-old woman[Note1]) live in the house; the man works in the university laboratory, and the woman stays in the house all day long. The man designed the basic concept of the house, which was aimed at reducing the number of partition walls to make the space open and easier to accommodate visitors and to integrate the greenery surrounding the house.

The house is detached and shares the eastern, western and northern walls with the neighbours. There are 6 rooms, 2 halls, 3 terraces and a courtyard on the north side of the house (Figure 3). The dining space is open to the south-side garage and to the north-side courtyard. Every room has small openings connecting to the outside (Figure 4a, b). The main structure is reinforced-concrete (RC) with brick walls and the wooden roof with aluminium film and insulations.

Resident's behaviour and thermal sensation in each space

Table 1 shows the schedule of the locations in which the residents stay throughout the day.

The dining/kitchen space (Figure 4c) is used during mealtimes in the morning and in the evening. Because the space is well ventilated and wind flows frequently, the residents feel slightly cool, neutral or slightly warm. On calm days, they sometimes use an electric fan all day. When they feel uncomfortable in the dining/kitchen space, they move to the bedroom on the first floor.

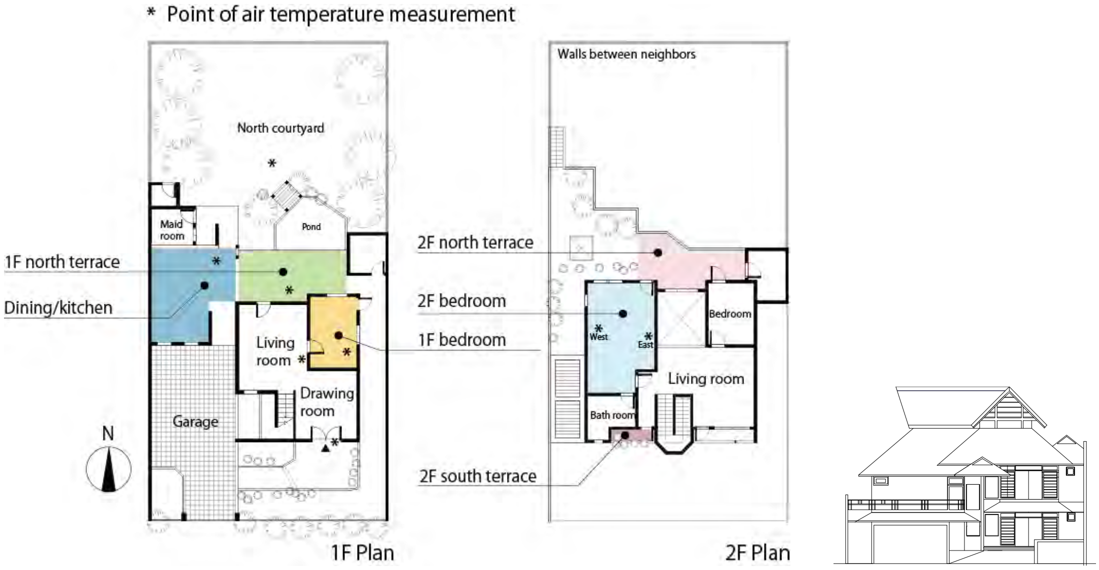

Figure 3. 1st- and 2nd-floor plans (left and middle) and south facade (right) of the house.

Figure 4. Inside of the house (a: 1F northern terrace, b: 2F bedroom, c:1F northern terrace and dining/kitchen, d: 2F southern terrace).

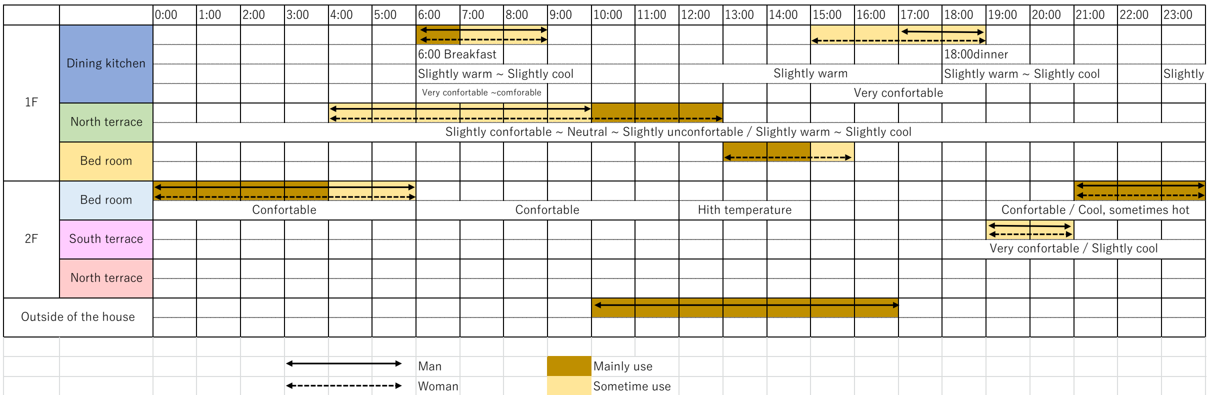
The wife stays on the northern terrace on the first floor as well as in the dining/kitchen space in the morning. Both of them describe the space as slightly comfortable, neutral or slightly uncomfortable.

The southern terrace on the second floor (Figure 4d) is used after dinner for a few hours in the evening instead of the northern terrace on the first floor. Because the southern terrace faces a public road, the wind flows frequently, making the residents feel comfortable. In addition, during this season (in August), not much solar radiation enters the southern terrace on the second floor, so the temperature does not increase.

The wife uses the first-floor bedroom during the daytime when she feels too hot on the northern terrace on the first floor.

The second-floor bedroom is used for sleeping during the night-time. While the doors are closed, the louver windows remain open for ventilation (Figure 4 b). When the residents are home, they always use the ceiling fan. When they feel hot, they use the air conditioner for 1 or 2 hours and switch it off before sleeping. They feel slightly hot in the second-floor bedroom in the evenings because solar radiation enters the room through the west-side windows, even though bamboo shades are installed on the outside of the windows.

Table 1. Locations in the house where the residents stay and their thermal sensations.



Thermal condition in each space

Figure 5 shows the temperature variability in the dining/kitchen, 1st-floor northern terrace, 1st-floor bedroom, 2nd-floor northern and southern terraces and 2nd-floor bedroom over a period of 2 days.

The outdoor temperature rises to 35°C–36°C during the daytime and drops to 26°C–27°C at night. The temperature in the 1st-floor northern terrace, where the residents mainly stay during the daytime, is 4°C lower than that of the outside. The temperature is lowest at 07:00 in all rooms. Because of the large heat capacity of the floor, the surface temperature of the floor stays at 29°C, which is lower than the air temperature in the morning. Although solar radiation reflects on to the courtyard, it does not enter the 1st-floor northern terrace. Therefore, the actual temperature on the 1st-floor northern terrace also does not rise and remains lower than that of the outside air temperature. Therefore, the low radiation temperature caused by the cool floor and walls makes the residents feel comfortable on the terrace.

Between 09:00 and 16:00, the temperature in the 1st-floor bedroom is the lowest in the house (remaining under 31°C) because of the large heat capacity.

The temperature in the 2nd-floor bedroom increases to 32°C–34°C at 15:00 and remains over 30°C even at 21:00. This is a slightly hot and uncomfortable night-time condition. The temperature increase is due to the solar radiation entering through the windows on the west side.

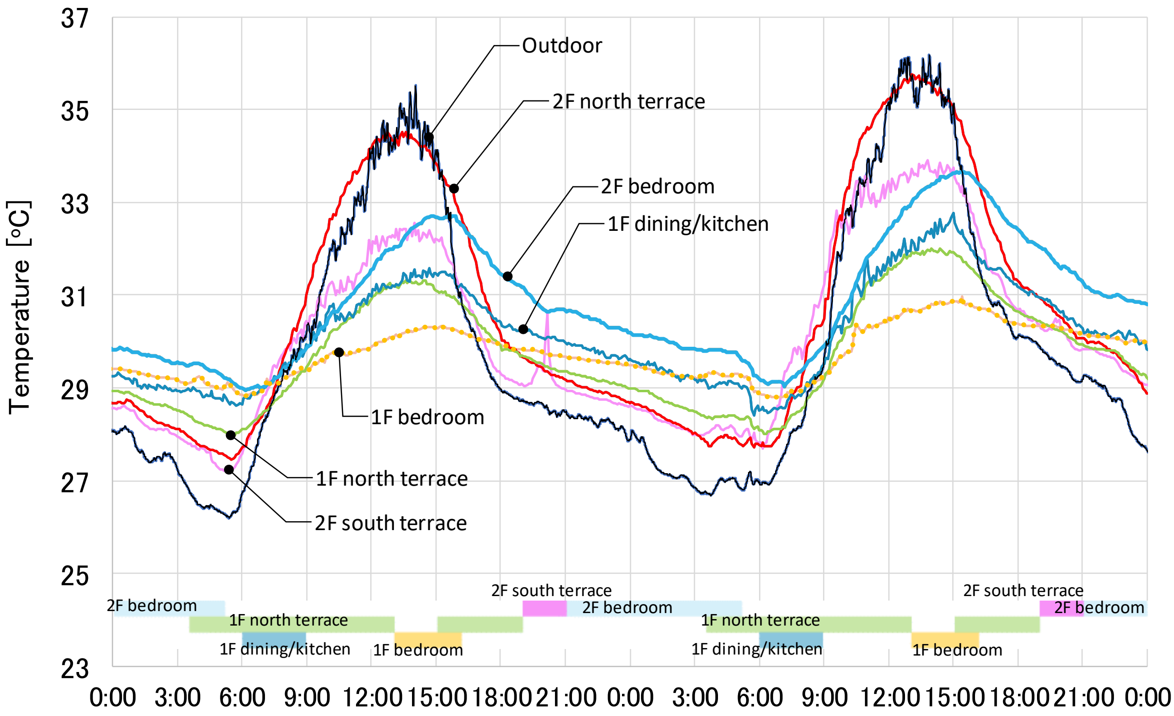


Figure 5. Measured temperature and relative humidity in each room.

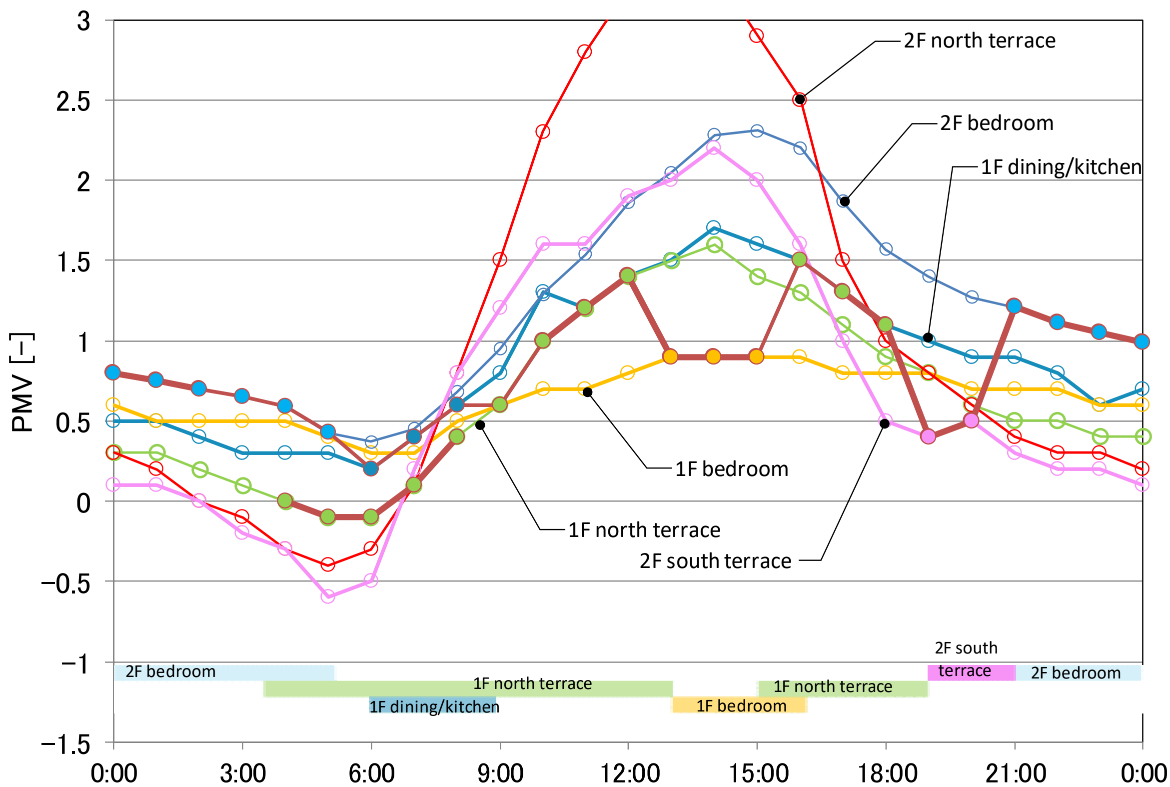

Figure 6. Predictive mean vote (PMV) in each room on August 31.

The temperature on the 2nd-floor southern terrace starts to rise before 06:00 and drops quickly after 15:00. When the residents stay on the terrace, which is mainly in the evenings (21:00), the temperature in this location is 29°C, which is the lowest in the house. Wind flows of around 0.5–3.0 m/s are often present, making the residents comfortable and cool. While the temperature on the 2nd-floor northern terrace decreases during the night, it is still higher or the same as the outdoor temperature in the evening. During this season (between March and October), the sun stays in the north in the daytime. Therefore, the northern terrace reflects direct solar radiation. Between November and February, when the sun stays to the south during the daytime, the condition of the northern terrace becomes better than that of the southern terrace.

The residents choose to stay on the 1st-floor northern terrace in the morning, where the temperature is lowest, and then when they feel hot, they move to the 1st-floor bedroom, where they are able to keep cooler. In the evening before sleeping, they move to the 2nd-floor southern terrace, where the temperature falls quickly and a good flow of wind makes the residents feel comfortable. When they feel hot in the main bedroom, they use the air conditioner for 1 or 2 hours. However, staying in the cooler 2nd-floor southern terrace before sleeping allows for reduction in air-conditioner use.

Thermal comfort of space where residents stay

Figure 6 shows the predictive mean vote (PMV) in the dining/kitchen, 1st-floor northern terrace, 1st-floor bedroom, 2nd-floor northern and southern terraces and 2nd-floor bedroom on August 31, 2016. The PMV is calculated using the measured temperature and relative humidity. The metabolic ratio of the resting condition (1.0met) is assumed as the constant value. The insulation of the clothes, which are T-shirts and short pants, is assumed to be 0.3 clo. The mean radiant temperature (MRT) is assumed to be equal to the room temperature. The normal wind velocity is 0.5m/s because of the natural ventilation flow through the dining/kitchen or the terraces. When no air-flow is present, the residents use either a ceiling fan or a portable fan.

In Figure 6, the PMV in each room is shown in outlined circles, whereas the PMV in the spaces where the residents stay throughout the day are shown as solid colour circles. The values of the PMV in these spaces are in the range between −0.1 and 1.5, which is equivalent to thermal sensations of 'neutral', 'slightly hot' or 'hot'. Even though the condition in the dining/kitchen area is hot, the actual thermal sensation may be lower than that of the estimation, because the average of the measured wind speeds around 14:00 was 1.3 m/s, which is higher than 0.5 m/s used in this estimation. Thus, in the daytime, it can be said that they choose the more comfortable locations from a thermal sensation viewpoint. During the night-time, the PMV in the bedroom on the second floor is almost the same as the condition in the 1st-floor bedroom and slightly higher than that of the other rooms. However, because the residents use the ceiling fan the metabolic ratio is smaller than the estimated value (1.0 met), the actual condition should be better than the estimation.

Assuming the residents stay in the bedroom on the second floor both during the daytime and evening, they should feel hot and will rely on using air conditioners for several hours to avoid being uncomfortable because of high temperature. There is no single space that has an optimal condition throughout the day. However, because there are several locations of different thermal conditions, they can choose the best location each hour. This behaviour can contribute to a reduction in air-conditioner use and, consequently, energy consumption. It is, therefore, highly important to make several spaces with different thermal environments to achieve a sustainable lifestyle.

Conclusion

The behaviour of people in choosing optimal thermal conditions in their house was investigated by conducting interviews with the residents and undertaking field surveys of the thermal environment. It is clear that the residents change location at various hours during the day on the basis of where they think the most comfortable conditions in the house prevail. The locations that the residents choose to be located during different times of the day have comfortable thermal conditions that were better than conditions in other locations.

There is no single space with an optimal condition throughout the day. However, because there are several locations of different thermal conditions, they can choose the best location each hour. This behaviour can contribute to the reduction of air-conditioner use and, consequently, overall energy consumption. It can be concluded that the behaviour to choose optimal spaces and thus reduce air-conditioner use results in a more sustainable lifestyle. It is important to make several spaces in the house with different thermal environments. This behaviour can contribute to energy savings and a better quality of sustainable life.

Note

1. The residents are slightly older. However, the aim of this study was to consider the effect of the people's behaviour in choosing optimal spaces in terms of the thermal environment. The thermal conditions of several spaces in the houses can be compared and evaluated on the basis of their thermal sensations. In terms of future studies, we will survey houses where several generations of the family live.

Acknowledgment

We would like to express our sincere gratitude to Prof. J. Silas, Institute Technology Sepuluh Nopember Surabaya to support our research. This research was supported by a JSPS Grant-in-Aid for Scientific Research (C) (No. 26420582).

Opportunities of Ground Duct Ventilation in Greenhouses

Peter van den Engel[1,2], Guiu Riera Sayol[1] and Willem van der Spoel[1]

[1]Delft University of Technology
[2]Deerns Consulting Engineers The Netherlands

Abstract: Greenhouses in The Netherlands contribute significantly to the total energy consumption of the country. One of the leading Dutch philosophies for greenhouses is "the new growing" which reduce energy and improve health, quality and growing of plants: a greenhouse with an adaptive kind of comfort with a free running climate. Heating is necessary to prevent cold stress of plants or condensation. The relative humidity should be just low enough to prevent heat stress of plants or development of fungus. Ground ducts can reduce heating and cooling of air, reverse stratification, improve circulation and dehumidification. These ducts are heated up during the day by the air from the top of the green house, above the screens. In the thermal buffer of the ground solar heat is accumulated and released in the cold early morning. After measurements in a greenhouse with ground ducts, a calculation-model in Matlab is developed and validated. The diurnal temperature-swing in a ground duct is evaluated with the mathematic model of Hollmüller. Via the Matlab-model the energy savings and the effect of the amount and size of ground ducts can be predicted. The system has proved to create better developed tomatoes with almost no diseases anymore.

Keywords: Greenhouse, ground-duct, stratification, screens, circulation

Introduction

In greenhouses, main issues are reduction of heating energy, increasing the CO_2-level to support the growing of plants and reduction of plant diseases. This is the basis of the development of the idea of the "(almost) closed greenhouse concept". Another challenging concept is "the greenhouse as an energy source", an energy producing, high productive greenhouse. Within the scope of the almost closed greenhouse concept an air-soil heat exchanger can improve indoor climate. With a ground duct-system it is possible to store a surplus of energy in the ground during the day, using it on cold moments, often in the early morning. Another goal is the prevention of cold draught via the screens due to better mixing of hot and cold air in the greenhouse. Other research about ground ducts in greenhouses showed that savings of 1 to 5 m^3 of natural gas per m^2 are possible, depending on the mutual distance of the ducts and type of outdoor climate (Raaphorst, 2012). A circulation control-system with ground-ducts can generally maintain a relative humidity below 90 %. Traditionally, dehumidification is realized via operable windows, since the humidity inside the greenhouse is generally higher than outside. This system has disadvantages, such as unnecessary heat- and CO_2-loss and draught. The duct-system that is evaluated here is applied in a greenhouse in 's-Gravenzande in the Netherlands, sized 160 x 90 x 5 m. The heat is extracted from the top of the greenhouse, above transparent screens, and transported to the ground ducts, which end just above the ground (figure 1 and 2).

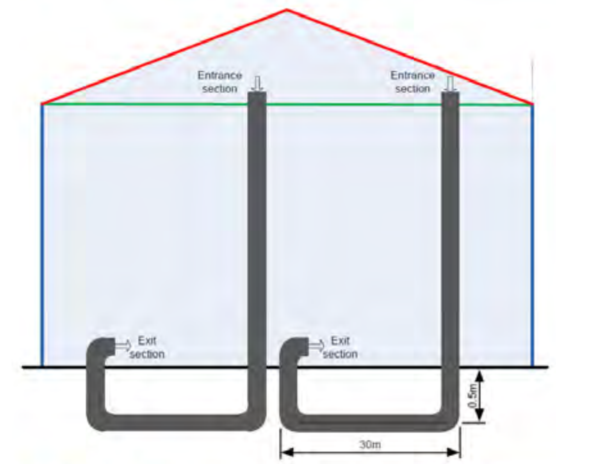

Figure 1: Cross-section of the ventilation principle. The height of the screen is 5 m above the ground.

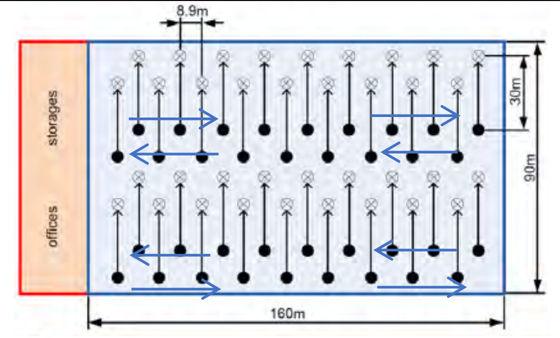

Figure 2: Top view. Black dots: air-intakes. Circles with a cross inside: outlets. Extra fans near the ground improve circulation (horizontal arrows).

The concept is developed by the greenhouse-keeper, Frans van Antwerpen. Each duct is 30 m long, has a diameter of 160 mm and a supply fan. The measured air velocity in the duct is 7.8 m/s. In order to improve the quality of the plants, stagnant air should be prevented and effective air circulation is necessary. As a consequence of the air circulation created by the first prototype of ground ducts, tomatoes until around 10-meters distance of the exhaust were bigger than the rest of tomatoes in the greenhouse. This motivated the idea to install more ground ducts. The current mutual distance of the ducts is circa 9 m. There is still no general consensus yet about how much and what kind of circulation in greenhouses is necessary. The plants near the duct-openings grow better, even with a limited (mechanical) air flow of 565 m^3/h per duct, which is equal to a total ACH of 0.28 for the greenhouse. Small fans just above the ground, perpendicular to the ducts, with a capacity of 100 m^3/h are added and always in use (figure 2). Due to induction the circulation rate is still unknown, but expected to be 1 - 2. Making use of the experience at the Delft University of Technology with greenhouse-simulation (Taal et al, 2013) and ground duct systems (Van der Spoel et al, 2014), it was possible to develop a mathematical and physical model. As background information the philosophy of the “new growing” (Geelen et al, 2015) is relevant as well. The way of using “the new growing” differs per greenhouse-keeper. Plant-growing is very much dependent on the amount of daylight, CO_2-level and the temperature. The more daylight, the higher the metabolism. In order to keep the CO_2-level high, windows should be closed as much as possible. This will increase the temperature. High temperatures in the greenhouse - to a certain maximum - are for many plants not a problem as long as the humidity level remains between the desired boundaries. Via stomata in the leaves CO_2 is absorbed and O_2 is produced via carbon assimilation ($6CO_2 + 6H_2O$ + light = $O_2 + C_6H_{12}O_6$). A high metabolism is only possible with a high percentage of leaf stomata. This makes a plant sensitive for drying out. This can be prevented by a high humidity level. This explains why for many plants a high temperature and a high humidity level are perfect boundary conditions for a sound and fast development. On top of that, plants have a high cooling capacity due to evaporation, as long as there is enough water supply, which can be more than 400 W/m^2 (10 l/m^2 evaporation per day). Due to evaporation the temperature in the greenhouse can remain 4 ^oC below the outside temperature. This explains why it does not become very hot in a rainforest and why in greenhouses with tomato’s non-transparent sunscreens are generally not used, even on very hot days. The cooling effect of an air duct is circa 23 W per m duct and negligible with the cooling effect of plants. Prevention of overheating by operable windows in combination with evaporative cooling is usually enough. Another important requirement of greenhouse-climate is that temperature-swings should be gradually. Here is a striking relation between human adaptive comfort and adaptive comfort for plants. Most greenhouse workers are - to a certain level - also adapted to high temperatures and humidity levels. If necessary, they limit their working hours till 13:00 h on very hot days. The usage of screens (transparent or not) is very much dependent on the type of plants. Pot plants are protected against the sun by screens that reduce solar radiation. For tropical plants that need high internal temperatures and humidity levels often double screens are used. The humidity level remains a critical parameter in all circumstances. The absolute humidity should always be circa 1.9 gram below the maximum, in order prevent heat stress and fungus on plants. Ground ducts are especially effective in autumn when the outside air in the night is cold and humidity level in the greenhouse is high. Increasing the insulation of greenhouses will increase the humidity level, because the condensation on the coldest surfaces will decrease. Consequently, humidity-control, combined with an effective air circulation, becomes more and more important. Other relevant functions of the screens are the reduction of downdraught during cold nights, the improvement of the insulation of the roof of a greenhouse and prevention of lighting hinder to the surroundings (with non-transparent screens). Cold air can flow down via openings between or via the screens depending on their porosity. A ground duct ventilation system reduces this downdraught, by better mixing of cold and warm air.

Methods

The temperature and relative humidity of the discussed greenhouse is measured continuously. In the duct, the velocity and temperature are measured as well. The control-system is installed by Greenspec in addition to the existing climate-control system. To make an evaluation possible data is stored and shared. The greenhouse simulation-model is an extension and adaptation of the recent developed simulation model of de Haagse Hogeschool and the OTB-institute (Taal et al, 2013, Guerra Santin et al, 2015). The OTB-model is validated with the greenhouse program KASPRO from the University of Wageningen. For this research, the model of the OTB-institute is extended with ground duct-ventilation, more detailed control strategies and building physical boundary conditions. Originally, the ducts were modeled with one node and its interaction with the soil was evaluated by Koschens and Lehmann method (Van der Spoel et al, 2005; Koschens et al, 2000). The model from Koschens and Lehmann calculates the output temperatures as a function of the input temperature via resistances in series that simulates the behavior between the air in the ground duct and the soil. For the validation of the model, this method is compared with Hollmüller's method (Holmüller, 2002) which gives exact mathematical results for a harmonic input in the ground duct, where the soil around the duct is considered to be infinite. For longer periods, more than a month, the results of this comparison were pore. Finally, an adaptation of Koschens and Lehmann's method in the Matlab and Simulink-model is used, which gives accurate results for diurnal swings. The model is optimized with the support of W.H. van der Spoel who designed several other ground duct systems (Van der Spoel et al, 2014). The final simulation-model includes the ducts subdivided into 5 different control volumes and the soil refined with 5 thin cylindrical layers around the ducts. The width of the cylindrical layers corresponds to what it is considered to be the thermal affected soil. The rest of the soil is modelled as flat layers along the entire greenhouse area, increasing its width while being deeper in the ground. The model is verified with real data from the greenhouse measured every 61 seconds. The measured outgoing temperature is compared with the calculated one. The optimal size of and velocity in the ducts was evaluated earlier by Mike Olsthoorn of the Haagse Hogeschool (2014) and Paepe et al (2003). The optimal length of the ducts proved to be circa 30 m with a diameter of 160 mm and the air velocity could be reduced to 2 m/s, instead of 7.8 m/s. Even at a velocity of 2 m/s there is still a high exchange efficiency due to turbulence near the wall of the duct. The total pressure difference over a duct-system can be reduced to circa 10 % of the current 275 Pa at 7.8 m/s.

Theory

The simulation is based on a linear matrix system with 50 nodes representing temperatures that have to be calculated every 1200 seconds over 8760 hours (one year). By simulating and determining all these temperatures from array T condensation, relative humidity and energy consumption is calculated, presented as: $A \cdot T = B \cdot Q$. An energy balance for each node is calculated using the relations showed in figure 3 and 4. Each term of the equations is classified either on the left side with a to be calculated temperature or on the right side with known data. The temperatures in each node can be calculated with iteration: $T = A^{-1}BQ$. In order to merge the greenhouse with the ground duct-system, the temperatures have to be calculated at the same time, known as implicit system. Loops have to be avoided and the equations are integrated in the Matrix system. This also reduces avoidable inaccuracies, caused by explicit systems. The model from Koschens and Lehmann uses a combination of 4 different resistances (figure 5). Nevertheless, only R_x has been used and the rest of the resistances has been changed by a refined system of nodes that simulate the change of temperature along the ducts and its air (figure 6). These nodes represent cylindrical soil layers around the duct. Koschens and Lehmann's method provides a resistance calculation that connects the outer temperature of the duct and the core temperature of the soil, found between two ducts, in the same plane. The duct has been divided in 5 sections, with a length of 6 meters each. By this distribution fast changes in temperature can be simulated. Following the movement of the air inside the duct, advection simulates this air flow. Each air node takes as an input the air from the previous air node and its air temperature is taken as an output. Using the geometrical characteristics of the system and the air properties, the convection between the air and the duct surface is calculated. From the duct node to the top of the layers, conduction thermally relates one node with its upper and lower adjacent nodes. The most important assumption is the non-interaction between duct and soil nodes that are at the same level. Therefore, the air interacts with the five duct nodes and from this time on, the mathematical equations only relate vertical positioned nodes (figure 4). This assumption has been evaluated with a mathematical test. The resistance R_x represents the resistance encountered by the heat to flow between the outer surface of the "equivalent duct" and the core temperature of the ground layer in the middle point between ducts. This core temperature is the same as the center of the star-shaped resistance representation, core temperature of soil layer 6, represented in figure 5. Due to its meaning, it depends on the geometrical characteristics of the duct and the thermal conductivity of the soil. After verifying the air-soil heat exchanger

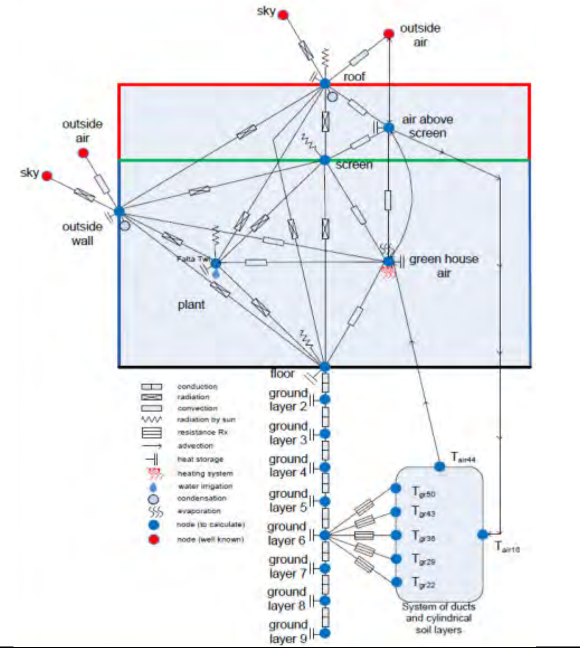

Figure 3: The relation between nodes. The air-soil heat exchanger is shown only by its interaction with the rest of the system.

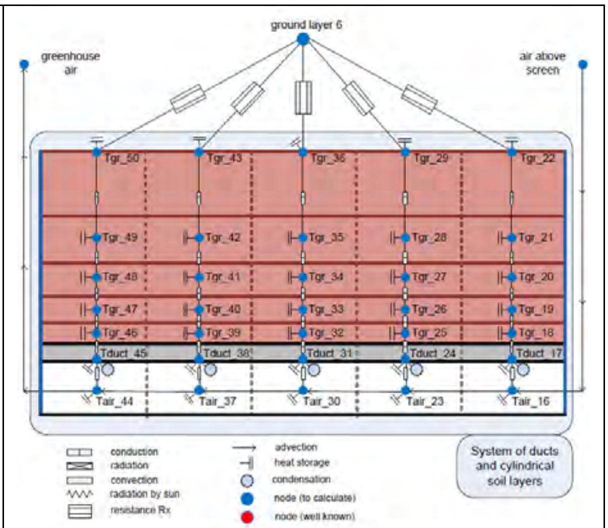

Figure 4: The relation between all the nodes related to the system of air-soil ground ducts.

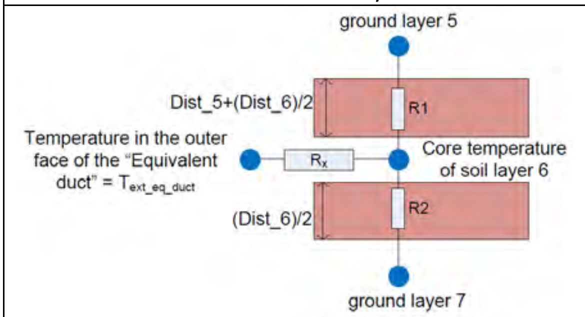

Figure 5: Diagram of Koschens and Lehmann method applied to the greenhouse simulation.

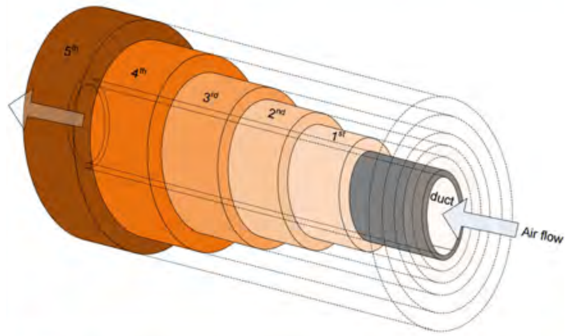

Figure 6: Ground duct mesh where the duct is covered by 5 cylindrical soil layers. It can be seen in color grey the hollowed duct and then the 5 cylindrical soil layers, all with the same soil properties. The size of the cylinder is 0.42 m.

with the mathematical model of Hollmüller, it is compared with real data of a greenhouse equipped with sensors. The ground duct system has been tested with a measured input temperature.

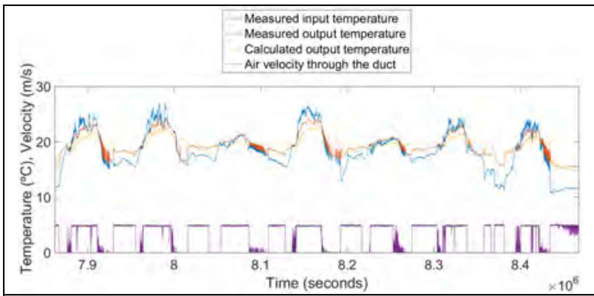

Figure 7: Plot of all the variables in the test during the 13th measured week out of 26.

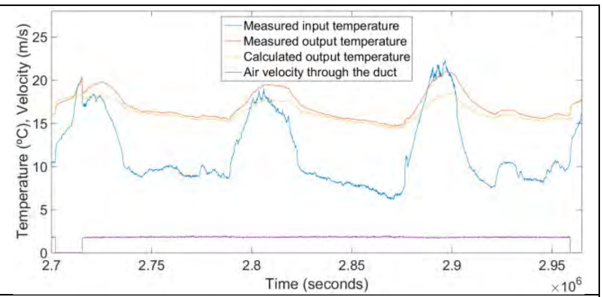

Figure 8: Detail of one of the longest periods where ground ducts are functioning. It corresponds to the period from the 31st until the 34th day.

The calculated output is compared with the measured temperature in the exhaust of the ground duct. Stored-temperature data for 183 days in a row is used which was measured every 61 seconds. Furthermore, the air velocity inside the duct is measured, giving also information about when the system is in use (figure 7 and 8). The model gives some inaccuracies for high inlet temperatures but they can be explained with two different parameters. Firstly, the inaccuracies are greater when the ground ducts are not working. This is not a problem because the calculated different is caused by the temperature of the greenhouse air and not due to the errors caused by the air-soil heat exchanger. Secondly, the greater differences are observed in the peaks of the input, which can be assigned to the heat caused by condensation inside the greenhouse, which is not yet calculated in the test. The effect of condensation can be better seen in figure 8. Finally, the results are also compared with previous research (Olsthoorn, 2014), a single zone model of the ground-duct. The differences of the measured and calculated outlet temperatures are reduced from circa 2,0 to 0,5 ^{o}C.

Results

After validation of the simulation, the greenhouse system was simulated. First, the greenhouse consumption without ground-ducts is taken as a reference. Later, 36 ground ducts are added, being continuously in use as long as the greenhouse has plants. The reference situation leads to a consumption of 840 MJ/m^2. A continuous flow of 7.8 m/s leads to a higher consumption of 842 MJ/m^2, 2 % higher than the reference, so it is obvious that the system should not use the ducts continuously. The program calculates different outputs for every time step. The optimization function chooses the output with the least consumption. In case of both having the same consumption, the lowest temperature which is still above the optimal minimum is chosen so that the excess of energy can be stored in the ground. Optimization 1 is the system-control of the real greenhouse, where ground ducts can either work at a certain velocity (7.8 m/s) or their fans are stopped. In Optimization 2 there is velocity-control of the air through the ducts, leading to a varying convection-coefficient between the air and the duct, with different ratios of exchange of energy. The following velocities are simulated: 0.5, 1, 2, 4 and 8 m/s. Because high air velocities lead to high energy consumption (pressure drop), 8 m/s has been kept as the maximum velocity. The third optimization combines speed-controlled fans with the ground covering, called Optimization 3 (table 1). When plants are cut there is still much energy stored in the ground, either through the ground ducts, transmission or solar radiation that penetrated to deep layers. The temperatures in the end of the year at the start of the new grow-season are higher with ground covering. Results are presented in table 2.

Table 1

Summation of the optimization methods used for the calculations with its characteristics.

Optimization	Velocities [m/s]	Measure
1	0; 7.8;	-
2	0; 0.5; 1; 2; 4; 8;	-
3	0; 0.5; 1; 2; 4; 8;	Ground covering

Table 2

Energy consumption along a year for the three different optimization methods and 36 ground ducts.

Simulation	Consumption [MJ/m^2]	Savings
No ground ducts	829.6	-
Optimization 1	828.4	0.15%
Optimization 2	827.0	0.31%
Optimization 3	822.8	0.82%

Note: Percentages are relative to the greenhouse without ducts.

Limited savings are obtained with 36 ground ducts, which are 8.9 meters apart from each other. Optimization 2 compared with 1 doubles the savings. With ground covering savings are 2.6 times higher than with Optimization 2. However, covered ground is (almost) the current situation. In the final simulations the amount of ground ducts and the optimization method are varied. Table 3 and figure 9 present the results for all the simulations. Van der Spoel (2014) and Raaphorst (2012) already showed that increasing the amount of ducts has economic benefits. The optimum amount of ducts depend on more parameters, like the practical usage of space and daylight. A distance of circa 2 m seems to be the optimum for this greenhouse with energy savings around 0.4 m^3 gas per m^2. In theory 1,131 ducts are possible, with some overlap of the cylinders of figure 6.

Table 3

Energy consumption during a year for the three different optimization methods.

Amount of ducts	Distance between ducts [m]	Optimizing method	Consumption of natural gas [MJ/m^2]	Consumption of natural gas [m^3 gas/m^2]	Savings of gas [m^3 gas/m^2]
0	-	-	829.6	23.6	-
36	8.9	1	828.4	23.5	0.03
		2	827.0	23.5	0.07
		3	822.8	23.4	0.19
100	3.2	1	827.0	23.5	0.07
		2	823.9	23.4	0.16
		3	819.6	23.3	0.29
320	1.0	1	821.2	23.3	0.24
		2	815.9	23.2	0.39
		3	811.4	23.1	0.52
640	0.5	1	812.3	23.1	0.49
		2	806.5	22.9	0.66
		3	801.8	22.8	0.79
1131 (max)	0.42	1	801.1	22.8	0.81
		2	794.7	22.6	0.99
		3	789.9	22.4	1.13

Note: In order to convert the consumption measured in MJ into m^3 of gas, 35.2 MJ/m^3 gas has been assumed.

Ground ducts are used differently in the seasons. Its overall usage is 21% of the time. In spring ground ducts are mostly used in the night and early morning. In summer most usage is during the hottest hours of the day by cooling the greenhouse. In an autumn ground ducts are mostly used from the early morning to the mid-afternoon. In the coldest week of the year ground ducts are mostly used in the afternoon.

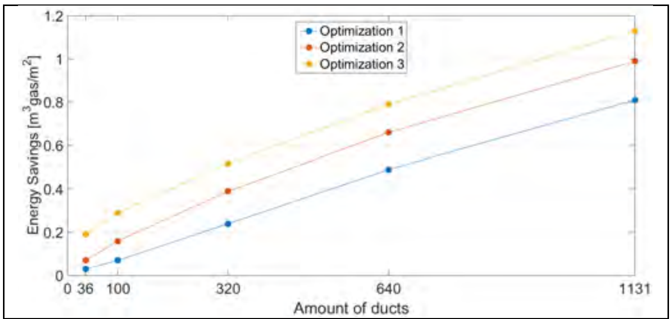

Figure 9: Energy savings that can be found for different amount of ground ducts using *Optimization 3*.

Discussion and conclusion

The Matlab-model makes a conservative estimation of the energy savings by ground-duct ventilation in greenhouses. The amount of savings is rather small (circa 0.2 – 1.2 m^3 gas per m^2), but more than enough (2.880 – 17.280 m^3 gas) to compensate for the electricity energy for the duct-fans, which is estimated as 4.000 kWh for the current situation without fan-optimization. The energy savings by condensation in the ducts and less heat-losses by the active heating system is not yet taken into account. A single fan, supported by the fan-characteristic, can also supply 4 ducts with almost the same effectiveness. Due to this effect, with around 160 ducts, the electricity consumption will hardly rise. The most positive effect is less-stratification and downdraught, effective air circulation, fewer usage of windows and better dehumidification leading to a better health and growing of plants. This was the main reason to install the current system. In addition to better insulation of roof and walls, usage of the earth remains an interesting option of the future to improve climate in greenhouses and can make additional ductwork and fans above the ground almost superfluous. Other optional improvements are active heating, cooling and dehumidification via the ducts and connection of the duct-system to outside. The condensation-calculation in the model still needs improvement. These optimizations will be studied in the next future.

Renewed Trombe wall passively reduces energy consumption

Yvonne Wattez[1], Tudor Cosmatu[1], Martin Tenpierik[1], Michela Turrin[1], Florian Heinzelmann[2]

[1] TU Delft, Delft, The Netherlands [2] SHAU Architecture and Urbanism, Bandung, Indonesia

Abstract: In order to reduce the energy demand of households, a new type of Trombe wall is being designed during a 'research through design project' called 'Double Face 2.0'. A Trombe wall is a passive system that reduces the energy demand of a building. In winter, it captures the heat from the sun during the day and releases this heat into the building at night. In summer, it captures the heat from internal sources during the day and releases that heat at night towards outdoors. First simulations showed that our prototype of a lightweight, translucent, adjustable Trombe wall reduces the energy demand for heating of a typical Dutch household by 25-30%. Instead of stone-like materials, the new type of Trombe wall will consist of translucent materials: phase change material (pcm) and insulating aerogel. The insulation gives the opportunity to direct the thermal mass of the pcm. In this way, the system is adjustable for cooling and heating purposes. A selection of the design concepts is described in this paper, explaining the design choices and method of validation. Depending on the level of detail, different simulation software has been used. This paper describes the comparison and the experiences of using it.

Keywords: Trombe wall, passive, heating, cooling, pcm

Introduction

Although there has been a lot of progress towards energy efficiency of households since 2000 (Gerdes, 2015), we still need to strongly reduce the energy demand of buildings in order to reach the European 20-20-20 targets (European Union, 2017). In the Netherlands, the majority of the energy consumed in households is used for heating. Nevertheless, the share of energy demand for cooling to prevent overheating increases.

During the two 'research through design' projects 'Double Face 1.0 and 2.0', a new type of Trombe wall is being designed in order to reduce the energy demand for both heating in winter and cooling in summer. A traditional Trombe wall is a passive system consisting of a massive stone-like wall placed behind a glazed façade. In between the glass and the wall a thin layer of air exists (Saadatian et al, 2012). Furthermore, it is common practice to install controllable vents at the top and bottom of the wall enabling air exchange between the inhabited space behind the wall and the thin layer of air whenever required. In winter, the Trombe wall captures the heat from the sun during the day and releases this heat slowly into the building in the evening and at night. Whereas the traditional Trombe wall was designed to be only used in winter, with adjustments it could also be used in summer. In summer, it then captures the heat from internal sources during the day and releases that heat at night towards outdoors by a combination of ventilation cooling and nocturnal radiation towards a clear sky. A new development in modern variations of the

Trombe wall is the inclusion of phase change materials in order to decrease the weight of the wall (Saadatian et al, 2012; Castellon et al, 2009; Fiorito, 2012; Kienzl, 1995; Manz et al, 1997; Weinläder et al, 2005). All of these Trombe walls, however, are fixed in place and can hardly be adjusted to the dynamics of the environmental conditions.

The Trombe wall presented in this paper consists of translucent materials: phase change material (pcm) and insulating aerogel. The insulating layer gives the opportunity to direct the thermal mass of the pcm towards either the room or the window. Furthermore, the system’s configuration can be adjusted so that it can be used for both cooling and heating purposes. This novel Trombe wall can be used in existing and new buildings.

This paper presents two of the design concepts, explaining the design choices and the methods of validation. Depending on the level of detail, different simulation software has been used.

Double Face 1.0

During the project ‘Double Face 1.0’, a first adjustable, translucent Trombe wall has been developed (Figure 1). Instead of concrete, the elements are filled with 4 cm pcm type RT25E2. This pcm has a transition temperature for melting and freezing around 25^{o}C and a latent heat storage capacity of 180 kJ/kg (Rubitherm, 2015). According to a numerical study by Bourdeau, a 15 cm concrete wall can be replaced by a 3.5 cm wall of phase change material and perform similarly (Bourdeau, 1980). By using pcm, a more lightweight system was developed with a thermal storage capacity similar to a traditional Trombe wall. Apart from the pcm, the Double Face Trombe wall consists of 1 cm of translucent Lumira aerogel insulation with a thermal conductivity of 0.018 W/(m·K) (Cabot, 2017). Both the pcm and aerogel are encased in transparent containers with a shape as can be seen from figure 1 (right). All together these modules form a 3D undulated Cairo pentagonal tiling pattern.

Figure 1. Artist impression and photo of the first adjustable translucent Trombe wall prototype.

Besides the use of new materials, the adjustability of the system plays an important role. If the pcm is facing the window during a winter day, it stores the energy of the sun. After rotation at night, the pcm faces the inhabited room in order to release the heat into the room. In summer, the cycle reverses: during the night, the pcm faces the window and releases the heat by night ventilation and nocturnal radiation towards the sky. During the day, the pcm faces the inhabited room and stores heat from internal sources. If the room temperature rises above 22°C, the pcm slowly starts melting. The higher the room temperature, the quicker the melting process, with an optimum at 25°C. During this process the temperature of the pcm stays stable; it only rises again after the pcm has fully molten.

To prevent the Trombe wall from taking away the view to outside, openings were realized in the design. Simulations in Design Builder v3.4 showed that the best trade-off between unobstructed views and heat storage capacity would lead to a ratio of approximatively 10% of openings in the system's overall surface. When increasing the percentage of openings, the heat transfer via convection between the cavity and the room increases which reduces the advantageous time lag of the Trombe wall.

One of the strengths of this new Trombe wall system is the ability to rotate the elements in order to orient the pcm either towards the room or to the window. Because Design Builder is not able to move or rotate elements during a simulation, a Matlab/Simulink model was set-up to simulate a 2D flat Trombe wall that rotates twice per day. The model is a full energy performance model for a small room with a window facing South including solar gains, internal gains, ventilation and infiltration losses, transmission losses through the façades, heat storage in walls, sun-blinds, temperature set-points, schedules, etc. The ceiling and floor were assumed to be adiabatic surfaces. Relevant settings are presented in Table 1.

Table 1. Settings used for the simulations in Matlab/Simulink.

calculated time (one winter)	1 Oct. - 30 Apr.	% of holes in Trombe wall element	10%
orientation Trombe wall	South	thickness of PCM	varies
size of room w*d*h	3.6*5.4*2.7 [m3]	thickness of insulation layer of Trombe wall	0.01 m
window to wall ratio South	80%	PCM: specific heat	2000 J/(kg·K)
window to wall ratio North	40%	PCM: density	1450 kg/m3
U-value of glass	1.65 W/m2·K (double glazing)	PCM: thermal conductivity	0.6 W/(m·K)
Rc-value of opaque walls	3.0 m2·K/W	PCM: latent heat of fusion	1.8·105 J/kg
solar heat gain coefficient - no sunblind	0.6	Insulation material: specific heat	1440 J/(kg·K
occupancy	18.00-8.00 h / 7 days a week	Insulation material: density	75 kg/m3
Internal heat gains	1.8 W/m2 according to NEN 7120 for dwellings	Insulation material: thermal conductivity	0.012 W/(m·K)
Ventilation rate of the room	1.2 when occupied	weather data	Dutch NEN5060 B2 reference weather data
PCM in solid phase	< 23 Celsius	set-point temperature of heating system	20oC
PCM in liquid phase	> 26 Celsius		

The results of the simulations are shown in Figure 2. It gives an overview of the amount of energy needed to heat the room. During one winter period, the energy use of this room without a Trombe wall would be 4.78 GJ. If a Trombe wall of 4 cm concrete is added, the heating demand is reduced to 3.71 GJ. When the concrete is replaced by an insulated and adjustable Trombe wall (rotates 180^o twice per day) of 4 cm pcm and 1 cm aerogel, the required energy drops to 3.18 GJ; a reduction of 33%. The optimal thickness, though, lies at 1-2 cm of pcm with a decrease of 30-32%. With these insights, new design concepts are being developed during the Double Face 2.0 project.

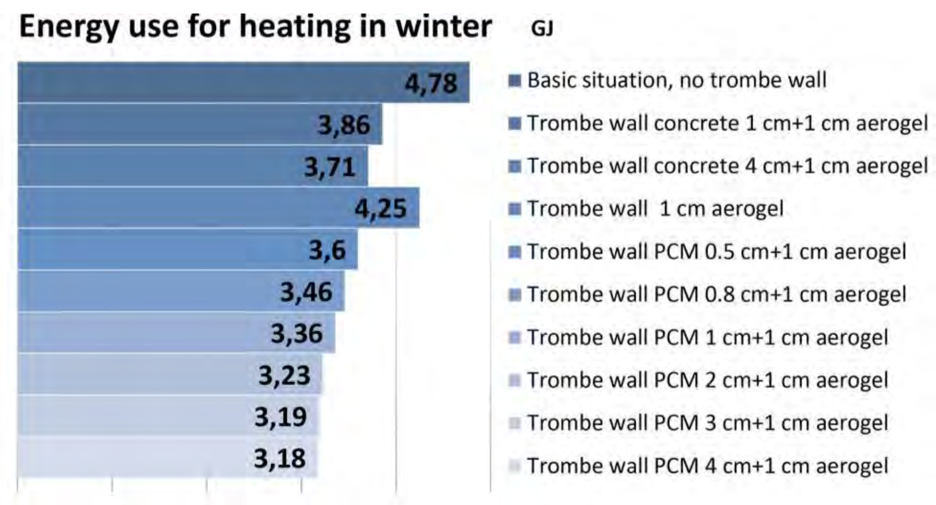

Figure 2. Results regarding the energy use.

Double face 2.0: a selection of developed designs

With the goal of a lightweight, adjustable, translucent Trombe wall, eleven different design concepts have been developed during the 2.0 project so far. Two of these concepts are explained in this paper: the 'Trombe panel' and the 'Jacobs ladder'.

Trombe panel

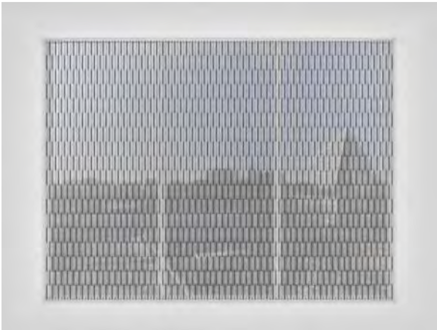
This design integrates thermal, structural and optical properties in one aesthetically designed panel. The panel stands behind a window and needs to be vertically rotated by hand or by an electro-motor, in the morning and afternoon. The design is based on a brain coral pattern which is filled with pcm with a melting temperature of around 25^{o}C. Due to this pattern some parts are filled with pcm and some parts remain open for view. The thickness of the pcm in the panels varies to optimize the translucency for daylight at certain positions. The total volume stays the same as for a flat panel with a thickness of 2 cm pcm.

The yearly energy savings resulting from the use of this Trombe wall are similar to the ones calculated with the Matlab/Simulink script in a previous section (Figure 2).

Figure 3. Design impression of Trombe panel concept

Jacob's ladder

The design concept 'Jacob's ladder' is based on a movement principle. The elements of the Trombe wall need to flip sides twice per day to orient the pcm in the required direction. The movement in this design comes from a toy (figure 5). If the ladder is held at one end, blocks appear to cascade down the strings. This effect is a visual illusion which is the result of one block after another flipping over. An arrangement of interlaced ribbons allows each block to act as if hinged to the next one at either of its two ends. An impression of the design is shown in figure 4 where the black, vertical lines show the strings of the ladder.



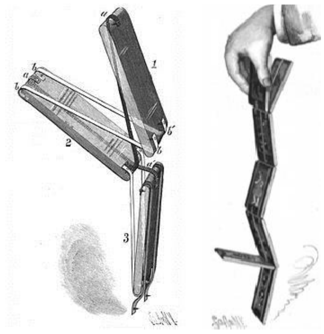


Figure 4 (left). Design impression of Jacobs ladder concept.
Figure 5 (right). Principe of Jacob's ladder movement (Scientific American, 1889).

Double face 2.0: selection of simulation results

Jacob's ladder

More detailed simulations are used to compare different design variations of the 'Jacobs ladder concept'. Therefore, a 2D simulation model in the program COMSOL v.5.2 was made. This program allows to simulate 2D and 3D models over longer time periods; import geometries; simulate with moving elements; simulate with real weather data; and use the same model for more detailed CFD-simulations (Computational Fluid Dynamics).

A simplified version of the Jacob's ladder design is shown in Figure 6, with 2 cm of pcm and 1 cm of aerogel, the properties of which are shown in Table 1. The floor, ceiling and walls are made of concrete and contain an adiabatic boundary along the outside. Heat transfer only takes place through the South façade with the Trombe wall via conduction and radiation from the sun. The opaque walls of this façade have a U-value of 0.34 W/(m^2·K); the double glass has a U-value of 1.65 W/(m^2·K). Moreover, no heating system is active, no sun-shades are used and no people are present inside the room. The panels rotate around their centre at fixed times: at 8:00h and 18:00h. The weather data used is shown in Table 1.

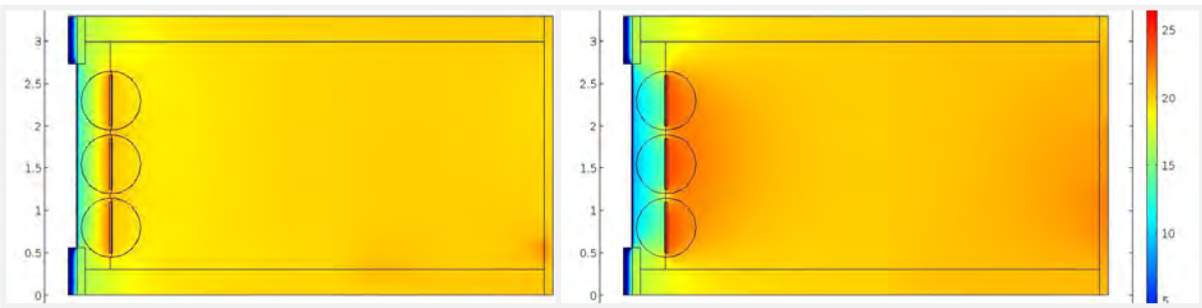

Figure 6. Simulation result of Jacob's ladder design concept; vertical cross-section of a room.
Left: January 9, 12.00h - pcm faces window. Right: January 10, 00.00h; pcm faces room

Figure 6 (left) shows the temperatures on day 9.5 (January 9, 12.00h) so the pcm faces the window and the aerogel faces the room whereas figure 6 (right) shows the temperatures on day 10.0 (January 10, 00.00h) when the position of the pcm and aerogel are reversed. Solar radiation clearly heats up the cavity during the day, visualized by the red colours on the left side of the panels. Some sunlight passes through the openings in between the panels, indicated by the orange dots in the bottom right corner. In the evening, the pcm, which now faces the room, clearly radiates heat into the room. The circles in the model are necessary to simulate a rotating mesh and are not part of the design.

The effect of the use of different materials

In order to understand the effect of material types and thicknesses in the Jacob's ladder concept, different configurations of this basic model were simulated in Comsol (Table 2). Figures 7 and 8 show the simulation results for Jan. 1 till Jan. 21, giving the average room temperature per configuration and the average temperature of the thermal mass component (pcm or concrete). The effect of the solar radiation is clearly visible in both graphs. The pcm heats up quickly in the configurations with 2 cm pcm. The release of the heat takes a long time. A thicker layer of pcm (7 cm) gives a more stable room temperature and a lower temperature of the pcm itself, see the purple line in Figures 7 and 8.

The positive effect of rotating the pcm panels on room temperature is visible in the results of day 0-10 where the red line, the rotating Jacob's ladder, shows a higher and more stable room temperature than both the configurations without a Trombe wall and with non-rotating panels. The rotating pcm Trombe wall is able to maintain a comfortable room temperature in winter for many days after a day of moderate sunshine (2.8 kWh/m^2 of global normal radiation on day 2) without the need for an additional heating system.

The advantage of pcm above concrete is also visible in the graphs. Where the concrete Trombe wall extracts heat from the room during day 10-20, the pcm stabilizes the room temperature and uses the radiation of the sun to heat. If the pcm temperature is always within the transition range on freezing and melting (shown by 'PCM_trans' in Fig. 8), the room temperature is stable. This is for instance the case for a Trombe wall of 2 cm of pcm facing the room and 1 cm of aerogel facing the window (1P_ins_room). The pcm is barely heated up by the direct sunlight because of the insulating layer, so its temperature stays within the transition range. Nevertheless, this configuration does not use the incoming solar radiation for heating the room optimally; for that the pcm needs to face the window.

Table 2. Different configurations simulated in COMSOL.

name	*description*	*material 1*	*material 2*	*rotate*
No_Trombe	no trombe			
Concrete_30	classical 30 cm	concrete 30 cm		no
Concrete_15	classical 15cm	concrete 15 cm		no

Conclusions

This paper describes a novel, adjustable, lightweight, translucent Trombe wall containing pcm and an insulation layer of translucent aerogel. One of the strengths of this wall is its adjustability allowing the pcm to face either the window or the inhabited room. As a result, the system can both be used in winter in heating mode and in summer in cooling mode.

Several design concepts have been developed, two of which were described in this paper. Simulations with a model developed in Matlab/Simulink, that includes the adjustability of the system, have shown that a layer of 2 cm pcm together with an insulation layer of 1 cm aerogel can reduce the heating demand of a room in the climate of the Netherlands by around 30%. More advanced simulations with a 2D model in Comsol have shown that in case of a well-insulated room, this 2 cm of pcm heats up very fast due to the solar radiation. To prevent it from overheating and to optimize the heating capabilities, the design should be equipped with a thicker layer of pcm in winter. However, since the release of the heat takes longer than the absorption of it, the extra pcm might be unwanted during summer where the transition works in reverse.

The simulation results showed the advantages of the rotation of the elements during a sunny winter day. However, on a cloudy winter day, the pcm slightly cools the room. During the next phase of the project, smart rotation algorithms will be investigated in order to optimize the thermal effect of the system. As such, innovative Trombe walls may be an important means of passively reducing the energy demand of buildings.

The climate-responsive design strategies of ancient timber-frame halls in northern China: a field study

Hong Xu[1], Qiong Huang[1], Anxiao Zhang[1], Qi Zhang[1]

[1] School of Architecture, Tianjin University, Tianjin 300072, PR China

Abstract: The risks of global warming and the depletion of fossil fuels call for a re-examination of traditional buildings. Although vernacular dwellings have received considerable attention, few studies investigate other building types. In this paper, the thermal environments of ancient timber-frame halls in northern China were investigated based on field measurements to obtain more evidence of traditional ecological ideology and related strategies. Six typical halls with different orientations, openings, and ceilings but similar spatial scales and materials were selected; their air temperature, relative humidity, air speed, surface temperature, and globe temperature on typical summer and winter days were measured. The results show that the indoor environments are comfortable in summer but too cold in winter. Further analysis shows that the key strategy for comfort in summer is to have high heat capacity to provide shelter from hot air and solar gains; natural ventilation is considered to be merely an auxiliary approach. Climate-responsive design strategies for winter consist of a south-facing orientation with a maximum window-to-wall ratio and significant thermal insulation to utilize solar gains and to provide shelter from cold air.

Keywords: ancient timber-frame hall, cold region, climate responsive design, thermal comfort, field measurement

Introduction

The risks of global warming and the depletion of fossil fuels call for a re-examination of traditional buildings. However, because almost all the traditional buildings involved in the above studies are vernacular dwellings, little attention has been paid to other building types, such as traditional buildings for the purposes of administration, sacrifice, religion, and education. Since vernacular dwellings have more similar functions and design principles with contemporary residential buildings than public buildings, their climate-responsive design strategies have been applied mostly to contemporary residential buildings accordingly.

In China, the electricity consumption per unit area of a large public building is 10 to 20 times that of a residential building due to the energy-intensive solutions. Therefore, it is necessary to revisit public buildings that were designed and constructed in ancient times.

Ancient timber-frame halls are one of the main public building types in ancient China. The primary difference between the halls and vernacular dwellings is size. In addition, they differ in their exterior forms, interior decorations, materials and details according to their official status and function. These differences could lead to differences in their climate-responsive strategies, which could be more applicable to contemporary public buildings.

This study aims to (1) investigate the indoor environments of ancient timber-frame halls and (2) discover the climate-responsive strategies used in them. In this study, the thermal environments of six ancient halls in northern China were measured in summer and winter. Based on the measurement results, the thermal comfort of each building was evaluated using the adaptive model proposed by GB/T 50785-2012, the Chinese standard for evaluating indoor thermal environments. Then, the results were analysed comparatively, and some building design elements were found to have important influences on the indoor thermal environment. Finally, conclusions were drawn to outline the climate-responsive design strategies.

Ancient timber-frame halls in northern China

General data on the geography and climate of northern China

China can be divided into four geographical regions in terms of location, natural conditions and cultural background: the northern region, the southern region, the northwest region and the Qinghai Tibet region (Figure 1a).

Figure 1. Geographic location and climatic data, a. four geographical regions of China, b. five climate zones in China and c. distribution of ancient halls in the climate zones in northern China.

Figure 1b shows the five climatic zones in China: the Severe Cold Zone, the Cold Zone, the Hot Summer and Cold Winter Zone, the Hot Summer and Warm Winter Zone, and the Mild Zone. Most of the ancient timber-frame halls in northern China are located in the Cold Zone (Figure 1c). The Cold Zone typically experiences cold, dry winters and hot, humid summers. In January, the mean minimum temperature varies between -10.4 and -4.0°C, and the mean maximum temperature ranges from 0.7 to 4.2°C. In July, the mean minimum temperature falls within the range of 18.8~23.4°C, and the mean maximum temperature falls within the range of 29.5~31.1°C.

Description of the ancient timber-frame halls

Throughout history, the Chinese have always employed an indigenous system of construction. An ancient timber hall consisted of a platform, a structure with a timber post-and-lintel skeleton and a curved roof (Figure 2). The raised platform served as the base of the structure, and the structure supported the curved roof with overhanging eaves. This construction permits complete freedom for walling and fenestration and, by simply adjusting the proportion between the walls and openings, renders a building practical and comfortable in many climatic conditions while also meeting the other occupant needs.

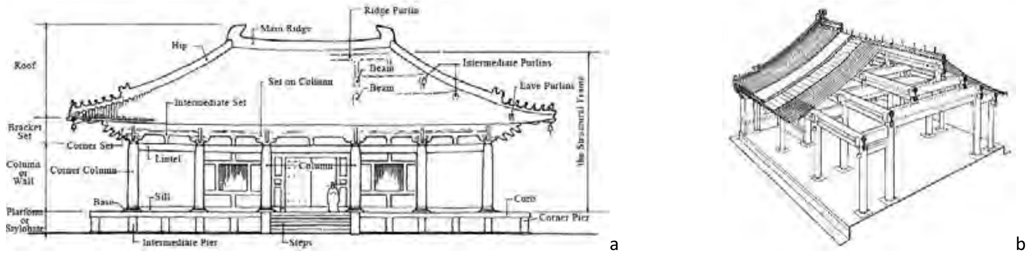

Figure 2. Structural system of an ancient timber-frame hall, a. principal parts and b. isometric view.

Outline of the field measurements

Building descriptions

The six timber-frame halls selected for this study were Xiang Hall of the Imperial Ancestral Temple (Building TM), Guanyin Pavilion of the Dule Temple (Building DLS), Long'en Hall of the Putuo Yu Ding Dongling (Building CX), Long'en Hall of the Puxiang Yu Ding Dongling (Building CA), Daxiongbao Hall of the Huayan Temple (Building HYS) and Daxiongbao Hall of the Shanhua Temple (Building SHS) (Figure 3). These halls were all built in different dynasties and were regarded as typical representatives of ancient halls in their own time. They shared similar external environments but differed in orientation, openings and ceilings, which were assumed to affect the indoor thermal comfort.

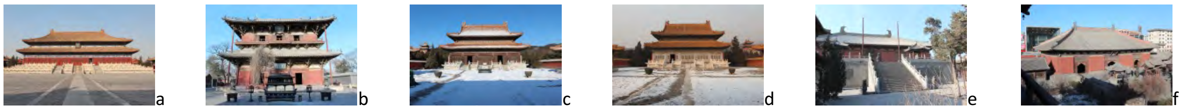

Figure 3. Studied buildings, a. Building TM, b. Building DLS, c. Building CX, d. Building CA, e. Building HYS and f. Building SHS.

To protect these cultural relics, all modern renovations are prohibited, and none of the halls have been fitted with HVAC, lighting, or other systems except Building TM, which has heating and lighting due to certain historical reasons. The use of electric equipment has also been prohibited. This means that their indoor thermal environments are mostly influenced by climatic conditions, building elements and occupants.

Measurement items

The factors that were measured were air temperature, RH, air speed, surface temperature and globe temperature. The measurement points were distributed according to the sizes, layouts and elevations of the studied halls. All of the parameters except the ground surface temperature were measured at a height of 1.7 m to represent individuals in a standing position as recommended by ISO 7726.

Measurement period

Every measurement was conducted on a day that was clear or cloudy with a temperature within the typical range of summer or winter. Because these timber-frame halls are tourist attractions, some regulation authorities restricted the duration of measurement to 24 hours. In addition, these six halls are located in four cities, and only Building CX and CA are located adjacent to each other, so measuring all of them simultaneously is unavailable. To ensure that the halls would be measured under similar weather conditions, the time intervals between the measurements were compressed as much as possible.

Measurement results and thermal comfort evaluation

Measurement results

In summer, the indoor air temperatures of all six buildings fluctuated from 22.52 to 29.46°C, which is a smaller range that falls within the range of the outdoor temperatures, i.e., from 20.31 to 34.88°C. Furthermore, the halls' thermal environments were uniform with very small standard deviations, i.e., from 0.12 to 1.01°C.

The variation tendency of the indoor RH is consistent with that of the outdoor RH, but in most cases, it fluctuates over a smaller range. The temperature and the RH have an inverse relationship in every building. For example, in summer, the outdoor RH of Building

CA varied from 45.8% to 59.0%, and the corresponding indoor RH varied from 56.9% to 65.7%. In winter, when the outdoor RH varied from 41.5% to 47.3%, the corresponding indoor RH varied from 38.8% to 47.9%.

The positions of doors and windows are known to affect the indoor air environment, as shown by the fact that the air speed of all of the buildings except Building DLS is too low to be perceived. Building DLS was measured with its doors open, including the six that face south and the six that face north; therefore, its indoor air speed ranged from 0.01 to 0.31 m/s when the outdoor air speed ranged from 0.13 to 1.70 m/s in summer, and its indoor air speed ranged from 0.03 to 0.45 m/s when the outdoor air speed ranged from 0.16 to 0.73 m/s in winter. Regarding the other buildings, their doors and windows face a single orientation, resulting in stagnant indoor air despite an occasional breeze near the open doors.

The exterior surface temperatures of the walls and doors vary significantly with orientation and fluctuate dramatically when they are affected by sol-air temperatures. However, the interior surface temperatures are relatively stable and consistent. In addition, the variation tendencies of the ground surface temperatures are consistent with those of the wall surface temperatures.

There are small differences between the globe temperatures and the corresponding air temperatures, which implies that there is weak thermal radiation from the interior surfaces.

Thermal comfort evaluation

The thermal performances of the ancient halls were evaluated using GB/T 50785-2012, which is the Chinese standard for evaluating indoor thermal environments. The range of comfortable temperatures (t_{op}) in northern China can be estimated from the running mean of the outdoor temperature (t_{rm}) in °C using the equations shown in Table 1. Category I is for thermal environments that satisfy more than 90% of their users, and Category II is for environments that satisfy 75–90% of their users.

Table 1. Calculation method for the comfort temperature.

Category	Evaluating indicator	Restricted range
I	$t_{op\ I,b} \le t_{op} \le t_{op\ I,a}$ $t_{op\ I,a} = 0.77t_{rm}+12.04$, $t_{op\ I,b} = 0.87\ t_{rm}+2.76$	18 °C $\le t_{op} \le$ 28 °C
II	$t_{op\ II,b} \le t_{op} \le t_{op\ II,a}$ $t_{op\ II,a} = 0.73t_{rm}+15.28$, $t_{op\ II,b} = 0.91t_{rm}-0.48$	18 °C $\le t_{op\ II,a} \le$ 30 °C, 16 °C $\le t_{op\ II,b} \le$ 28 °C, 16 °C $\le t_{op} \le$ 30 °C
III	$t_{op} < t_{op\ II,b}$ or $t_{op\ II,a} < t_{op}$	18 °C $\le t_{op\ II,a} \le$ 30 °C, 16 °C $\le t_{op\ II,b} \le$ 28 °C

The results of the calculations show that, in summer, the indoor environments of Buildings TM, DLS and CX fall within the Category II comfortable range, and those of Buildings CA, HYS and SHS fall within the Category I comfortable range. In winter, the indoor environments of all of the buildings except Building TM fall below the comfortable range.

Analysis of climate-responsive design strategies

Climate-responsive design strategies in summer

According to the thermal comfort evaluation, the indoor environments of all ancient timber-frame halls meet the basic requirements for thermal comfort in summer, which indicates that their climate-responsive design strategies are mostly effective for relieving heat.

The indoor air temperatures, RHs, and interior surface temperatures of all six buildings fluctuate over much smaller ranges than the corresponding outdoor parameters, which indicates that the building envelopes of ancient halls have high heat capacities. In addition, thermal interactions between the outdoor and indoor environments can be identified using the calculated correlation coefficient. In summer, the mean correlation coefficient of the six buildings is 0.81 (Figure 4a), which suggests that these buildings interact with their environment and that their building envelopes function as permeable boundaries.

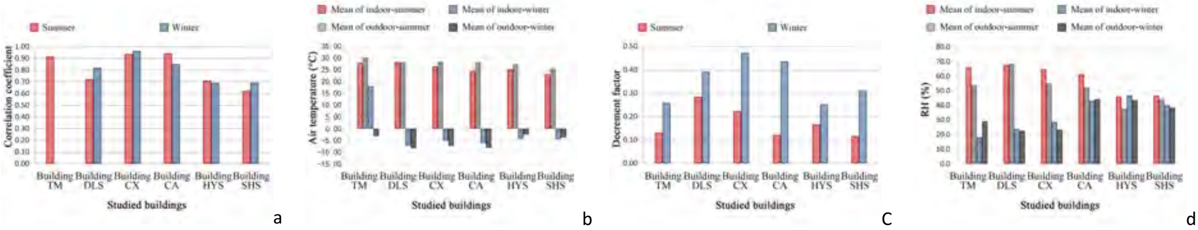

Figure 4. Further analysis of the measurement results, a. the correlation coefficients of the studied buildings, b. the mean air temperatures of the studied buildings, c. the decrement factors of the studied buildings, and d. the mean RHs of the studied buildings.

However, these buildings have some differences in thermal performance that can be detected through the comparative analysis of the measurement results. First, it is clear from Figure 8b that the mean indoor temperature of Building DLS is close to the mean outdoor temperature, while the mean indoor temperatures of the other buildings fall below the mean outdoor temperature. The primary difference between Building DLS and the other buildings is the position of the openings. In summer, the outdoor temperature is higher than the indoor temperature during the day. Therefore, indoor-outdoor air exchange could increase unnecessary heat gain through ventilation and worsen the indoor thermal environment.

Second, no time lag between the outdoor and indoor temperatures is observed in Building CX and CA; however, the other buildings exhibit time lags ranging from 1 to 3 h. Numerical and laboratory studies have reported that the insulation thickness has a very profound effect on the time lag. As the thickness of the wall increases, the time lag increases; when the wall thickness increases beyond a certain limit, the time lag becomes 24 h, and it seems as though there is no time lag. From these results, it can be concluded that Buildings CX and CA have longer time lags than the others, which could mainly be due to the actual opening ratios of the doors and the windows. As more doors and windows are opened, more thermal exchange occurs between the indoor and outdoor environments, which reduce the insulation performance of the building envelope.

Third, the decrement factors of the six buildings are shown in Figure 4c. Building DLS has the largest decrement factor, followed by Building CX and then Building HYS; the decrement factors of the other buildings are small and close together. Regarding Building DLS, it is obvious that cross-ventilation has an important influence on the decrement factor. The difference between Building CX and the other buildings is the ceiling. Since Building CX and CA are located next to each other and have the same building elements except the ceiling, they were measured simultaneously and their difference in measurement results could indicate the ceiling's influence on indoor thermal environment directly. Compared with Building CX, the air temperature of Building CA is lower and has relatively small fluctuations in summer (Figure 5), which could be attributed to the improved thermal insulation supplied by the ceiling. Building HYS faces east, while the other buildings face south. Obviously, the overhanging eaves of these ancient halls do not keep solar radiation out on summer mornings, reducing the insulation performance of the building envelope and increasing the decrement factor.

Fourth, the mean indoor and outdoor RHs are compared in Figure 4d. Because the indoor temperature is lower than the outdoor temperature during the day, the indoor RH is higher than the outdoor RH. This phenomenon occurs in most of the studied buildings, but Building DLS is an exception. The indoor RH of Building DLS is close to the outdoor RH, which is related to its efficient ventilation. Although the lack of ventilation in the summer can reduce unnecessary heat gain and maintain a good thermal environment, it also results in a high RH, which might threaten structural safety and the users' health.

Finally, there are also differences between the studied buildings in terms of the relationships between the surface temperatures of the inside walls and the floors. In Buildings DLS and HYS, the inside walls have lower surface temperatures than the floors (Figure 6), and in the other buildings, the inside walls have higher surface temperatures than the floors. In summer, the surface temperatures of the outside walls are dramatically affected by the sol-air temperature, and those of the inside walls are affected by the heat conducted through the building envelope. The floor surface temperatures may increase if sunlight and hot air enter the buildings. In Buildings TM, CX, CA and SHS, the surface temperature of the inside walls is higher than that of the floor. This indicates that the sol-air temperature has a stronger influence on the walls than on the floor, meaning that the envelopes of these buildings effectively mitigate solar radiation and increases in the indoor air temperature. The opposite pattern occurs in Buildings DLS and HYS, which could be related to the ventilation of Building DLS and the orientation of Building HYS.

Based on above analysis, except for the building material, the orientation, ceiling, opening direction and actual opening ratio influence the indoor thermal environment in summer. Although these studied buildings have differences in thermal performance, their indoor environments almost satisfy comfort requirements. It can be concluded that the high heat capacity of the building envelope is the key strategy in summer and can reduce the adverse effects caused by other unsuitable factors. Moreover, ventilation is generally considered the main reason that ancient Chinese buildings remain cool in summer, but this has been proven incorrect by this study. Stack ventilation is only an auxiliary approach.

			Figure 5. A comparison of the measurement results of Buildings CX and CA.	Figure 6. Time variation of the surface temperature of Building HYS during a typical summer day.	Figure 7. Stack ventilation in Building DLS	Figure 8. Time variation of the surface temperature of Building HYS during a typical winter day

Climate-responsive design strategies in winter

Thermal comfort evaluation indicates that the indoor environments of all of the ancient halls except Building TM fall below the comfort standard in winter. This means that ancient halls have difficulties maintaining a comfortable temperature without artificial equipment, which could be attributed to the cold winter in northern China.

Although the indoor air temperatures cannot meet the comfort demands, their fluctuation ranges are significantly smaller than those of the outdoor temperature. This could reflect the significant heat insulation of the building envelopes. In addition, in winter, the mean correlation coefficient of all buildings except Building TM is 0.80 (Figure 4a). The halls without HVAC systems are able to influence the climate effects when they interact with their environment. Furthermore, because of differences in some building design elements, these buildings have different thermal performances.

First, there are differences in the relationship between the mean indoor and outdoor temperatures. As shown in Figure 4b, the indoor temperatures of Buildings CX and CA are always higher than the outdoor temperatures; the mean indoor temperatures of Buildings DLS and SHS are close to the mean outdoor temperatures; and the mean indoor temperature of Building HYS is lower than the mean outdoor temperature. This demonstrates that orientation and the window-to-wall ratio play important roles in solar gain. In terms of orientation, Building HYS faces east, and the other buildings face south. Regarding the window-to-wall ratio, Buildings CX and CA have the largest values, and the other buildings have the smallest values. Obviously, an east-facing building receives much less solar gain than a south-facing building. Therefore, Building HYS has the worst indoor environment. In the buildings that face south, larger openings significantly increase the solar transmission and improve the indoor thermal environment. This explains why the indoor environments of Buildings CX and CA are better than those of Buildings DLS and SHS.

Second, time lags of 1 h show in Buildings DLS and HYS, and no time lags are observed for the other buildings. In winter, Building DLS has unnecessary ventilation that removes heat from the solar radiation. Building HYS receives very little solar radiation due to its orientation. Therefore, their indoor environments are mainly affected by the outdoor temperature rather than by direct sunlight, and their time lags are caused by the heat storage of their envelopes. Buildings CX, CA and SHS face south, and the positions of their openings restrict heat convection. Consequently, solar radiation has important effects on their indoor environments. In winter, solar radiation reaches its maximum at noon, and the peak air temperature occurs in the afternoon, which could lead to the lack of a time lag.

Third, as shown in Figure 4c, Building HYS has the smallest decrement factor of all of the buildings, which might serve as additional proof that the building envelope's thermal performance is satisfactory. However, it cannot be concluded that Building HYS has the best thermal performance. This view is contrary to the analysis of the other measurement results. Due to this building's south-facing orientation, the indoor temperature, especially the maximum temperature, of all of the buildings except Building HYS increases in response to solar radiation, which expands the temperature fluctuation range and increases the decrement factor. In Building HYS, the lack of solar gain decreases the fluctuation of the indoor environment.

Finally, there is a difference in the relationship between the interior surface temperature of the walls and that of the floor. In Buildings DLS and HYS, the interior surface temperature of the walls is higher than that of the floor (Figure 8). In contrast, the wall surface temperatures in the other buildings are lower than the floor surface temperatures. This can also be attributed to the position of the openings and the orientation of the buildings. Compared to Buildings DLS and HYS, Buildings CX, CA and SHS receive more solar radiation due to their excellent thermal insulation, increasing the floor surface temperature.

In general, the building material, orientation, opening direction and window-to-wall ratio of ancient halls all influence the indoor environment, and these building elements are equally important for maintaining a comfortable temperature.

Conclusions

The thermal environments of six ancient timber-frame halls in northern China were investigated to identify their climate-responsive design strategies in this paper. The measurement results show that the indoor air temperatures of all six halls fluctuated between 22.52 and 29.46°C in summer and between -8.91 and -2.64°C in winter, meaning that the indoor environments were comfortable in summer but too cold in winter according to GB/T 50785-2012. For ancient halls in northern China, their high heat capacity provides shelter from hot air and solar radiation in summer, which is the key to indoor thermal comfort, and stack ventilation is only an auxiliary approach. In winter, the method for creating a comfortable environment is a south-facing orientation with a maximum window-to-wall ratio and significant thermal insulation to not only utilize solar radiation but also provide shelter from cold air.

Climate-responsive design strategies used in ancient halls, such as a suitable orientation, a high heat capacity, plenty of insulation, a rational layout of openings, and reasonable window-to-wall ratio, are still usable in the design of contemporary public buildings. Compared with ancient halls, contemporary public buildings have much higher internal gains, which means that ventilation is critical for the indoor environments of contemporary public buildings. Contemporary public buildings always have a large depth, making cross–ventilation ineffective. Drawing on lessons from ancient halls shows that taking advantage of elevated space, such as an atrium, organizing the openings, and using mechanical ventilation assistance are effective and sustainable ways of ensuring thermal comfort.

Abstract: Since the high rise gated community appeared in China, the sense of neighbourhood seems to have disappeared from the modern city. Moreover, in the hot and humid climatic region of China, the presence of air-conditioning units, typically hanging from the outer walls of dwellings, has made living conditions on balconies and outdoor communal spaces unbearable due to the heat released. In the quest for an alternative to recover these lost facets, a design research explored a courtyard community as a means of providing spatial cohesion and a better neighbourhood. Fieldwork undertaken to assess how the AC contributes to outdoor overheating revealed the importance of free-running. Analytic work was carried out to simulate the impact of various design solutions aiming at improving environmental performance of a base case. The results show that, in addition to a careful design and ventilation, transitional space with shading device, free-running could be achieved. A design application shows the proposed model to provide better thermal comfort indoors as well as quality of social life for residents than local typical residential buildings. This paper discusses the main findings of this study and the design process which led to the proposed design scheme.

Keywords: courtyard, passive cooling, solar control, adaptive architecture, low-income housing.

Introduction

Courtyard communal living involves a group of people living together and sharing one courtyard, which is a traditional living style in China (Figure 1). These courtyards are like a small community. The central courtyard strings each household together and serves as a place for communication and leisure. This charming, cohesive and vibrant public space creates social contacts and an enjoyable living atmosphere. However, as the high-density community develops, the sense of a neighbourhood seems to disappear (Figure 2).

Research Objectives

This paper presents the design process leading to a design proposal for a new residential development for low-income people in Guangzhou. The design development focused on a courtyard community as a means of providing spatial cohesion and a better neighbourhood (Yang, 2016). A key objective was to create a good quality of social life for residents. Another important objective was to provide low-cost accommodations that can achieve thermal comfort conditions throughout the year and eliminating the need for active cooling.

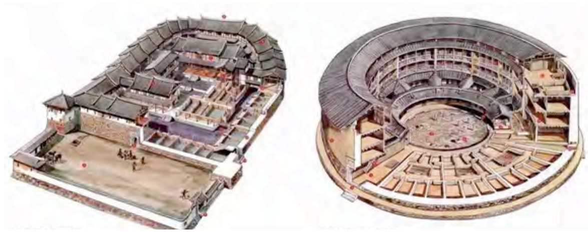

Figure 1. Different typology of courtyard communal living in China (source: Li, 2009)

Figure 2. High-rise development in China (source: gz.58.com)

Climate of Guangzhou

Guangzhou (Canton) is located in South China just south of the Tropic of Cancer, Figure 3. It has a hot summer and a warm winter. The annual average temperature is 23.0 °C with the coldest monthly average temperature of 14.3°C in January and a maximum monthly average temperature of 29.5°C in July. The annual relative humidity (RH) is 68%, with the lowest monthly average RH of 57% in December and highest monthly average RH of 76% in June (Figure 4).

Figure 3. Location of Guangzhou

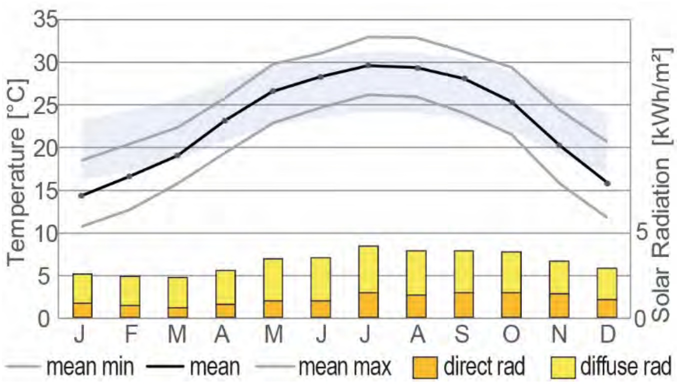

Figure 4. Guangzhou climate (source: Meteonorm 7.0)

Since the weather is cloudy most of the time, the amount of diffuse solar radiation is high, far more than direct solar radiation. Except during October, November and December, the amount of diffuse solar radiation is more than twice the amount of direct solar radiation. Therefore, in addition to controlling direct solar radiation, shading aimed at reducing the diffuse solar gain independently of orientation is also an important design feature.

Field Studies in Tulou Commune

Figure 5. Tulou Commune (source: www.urbanus.com.cn)

The Tulou commune is a courtyard community that aims to be affordable to accommodate low-income migrants in Guangzhou and Foshan (Figure 5). Field studies were undertaken inside this building over a period of four days in August 2016 in order to investigate how a courtyard community performs in an urban environment.

The monitored spaces included one bedroom (without air conditioning), the balcony of a unit located on the third floor and the courtyard (Figure 6). Hourly weather data was obtained from *Weather Wunderground* (2016). Results are shown in Figure 7.

The temperature increase on the balcony is explained by the existence of a split air conditioner outdoor machine, which was used during occupancy hours. This led the balcony to become an intolerable hot and humid place during this period of time. The courtyard temperature follows the trends of outdoor temperature but with a time lag of 1.5-2 hours. During the day the air temperature in the courtyard is lower because the space is shaded by the surrounding buildings. At night, however, the concrete surface and air conditioner units emit heat to the courtyard, increasing the air temperature 2-5K above the outdoor air temperature. Indoors, the air temperature is kept steady at 31-33^{o}C throughout each day. This is possibly due to the combine effect of the thermal mass of the building, the buffering effect of the balcony and courtyard, and the lack of ventilation.

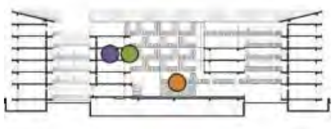

Figure 6. Data logger location

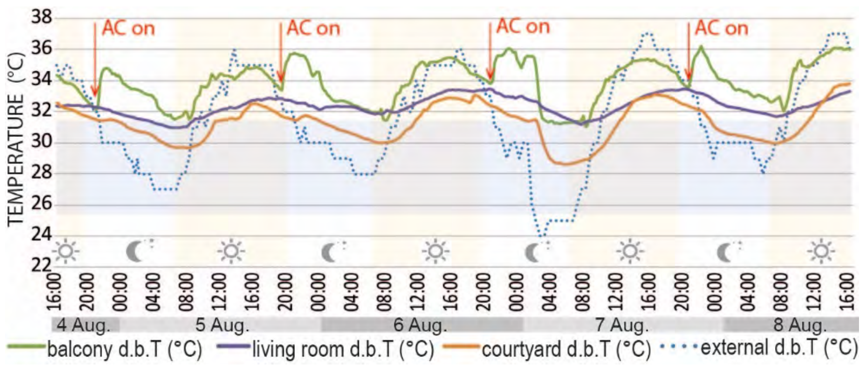

Figure 7. Data logger result

The fieldwork revealed that the discomfort of indoor spaces instigates occupants to install air conditioning units, which releases heat, leading the thermal conditions on balconies and courtyard to become unbearable. Therefore, indoor comfort is the indispensable factor for achieving comfort in an outdoor communal space. Moreover, increasing the air flow inside the courtyard should help removing excessive heat.

Analytic Studies to Improve Environmental Performance

Analytic work was carried out to assess the impact of various design solutions aiming at improving environmental performance of a base case. Parameters studied included solar control and courtyard form.

Solar control

In order to decrease the indoor temperature and achieve a free running apartment, various shading solutions suitable to control both direct and diffuse radiation have been tested with the use of *Ecotect* and *EDSL TAS*. The base case model was defined with a typical living room/kitchen and a 1.2m deep open balcony, Figure 8. Four scenarios, described below, were tested:

Case 1: base case + vertical horizontal shading element
Case 2: base case + horizontal shading element
Case 3: base case + movable vertical panels with horizontal shading element
Case 4: base case + movable horizontal panels with horizontal shading element

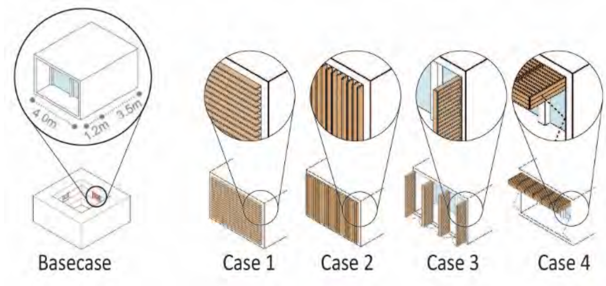

Figure 8. Five cases set up

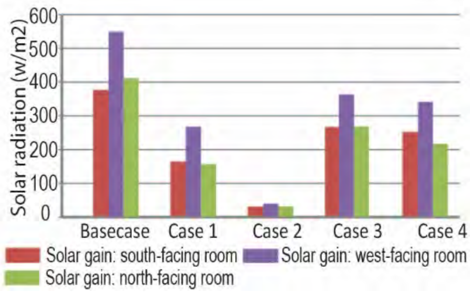

Figure 9. Amount of solar gains (source: Ecotect)

Figure 9 shows the solar gains inside the room for the South, North and West orientations. The scenario described as Case 1 helps blocking about half of the sunlight, while the solution shown in Case 2, the room only captures 30-39 W/m² solar radiation. The study indicates that all the shading panels should feature horizontal shading elements and that the shades should be kept closed during daytime. The solutions shown in Cases 3 and 4 are scenarios for when the occupants need daylighting indoors or to open the shades for more ventilation. The amount of solar gains for both the movable vertical panels (Case 3) and the movable horizontal panels (Case 4) is similar.

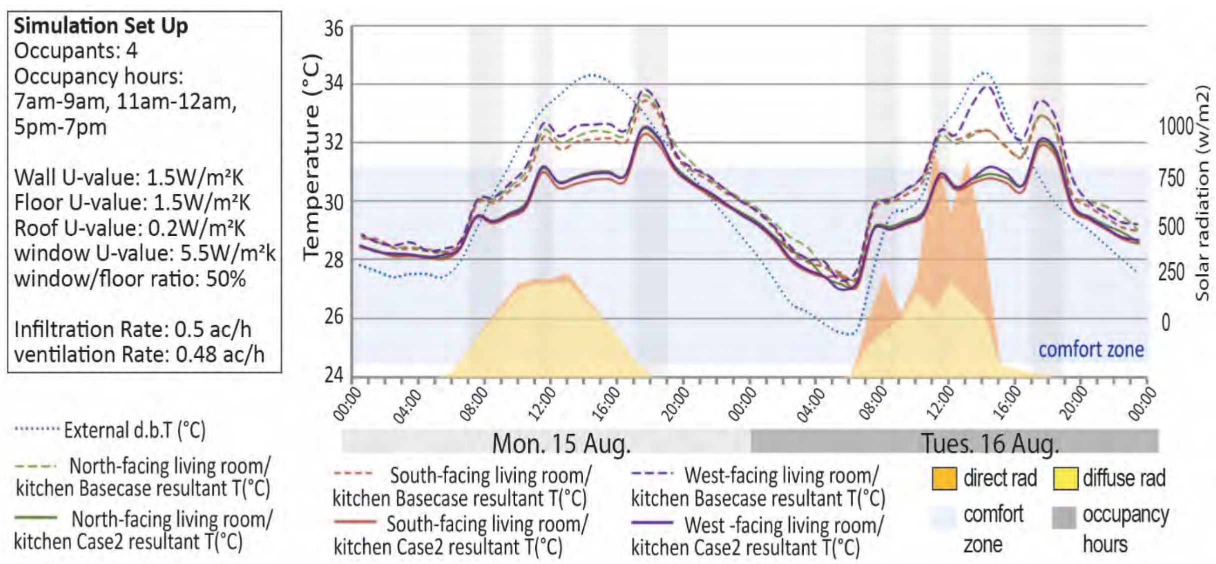

Figure 10. TAS simulation result in summer (source: EDSL TAS)

Figure 10 indicates the resultant temperature inside the room on typical summer days under Case 2. On a cloudy day (the first day), the shade helps reducing the temperature by 1.5K-2K during the daytime, while on a sunny day (the second day) it decreases it 2K on the South and North facing rooms and about 3K on the West-facing room. Except during cooking hours (17:00-19:00 pm), the resultant temperature is consistently in the comfort zone. This shows that the indoor temperatures can be kept within the comfort range if the room is protected by a 1.2m deep balcony overhang and shading panels with horizontal shading elements.

Courtyard Form

As discussed earlier, the courtyard should have openings facing the prevailing wind to let air flow into the courtyard. However, in an urban environment, due to various constraints (e.g. obstruction, regulation), the opening cannot always face the prevailing wind. Therefore, the degree of deviation was analysed, with the help of *WinAir for Ecotect* software, with two kinds of openings, Figures 10 and 11.

Figure 10 shows the effect of different angles between the opening and the wind direction. The air velocity at the central point of the courtyard reaches its highest value when the opening is facing the prevailing wind. The air velocity at the central point of the opening reaches its highest point when the angle is 90^{o}. Figure 11 shows the results when the opening is in the middle. The air velocity at the two points exceeds or is equal than 0.5 m/s only when the orientation angle is less than 45^{o} or equal to 180^{o}. Therefore, in order to enhance air flow penetration inside the courtyard, the angle between the opening and the wind direction should be less than 90^{o}. If the courtyard has the opening in the middle, then the angle between the opening and the wind direction should be less than 45^{o} or equal to 180^{o}.

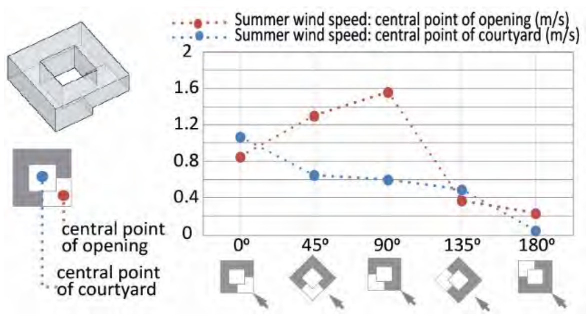

Figure 10. Wind velocity of courtyard centre and opening (opening at corner) (source: WinAir)

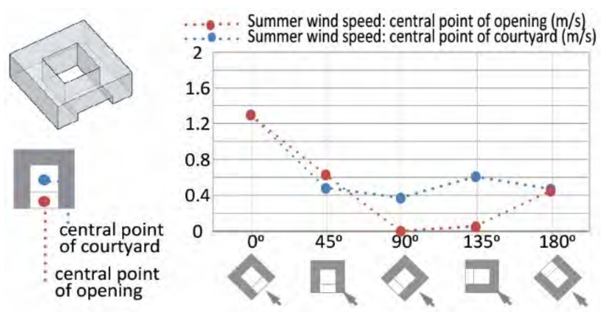

Figure 11. Wind velocity of courtyard centre and opening (opening in the middle) (source: WinAir)

Design Application

Figure 12. The proposed new building scheme

The proposed new buildings were designed for a low-income community located in the city centre of Guangzhou (Figure 12). In China, young Chinese couples tend to live close to their parents to look after one another. Therefore, the unit typology consists of two zones, the lower floor is for elderly couples (grandparents), and the upper floors comprise a duplex for young couples (parents and children). The unit layout is illustrated in Figure 13.

The balconies were designed to protect the space from the strong solar radiation from all orientations. Additional adjustable shading devices were designed for different façades.

Figure 13 illustrates various transitional spaces designed for the targeted people and allowing various activities to take place.

Figure 13. Transitional Space and dimension of a typical unit

Figure 14 exemplifies how cross-ventilation can be achieved. The shading device is made of bamboo and is permeable, to allow wind penetration and heat dissipation. Occupants can adjust the angle of the shading device to control the sunlight and air movement flowing into the room.

Figure 14. Flexible shades and cross ventilation

The residential block is open at the ground level to encourage pedestrians' use of the courtyard as a public space (Figure 15). The orientation and shape of the openings encourage cooling winds. It was estimated that at the North entrance of the courtyard an average wind speed of 2m/s can be achieved; while elsewhere, except at the centre of the courtyard, the wind speed is predicted to be only 1m/s, Figure 16.

Physiologically equivalent temperature (PET) and PMV values were calculated with RayMan software (Matzarakis, 2014) for several scenarios, including summer morning and noon, Figures 17 and 18, respectively.

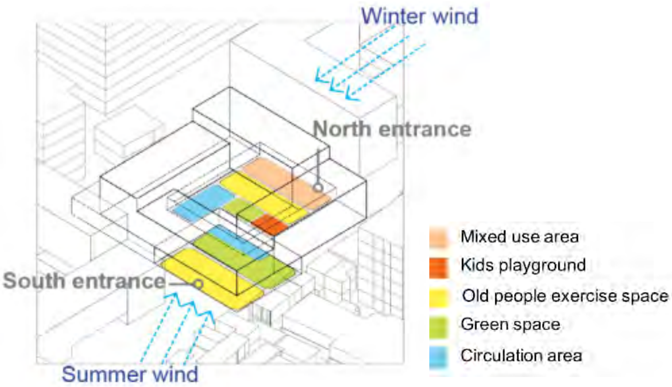

Figure 15. Courtyard design

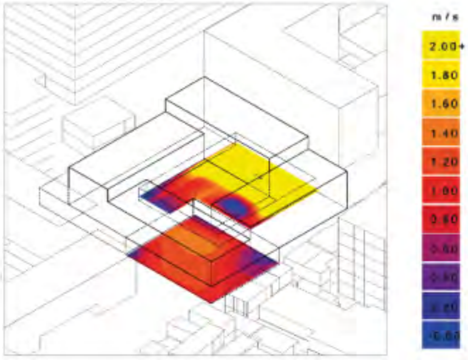

Figure 16. Wind simulation results (source: WinAir for Ecotect)

Figure 17. Typical summer day morning (7am, 22 July) (source: RayMan)

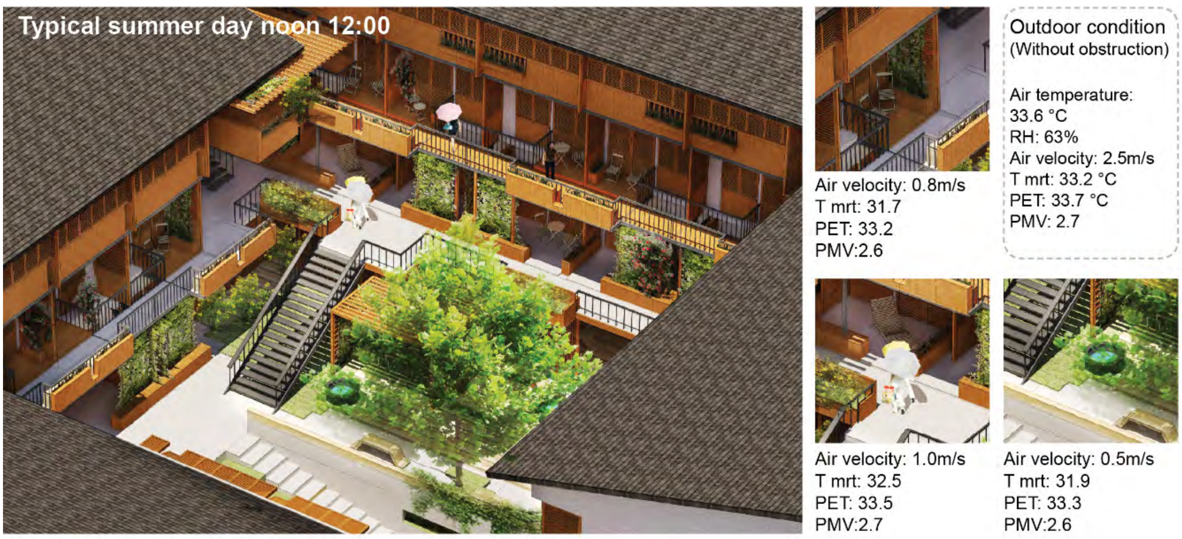

Figure 18. Typical summer day noon (12am, 22 July) (source: RayMan)

During the mild season, people can stay outdoors for almost the entire day, allowing many activities to be performed in the courtyard or in the balcony (terrace). Figure 19 illustrates possible activities and residents' adaptive behaviours (10:00 am, 22 March). The shades can be opened to allow sunlight and ventilation inside the room.

Figure 19. Typical mild season (10am, 22 March)

Conclusion

The study demonstrated that comfort is achievable in a free-running residential courtyard form urban block. The absence of air conditioning units hanging on the balconies further allowed the balcony to be a usable extended semi-outdoor space.

The proposed final design scheme incorporates the environmental strategies studied at the pre-design stage and during the design development. This includes several key decisions. Firstly, the provision of a movable and permeable shading device on the balcony to block both direct and diffuse solar radiation. Its permeability allows air movement through the semi-outdoor spaces and indoors, and its adaptability permits the user to control and adjust it according to the seasonal needs. The careful design of the courtyard form and the location of an opening to allow wind penetration helped creating a better microclimate, thus contributing to improving outdoor and indoor environmental conditions. While serving as an outdoor habitable space, the courtyard also offers residents a cohesive and vibrant place where they can socialise and enjoy community living.

Abstract: The best way to save energy is not to need it. This paper will present the application of an optimization algorithm that assesses the degree of insolation in relation to architectural form. One of the key factors in achieving lower energy consumption in buildings is minimizing the heat gains due to incident solar radiation or insolation. This holds especially true for buildings within the Middle East and regions that share a similar climate with high levels of solar radiation. Upon inputting a project's latitude, allowable development areas and the dates when incident solar radiation on the building should be minimized, the optimization tool will generate and iterate through different building forms with the sole aim of minimizing insolation while satisfying the givens. Preliminary optimization results show that an optimized form could receive about 35% less solar radiation than a conventional building form (a rectangular prism). The development of this tool will enable design teams, during the early design stages, to make informed decisions that aim at having energy efficient buildings. In addition to this optimization, other parameters (such as adjacent buildings, resistance to wind and sloping sites) and window / wall ratios could eventually be integrated.

Keywords: Insolation, building form, optimization, energy efficiency.

Introduction

The growing world economy is coupled with increased energy usage in the domains of industry, buildings, transportation, agriculture, etc… (Sachs, 2015). In 2014, primary energy consumption had grown by 22% relative to the consumption in 2004 (Chen et al, 2017) which had already grown by 49% relative to that of 1984 (Perez-Lombard et al., 2008). In addition, energy-related greenhouse gas emissions account for over 80% of global anthropogenic emissions (Quadrelli et al, 2007). These figures are a cause of concern given that with the projected increase in the world population (United Nations, 2015) and the rapid rate of urbanization (UN-Habitat, 2016), energy consumption and its associated CO_2 emissions will continue to rise (UNEP, 2016). This will result in massive changes in climate (floods, droughts, extreme storms, crop failure, sea level rise, ocean acidification, etc.) (Perez-Lombard et al., 2008). Buildings contribute a substantial portion of the energy consumption worldwide. In fact, 36% of energy consumption is used in buildings, 27% of which goes into residential buildings (Elgendy, 2012). Therefore, optimizing building form to reduce insolation should be the first step in reducing the energy consumption of buildings and designing energy efficient buildings.

Vernacular architecture shows a clear relationship between the sun and buildings whereby the later were protected from the sunrays in summer and benefited from incident solar radiation (will be referred to as insolation throughout this paper) in winter. This concept was addressed by Socrates almost 2500 years ago. Socrates described how the relative movement of the sun could define the shape, form and construction of a building (Davor, 2015). Since then, numerous builders, architects and designers have studied and developed these issues and the results have ranged from different vernacular types (relating instinctively to the sun as per different geographical locations) to allowing for adequate solar access for individual buildings as well as groups of buildings or neighborhoods (Knowles, 1985).

Recently, numerous studies have addressed the reduction of energy consumption in buildings (Evins, 2013). There is research suggesting that the energy use of buildings can be reduced by adopting designs that are sensitive to the thermal performance of the building envelope, the proportion of the window and wall areas, the type of glazing, the efficiency of the mechanical systems, efficient construction systems, potential for renewable systems, etc. Although all of the strategies mentioned above are important, the 3 dimensional shape of a building has a significant impact on the reduction of energy use (Adamski, 2007). Areas that are subjected to high levels of insolation, can benefit significantly from building shapes that receive less insolation because the less the building receives solar radiation, the less it will have to cool the interior spaces.

A primary goal in the design of a building is to achieve thermal comfort for occupants within it. In parallel, the aim of the design should be to minimize energy expenditure to reduce both operation costs and environmental impact. Today, computers allow the design team the possibility and capability to analyze and evaluate the extent of solar access on a three-dimensional form. This can provide the team with useful information at the initial stages of the design process. For that purpose, this study aims to generate building shape based on optimizing insolation in order to assess the performance of the building geometry so that it is less reliant on energy (e.g. for cooling buildings in a hot climate).

Methods

This case study used an optimization algorithm that can take an initial predefined form with a set of constraints and iterate upon various options and geometric parameters, calculating the insolation upon the building for every iteration until the optimal form (minimum insolation) is reached.

Initial Parameters

The algorithm was applied on a hypothetical building at latitude 33.5°N (such as Beirut, Lebanon) where the weather is characterized as having mild winters and sub-tropical summers. The temperature profile for Beirut is shown in Figure 1 (UNDP, 2005).

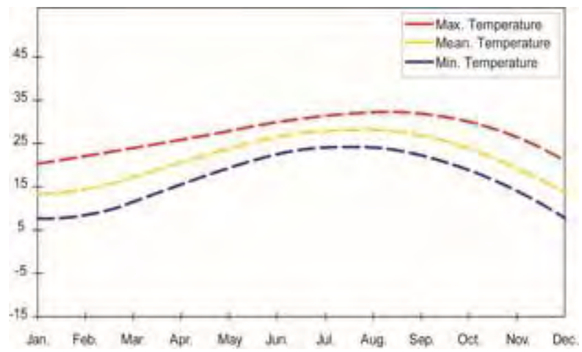

Figure 1: Monthly temperature fluctuations in Beirut

As a first step a two-dimensional rectangular shape was optimized using the algorithm. The date was set at June 21. This was followed by two optimizations for a three-dimensional form with the same built up area having 10 floors but with different roof configurations. In the first example the roof is horizontal (comparable with the initial rectangular solid shape) while in the second the algorithm was run to optimize the roof component also.

Optimization

The optimization algorithm used was developed by the research team (details provided elsewhere). It consisted of a nonlinear program which can be solved using popular solution algorithms including sequential quadratic programming, and more recently interior-point methods (MATLAB, 2017). In summary, this algorithm integrated information relative to the climate at a certain latitude and the building shape. It took into account the position of the sun relative to a shape, the intensity of radiation associated with the solar angle and the date for which the optimization was required.

Validation

A two-dimensional optimization was performed to validate the expected result.

Constraints

The approach governing the optimization process was such that the algorithm was free to manipulate the shape until reaching the desired outcome. Furthermore, in order to relate the study to contextual requirements, a number of constraints were defined namely, minimum usable area, maximum allowable area and maximum building height.

Output

The output provided both a shape that respected the built up area in terms of floor plan area and number of floors as well as the amount of insolation on the shape. This was useful in calculating the percentage reduction of insolation with respect to the initial shape.

Results

Two-dimensional optimization

The first step consists in optimizing a two-dimensional rectangular shape while keeping the total area of the horizontal surfaces constant. After inputting the initial geometry of the shape, the latitude of the location and the requirement of receiving minimal insolation on June 21, the optimization process results in a shape that has its long axis aligned with the East West orientation, as shown in Figure 2.

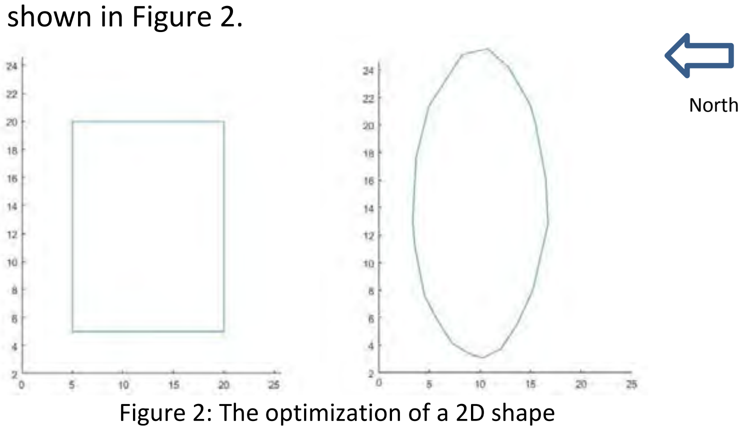

Figure 2: The optimization of a 2D shape

Three-dimensional optimization on June 21

The second step consists in optimizing a building shape that complies with the application of the allowable exploitation rights. This building shape, shown in Figure 3, is conventional in shape because there is no attempt to modify the geometry of the building from an energy efficiency perspective.

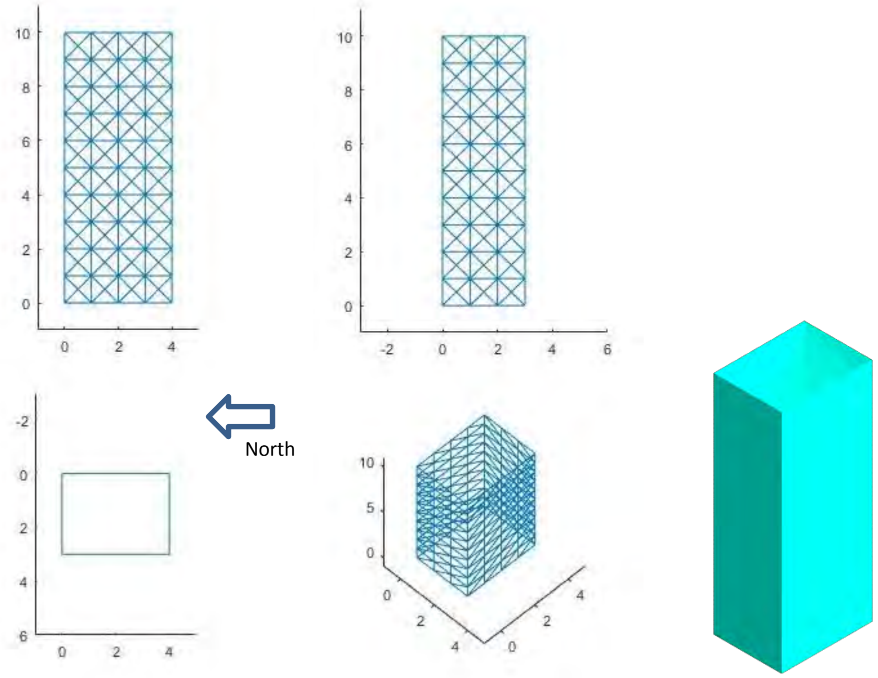

Figure 3: Initial 3 D building shape (complying with exploitation rights)

The total insolation on this building form on June 21 is 802 KW. The rendered shape on the right in figure 3 represents the initial form which is that of a rectangular solid like many of the buildings we see in Beirut city, shown in Figure 4.

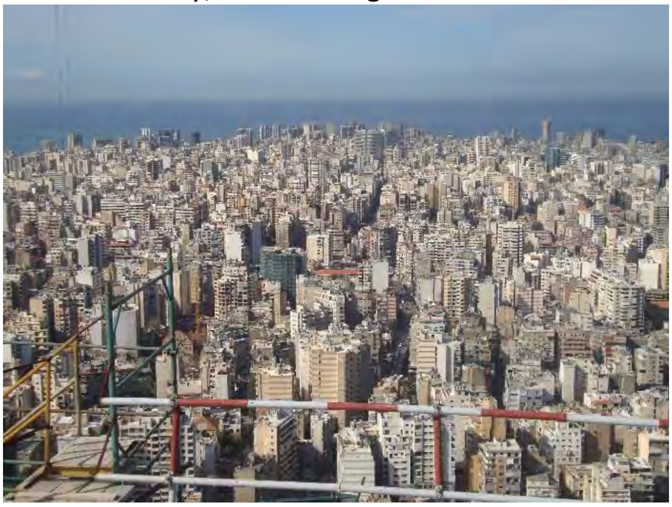

Figure 4: Buildings in Beirut

Three-dimensional optimization on June 21 (with a flat roof)

After specifying the latitude of the location and the date, the third step is to have the algorithm optimize the shape (leaving the roof component horizontal) so that the building envelope configuration receives the least amount of solar radiation on June 21. Therefore, the initial form – again a rectangular solid (Figure 3) - is optimized resulting in the shape shown in Figure 5. The optimized shape has a curved overall form with its long access oriented East-

West. The shape also tilts towards the South at an angle equal to that of the solar altitude at noon for the Latitude. In this case, the roof is maintained as flat due to the consideration that many buildings still locate numerous services on the roof. Therefore, having a flat roof would allow the proper installation of water tanks, mechanical cooling and heating machinery, receptors as well as, in some cases, an accessible planted green roof as an amenity for the building. Such a building typology requires that all the mechanical services would be located in a place other than the roof and the water system would be pressurized.

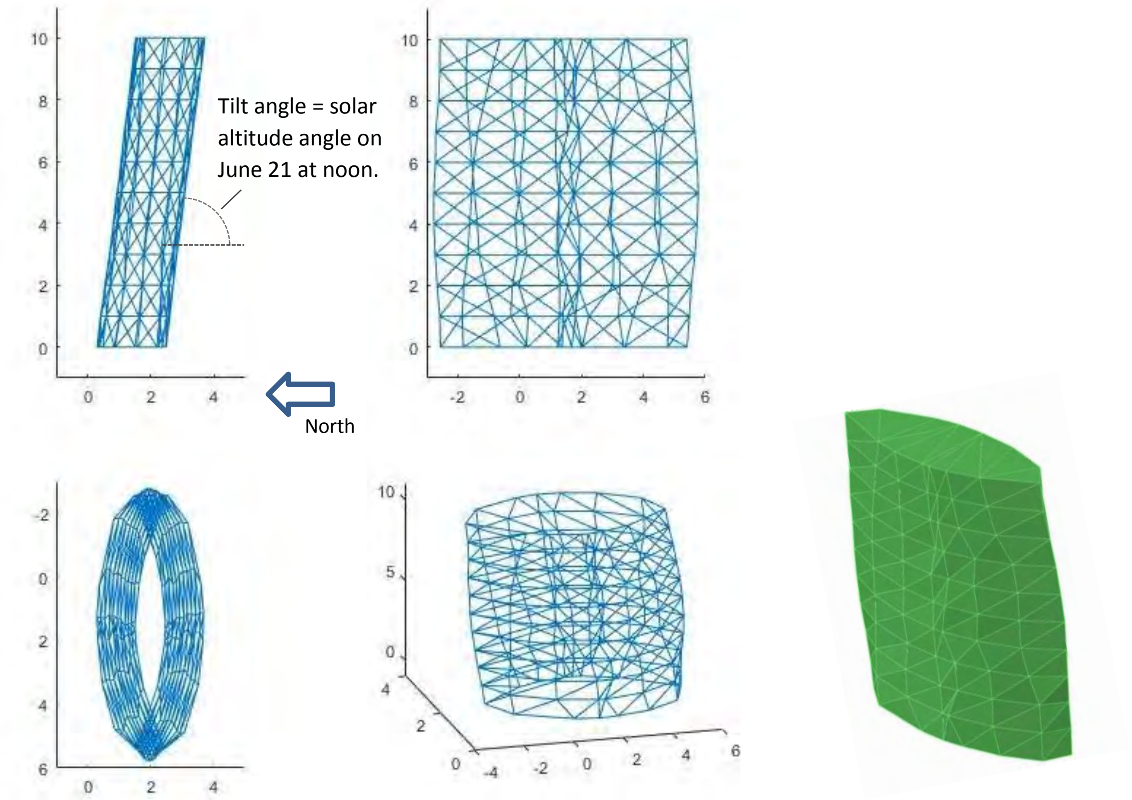

Figure 5: Building shape optimized for June 21

The initial insolation of 802 KW was reduced to 544 KW; a 32% reduction of insolation with respect to the initial shape.

Three-dimensional optimization on June 21 (with an optimized roof)

In this fourth step, the algorithm is run to optimize the initial building shape shown in Figure 3 to receive the least amount of insolation (on June 21) not only on the vertical surfaces but also on the roof (Figure 6). The initial inputs of latitude and exploitation rights remain unchanged. In this case, it is considered that the roof space is not used for particular services as mentioned previously, but can actually be integrated as interior space into the final level of the building – either as a penthouse, office space, common multi-functional space for the building or other.

The amount of incident solar radiation on this optimized form is 503 KW. This represents a 37% reduction when compared to the initial building shape shown in figure 3.

It is worth comparing the insolation on the elevations only since this could allow the analysis and evaluation of the form with varying numbers of floors. The design team can therefore assess the amount of incident solar radiation if a building is 1.5 or 2 times higher than the initial simulated building. Table 1 summarizes the results of the different optimizations.

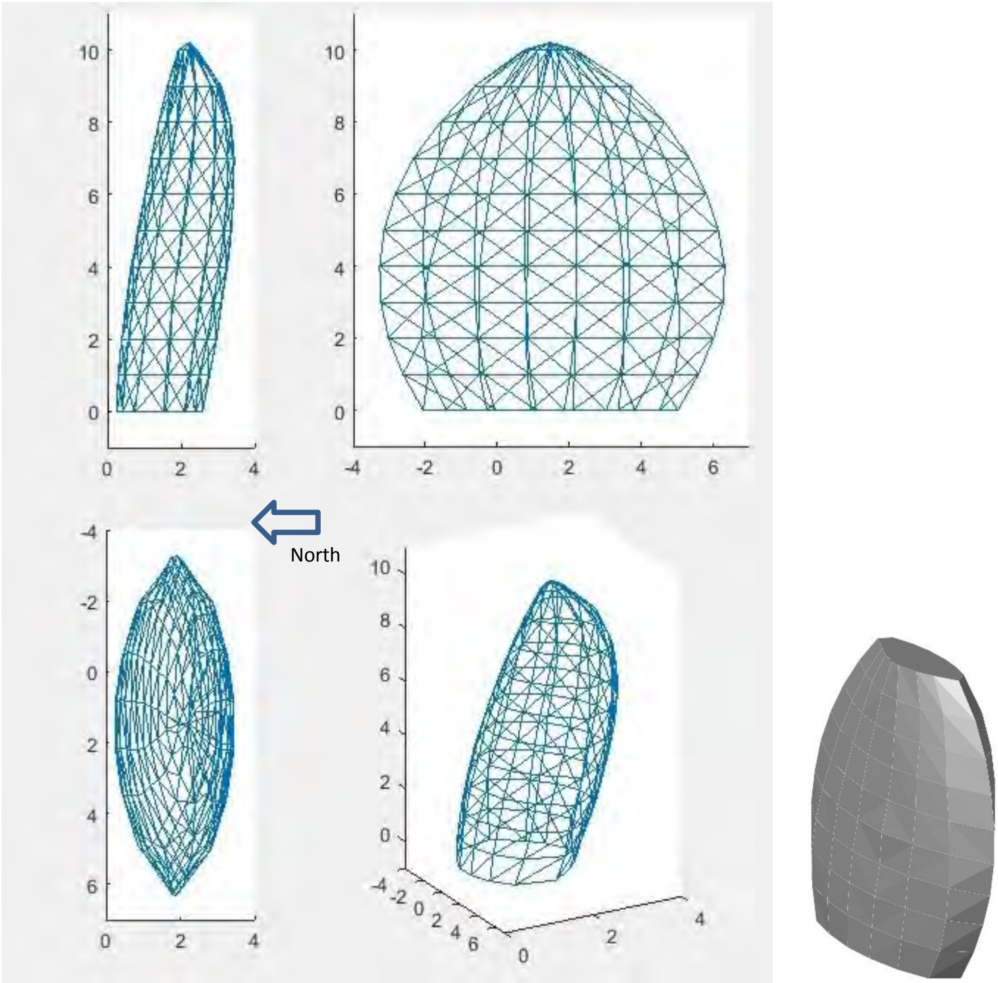

Figure 4: Optimization of the building form including the roof for June 21

Table 1: Comparative simulation results

Insolation	Shape excluding the roof		Shape including the roof		
	Initial rectangular shape	Optimized elevations	Initial rectangular shape	Optimized elevations only	Optimized elevations and roof
Value (KW)	602	344	802	544	503
Reduction (%)		43		32	37

Discussion

The algorithm optimizes the initial shape supplied by the researchers to reduce insolation during a given time frame. As presented in the results, the reduction in incident solar radiation, in both optimization runs, is considerable at 43 % (without an optimized roof) and 32 % (with an optimized roof) as shown in Table 1.

It is important to note that for comparison purposes, all the 3 shapes have the same number of floors and the same total built up area. Therefore, the developer will not lose any sellable area due to this optimization process. Moreover, one can input a constraint regarding the width of a building so that the efficiency of the floor plan, related to the building typology, is not compromised.

Building shape

The optimized building shape has a long access oriented East-West thus reducing the exposure of the East and West elevations. This is important as the elevations that are oriented towards the East and the West receive substantial amounts of insolation because of the low solar altitude angles. This, coupled with the high ambient temperatures during the day result in increased cooling loads to make the indoor spaces more comfortable. Also, the overall shape tilts towards the South thus shading itself from the high solar altitude angles during the midday.

The shape's tilt is equal to the solar altitude for the given context thus minimizing the intensity of insolation at noon as the solar rays are parallel to the shape. In addition, the optimized configuration of the building's rooftop significantly reduces the incident solar radiation as compared to the flat roof.

Strengths and Limitations

The strengths of this optimization process are:
First, the optimization algorithm is latitude specific rather than country specific. This suggests that this algorithm can be useful in analyzing the relationship between building shape and optimization as a function of latitudes. So, given the variations of the relative movement of the sun associated with different latitude degrees, interesting results are anticipated. Second, it should be noted that a similar approach could be used for buildings in cold climates where the desire is to optimize the building form to maximize solar heat gain, hence reducing heating loads. Third, the algorithm can be applied to a group of buildings (rather than just one building as presented in this paper) whereby the assessment of insolation can be evaluated while including the effect that adjacent buildings have on each other. Moreover, this will allow the study of insolation on outdoor areas between the buildings since the environmental conditions of these negative spaces between buildings is an important parameter that affects the thermal comfort sensation of pedestrians. This is important because if the space outside a building is shaded then the cooling load in a building is significantly reduced. Finally, this algorithm can be developed to process additional constraints as outlined in the section "Further work" below.

The limitations of this optimization process are:

First, within the framework of this study, the roof component remains excluded from the insolation calculations. Second, at this point, running the optimization is time consuming and does not really provide an interactive tool which is its intent. Therefore work needs to be done to reduce the time required for the calculations at each iteration to allow the design team to consider the results of the optimization and investigate different options.

Conclusion

Presently, buildings have rectangular solid shapes whose energy efficiency is enhanced by the design team to reduce the solar loads by manipulating the thermal transmittance of the building envelop components and mechanical systems.

Rather than designing buildings with a conventional approach, optimizing building shapes to reduce insolation in the building will change the design process to include the possibilities of design investigations that will help conceive buildings whose shape receives less solar energy. After testing, investigating and assessing this shape, the design team can either study other options (such as reducing the number of floors and increasing the floor area), or can develop this shape further. This development could be in identifying the envelope configuration (continuous with different window wall ratios, loggias, balconies, etc.) to further re-assess the impact of solar radiation on the building shape. It is understood that the site should allow for some massing flexibility in order to allow taking full advantage of the results. In other words, if the site restricts the investigation of the building shape, then the full potential of this tool would be compromised.

Further work

Once the limitations of the optimization process are resolved, the next steps would consist of including constraints pertaining to site limit and site setbacks, resistance to wind load as per applicable codes, sites having a slope (with a particular orientation). In addition, adding the following constraints to the algorithm would render the outcome more comprehensive:

First, the "buildability" of the three dimensional form can be addressed by having the components of the envelope’s triangular mesh equal to a specific dimension (e.g. 90 cms).

Second, the ability to indicate balcony and / or loggia components can be very informative because their spatial configurations and orientations could have a considerable impact on reducing incident solar radiation.

Third, further modelling would include the distribution and location of fenestration according to respective orientations and incident angles of insolation. The "window /wall ratio" of the envelope would be studied as per the amount of solar radiation that enters the space - considering that it is an open floor plan with an identified core. The amount of solar rays that directly impact the internal horizontal and vertical surfaces would be assessed.

In conclusion, further development of this algorithm can be instrumental in informing the thinking process of design teams aiming to align their projects with global initiatives and targets to reduce energy consumption in buildings and cities.

Design to Thrive

Effect of External Shading Blinds Provision on the Energy Consumption and Visual Comfort

Zhang Yi[1] Huang Qiong[1], Zhang Anxiao[1]

[1] School of Architecture, Tianjin University, Tianjin, China, email@kclara1017@163.com

Abstract: External shading blinds, which operates directly with daylight, has close relationship with energy consumption and comfort of building. As a double-edged sword, external shading blinds can optimize cooling energy consumption in summer and increase heating energy consumption in winter, reduce the possibility of discomfort glare and decrease essential illumination on working face. Therefore, the selection of external shading blinds should satisfy multi-dimensional objective of energy consumption and comfort considering both of its advantage and disadvantage. In this paper, an office model in cold climate region of China is used for exploring the influence mechanism of external shading blinds by computer simulation and subjective experiments. The variables are the direction, width and angle of blinds. The targets are low energy consumption and high visual comfort. By a graphical optimization method, the results summarize the influence mechanism of the variables, explain the incomplete coincidence between variable interval and target requirement, tries to ascertain the balance point for multiple target orientation, and enhances practical significance. In the process of architectural design, architect should adjust the weight ratio of each target according to the different needs of building in order to assist design decision.

Keywords: External Shading Blinds, Cold Climate Region of China, Energy Consumption, Visual Comfort

Introduction

Daylight is an indispensable element for human survival. Suitable daylight into indoor will improve working efficiency and ensure physical and psychological comfort. However, excessive daylighting will increase solar heat gain and augment cooling consumption, with the easy occurrence of disturbing glare. External shading blinds are considered to be an effective way to reduce energy consumption and improve comfort, by keeping daylight out and reducing the amount of light and energy by solar radiation into the room. In addition, external shading blinds can be used in both new buildings and retrofit projects.

Single objective optimization of a building component is found frequently in literature. Examples include obtaining high visual performance or lower energy consumption. Some studies proved that external shading blinds can help decrease cooling consumption, with increasing lighting consumption in the areas with adequate solar radiation. It would reduce total consumption, if appropriate form of external shading blinds were chosen.

Other studies tried to demonstrate that external shading blinds are an ideal way to eliminate glare and make use of daylight, with illumination and glare into comfortable range for written and computer operation. Architectural design is a comprehensive job to consider a variety of issues and balance multiple actors. As a decision-making tool, multi-objective optimization technique has been used to determine the best solution. Since architectural design is to consider simultaneously multiple objectives in an almost infinite number of possible design solutions, the form of external shading blinds should be chosen by multi-objective optimization techniques. And it will provide a new angle for green building design. The results will be used for elevation design.

Visual and energy evaluation criteria

Examples of evaluations for energy and visual aspects.

At the early stage of research, the contradiction of energy consumption and visual comfort was mentioned. An example is a study that focuses on the difference of light environment and monitoring energy consumption with shading fabrics and shading blinds for different façades. Another example is about light environment and thermal comfort by combination of different forms of shading blinds and window size. However, low energy consumption and high visual comfort are not the focus of the studies.

An in-depth examination of different forms of external shading blinds shows that the integration of louver shading devices in building leads to comfortable indoor thermal conditions and might lead to significant energy savings, by comparison with that of the building without shading devices. Energy requirements for a building in cool and hot seasons are quantified for different window and louver areas under the climatic conditions of five cities at different latitude through simulations using TRNSYS software. In this study, different directions and angles of blinds are discussed, but without visual comfort.

Simultaneous optimization for low energy and visual comfort for window size was made. Whole-building computer simulations were performed on a standardized office located in a temperate climate. This work aims at determining the suitability of combined optimization criteria on window sizing procedures for low energy consumption with high visual comfort and performance. A series of energy and visual criteria were selected.

Energy and visual performance evaluation criteria

Energy performance criteria

The evaluation standard of energy consumption is based on the quantitative analysis of the energy consumption of different equipment. Energy consumption can be divided into cooling consumption, heating consumption, ventilation consumption, lighting energy consumption and equipment consumption. They can be expressed in terms of energy units (kWh or GJ) per unit area per time unit. Typical goal is to select the least energy consumption system, which is in accordance with local regulations on temperature. User comfort can also be used for evaluating energy performance, but it is not used universally with little evaluation indexes of thermal comfort in different climate areas.

Visual performance and comfort criteria

Some studies noted that discomfort due to visual effects is reported more frequently than discomfort due to thermal effects, because discomfort by visual effects, like glare, headaches, deregulation of circadian rhythm leading to depression, is more immediate and real-time. Therefore, the evaluation of visual effects is important and assignable in building design due to the possible rejection by users of the built environment.

The evaluation of visual comfort can be divided into static light environment evaluation and dynamic light environment evaluation. Static light environment evaluation is based on static image brightness and optical index data for a certain time point of daylighting and artificial lighting. The illuminance-based and glare-based criteria of static one are Daylight Factor (DF) and Daylight Glare Index (DGI). Dynamic light environment evaluation is based on the dynamic change of indoor light environment for 8760 hours in a year. And the illuminance-based and glare-based criteria of dynamic one are Daylight Autonomy (DA) and Daylight Glare Potential (DGP).

Evaluation method used

Location and climate type description

The computer model was evaluated for the climate of Tianjin, China (39°N, 117°E) using the CSWD file. According to Chinese standards, Tianjin belongs to Cold Region and Class Ⅲ Daylight Climate Zone. Average winter temperature for the locale range is between -10°C and 0°C, average summer temperature between 18°C and 28°C, and annual average illuminance is between 35klx and 40klx, with buildings here having heat-preservation in winter and heat-proofing in summer. North China, part of northeast China and northwest China are in the same zone region as Tianjin. And it is also described in the Köppen climate classification as Dwa Climate Region. It characterizes hot summer and dry winter.

Test room description

In order to highlight how different optimization criterion affects solution space, the module consists of a hypothetical office room (dimensions being 6.0m*6.0m*5.0m) is based on the size of the office room in China. There is a single external wall, which can exchange energy with the outside through windows (dimensions being 5.5m * 2.0m), but other walls, roof and floor are of insulation values. Based on GB50189-2015 and GB50033-2013, which are China standard, glazing in windows is double 6mmpane clear with 13mm Argon gas interlayer (U-value 2.511 W/m2 K, SHGC 0.697), the external wall is Lightweight concrete block poly insulation & plasterboard (U-value 0.464), and the reflectance of wall, roof and floor is 0.6, 0.8 and 0.3 respectively.

The west façade and south façade were chosen to be the external wall, which has great influence on indoor environment in Cold Region. The variables are the direction, width and angle of the shading blinds (Figure 1). The horizontal blinds were selected for south façade with no-shading and overhangs as reference, and the horizontal blinds and vertical blinds were selected for west façade with no-shading as reference. Besides that, the width of the blinds is 100mm, 200 mm, 300 mm or 600mm, which is used in buildings in China, and the angle of the blinds is 0°, 15°, 30°, 45°, 60° or 75°(0° blinds are the minimum shading of external wall and window and are perpendicular to the wall; 90° blinds are the maximum shading of external wall and widow and are parallel to the wall). The control methods of blinds angle are divided into fixed methods and manual methods. Manual control of the external shading blinds can be adjusted according to season, time, weather or other factors. Usually, the angle of blinds is adjusted to cut off daylight in summer when solar radiation is strong, and the blinds are opened to guarantee indoor illumination and temperature at the end of summer. However, it is very subjective to manually control the blinds. Therefore, it is very effective and convenient to adjust the angle of blinds twice a year. In one year temperature change is after the change of solar altitude. So the time needed for shading measures does not correspond exactly to summer. It needs shading measures when outdoor temperature is above 29°C, and total solar radiation is above 280W/m2. The time of shading stage for the west façade and the south façade is from April 16th to September 24th, and the time of no-shading stage is from September 25th to April 15th next year.

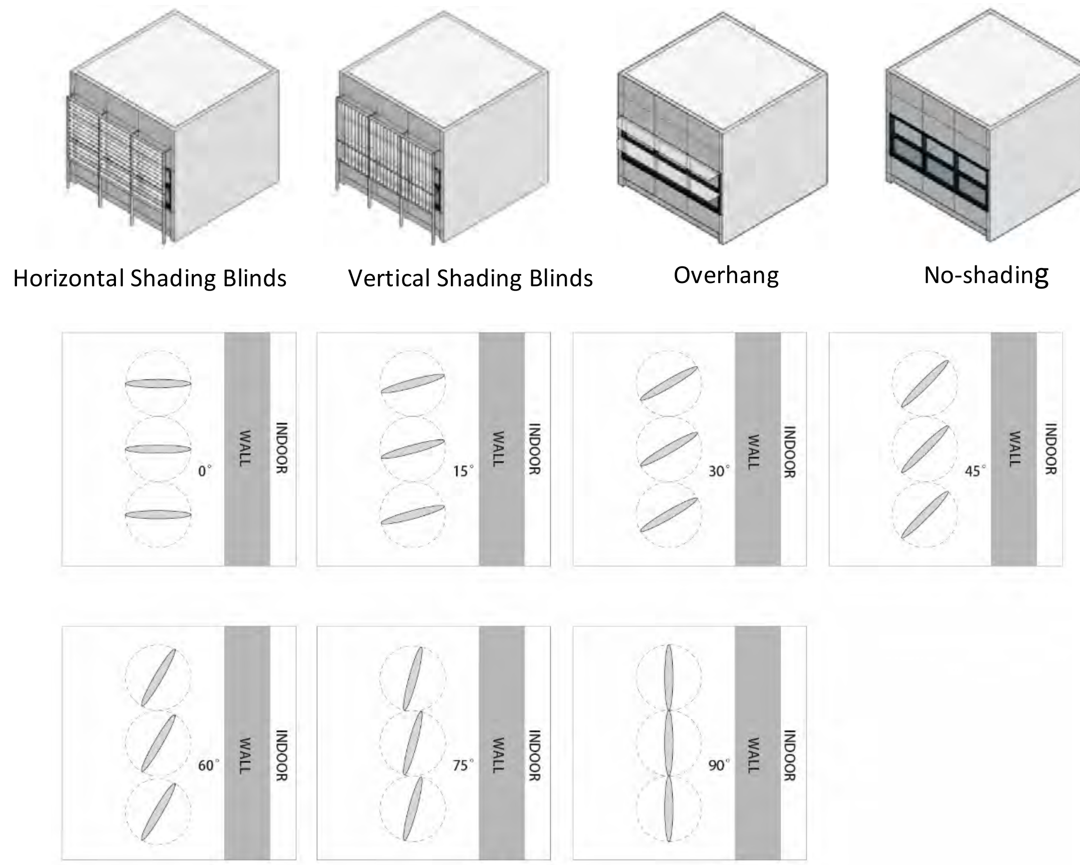

Figure 1 Measured energy consumption and visual comfort of all the studied forms of shading blinds with different directions and angels

Evaluation criteria

Energy consumption evaluation benchmark is minimal total consumption, which includes heating, cooling and artificial lighting consumption simulated by the software Design Builder.

Daylight Autonomy (DA) and Daylight Glare Potential (DGP) were chosen as quantitative indicators for visual aspect. Dynamic light environment is simulated by the software Daysim. The DA threshold in the following analysis was assumed to be 500 lux, which was approximated from the IES lighting handbook. The DA for most of the sensors resulted in above 50% means, and that in more than 50% of all the daylight time occupants will be able to fulfill tasks that require 500 lux using daylight. And more than 80% sensors with DA over 50% means that the space is bright enough for the needs of users in most daytime of a year. DGP above 0.40 means the degree of perceived glare is disturbing or intolerable, and the space dazzles for users. More than 80% of all the daylight time with DPG under 0.40 means the glare of the space is perceptible or imperceptible in most daytime of a year.

In conclusion, the evaluation criteria of energy consumption and visual comfort are as Table 1.

Table 1 Summary of criteria being tested

Type of aspect	Criteria	Dynamic evaluation of acceptance value
Energy	Total consumption	Least energy consumption of the studies case based on building codes
Visual	Area DA exceeds 50% Hours DGP below 0.4	80% of total area of office room occupancy 80% of total time during office occupancy

Simulation results and discussion

According to the results, the direction and angle of the blinds have significant influence on energy consumption and visual comfort, but the influence of the width of the blinds is insignificant. Therefore, take200mm-width blinds as example, the influence mechanism of different direction and angle of blinds on energy consumption and comfort was analyzed.

The results show that, there are different forms of external shading between the lowest energy consumption and the highest visual comfort, and the forms of illuminance-based criteria and glare-based criteria are inconsistent. Therefore, to select a form of external shading blinds, not only reducing energy consumption should be taken into account, high visual comfort should also be satisfied (Table 2).

Table 2 The forms of shading blinds for energy consumption and visual comfort

	West façade		South façade
	Horizontal blinds	Vertical blinds	Horizontal blinds
Energy Consumption	Fixed 0-30° Shading Stage 15° No-shading Stage 0°	Fixed 0-60° Shading Stage 45° No-shading Stage 0°	Fixed 0-15° Shading Stage 0° No-shading Stage 0°
Illuminance-based Criteria	Fixed 0-15° Shading Stage 0-45° No-shading Stage 0-30°	Fixed 0-30° Shading Stage 0-30° No-shading Stage 0-30°	Fixed 0-30° Shading Stage 0-30° No-shading Stage 0-30°
Glare-based Criteria	Fixed 45-90° Shading Stage 30-90° No-shading Stage 30-90°	Fixed 45-90° Shading Stage 45-90° No-shading Stage 30-90°	Fixed 45-90° Shading Stage 15-90° No-shading Stage 45-90°

In order to meet practical needs of multi-objective, the data of energy consumption and visual comfort can be synthetically considered, with the assumption that all of the objectives are of equal importance. If the objectives cannot be taken into account, they should be satisfied as much as possible, and the importance is as follows: energy consumption ≥ illumination-based criteria ≥ glare-based criteria.

Under fixed control, for west façade, the angle of horizontal blinds should be 30 °, the angle of vertical ones should be 45°,and the angle of horizontal blinds for south façade should be 45° (Figure 2).

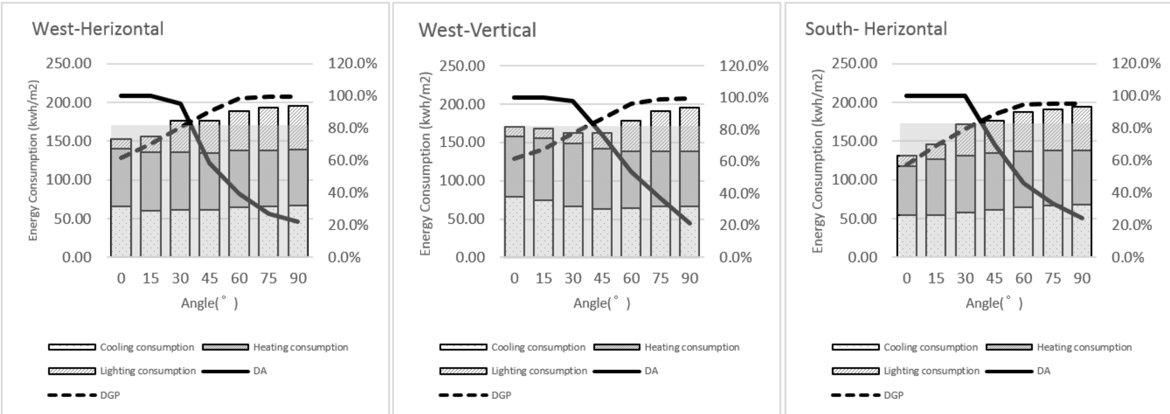

Figure 2 Solution space for energy use and visual performance and comfort of shading blinds with fixed control

Under manual control, the angles of horizontal blinds for west façade at shading stage is 45°, and that at no-shading stage is 0°. The angel of vertical blinds for west façade at shading stage is 45°, and that at no-shading stage is 30°. The angel of horizontal blinds for south façade at shading stage and no-shading stage are 15° (Figure 3).

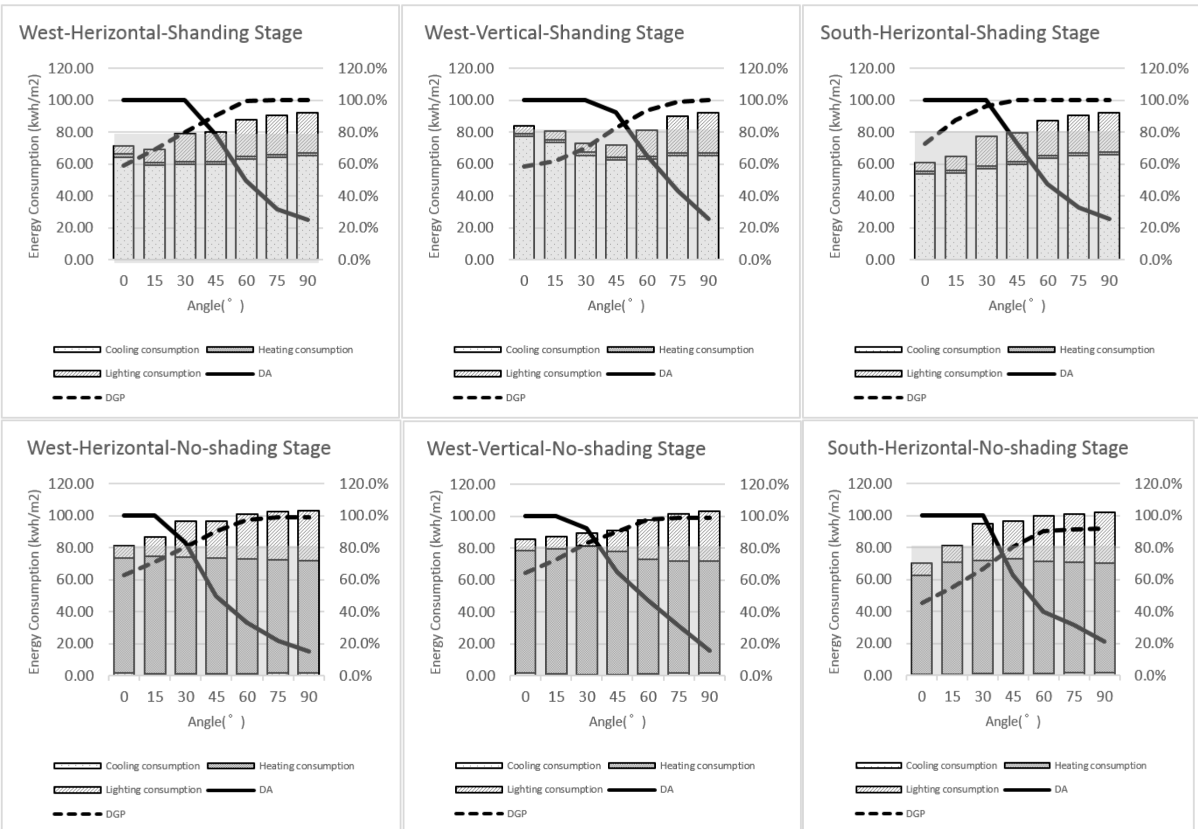

Figure 3 Solution space for energy use and visual performance and comfort of shading blinds with manual control

The results provide a reference basis for the selection of external shading blinds of one climate type. The prototype already has high-performance elements optimized for energy savings. Therefore, it allows us to optimize external shading blinds only. The results show that it will cause great problems to focus on energy saving without high visual comfort in some cases, because of the difficulties to meet the varied requirements of users. Therefore, combined with climate characteristics, the form of external shading blinds for high comfort and low energy consumption should be considered in design and update process. Optimized building design requires specialists working together.

Conclusions

The influence of external shading blinds on indoor environment is various, and the result of multi-objective optimization techniques combined with energy consumption and comfort was provided in this study. In the process of building design and construction, the weight of each objective is different. In the case that one objective is prior than others, it is significant to balance the proportion of them on the basis of the sole objective during the research and design. This sort of weight division is also the focused issue in the future. The weight division of multi-objective optimization is the focus in future. And the evaluation standard of visual comfort is more than DA and DGP. Besides, architecture design is comprehensive, multi-factored and multi-objective. When selecting the form of external shading blinds, other objectives should be considered, including overall effect, construction cost, maintenance cost, etc. With technology development, new forms of shading blinds will continue to bring forth new ideas to solve the contradiction between low energy consumption and high visual comfort. In this study, only the common form of external shading blinds was involved. With the invention of new products, further study of new form should be focused on.

Passive Architecture in Very Hot Climate: a Simple and Flexible Bioclimatic Approach for Architects

Ferran Yusta-Garcia[1], Catherine Semidor[1] and Denis Bruneau[2]

[1] GRECCAU, Ecole d'Architecture et de Paysage de Bordeaux, France,
ferran.yusta@bordeaux.archi.fr
[2] I2M, UMR 5295, Université de Bordeaux, France, denis.bruneau@u-bordeaux.fr

Abstract: The last 25 years have been ground-breaking in architectural design on low energy consumption in cold climate, mainly in north-western cultures. For an architect today, the method to design a passive house in cold weather and the choice of the Architectural Actions (AA), are clearly established. When the question comes to how to build a passive house in warmer, hot, and very hot climates, the strategies are poor and often results of a combination of western strategies with a local relook. From several visits in Middle East countries, Saudi Arabia, UAE, Oman, Palestine, Qatar, we concluded that the strategy for low consumption houses is not established yet and poorly grasped. The lack of training on low energy consumption in hot climate and the low price of energy, force designers and owners to relay on over usage of air-conditioning systems as measures to catch up on poor bioclimatic design. This paper proposes a new approach on bioclimatic design for hot climates from an architect point of view. It is based on a Cooling Degrees Days approach, a state of art of contemporary architecture and professional experience. Local climates are classified according to passive strategies: cold/cold, cold/cool, temperate/temperate, cold/hot, warm/hot, and hot/hot.

Keywords: Hot climate architecture, early design stage, passive architecture, low energy consumption architecture, cooling degrees day method.

Introduction

The low energy consumption tendency and know-how in hot climate countries is awakening from a dark period on high energy dependency, even though still much work is to be developed and promoted: methodologies, tools, labels, training... etc. Today more than 80% of people in the world live under a warm-hot climate, and millions of them under very hot climate, and so far in recent and modern construction, buildings follow a model of architecture called "international" with little efforts on architectural principles for low energy consumption. Finally the comfort is achieved relying on technical equipment, including air conditioning with high energy consumption.

Today, the international comfort standards cannot avoid the massif use of air conditioning systems, and its omnipresence and over-use has become a fact in the everyday life of the middle class in developed or emerging countries in hot climates. However in hot climate, like in cold climate, we find extreme contexts, countries that have shortages of access to electricity as some cities in Palestine or many countries in Africa and those who have an important energy access situation, as in Saudi Arabia or the United Arab Emirates. Paradoxically in both cases reach the low energy consumption is now a priority in national strategies for different reasons: one is designed to minimize the energy shortage, while rich countries aim to reduce exorbitant spending on subsidies in energy sold at prices below the cost of production for reasons of social solidarity.

In this paper we aim to explore a simple method for architects to produce well founded architectural solutions which could help to improve the comfort and the future quality of life of low-income families in hot climates combining a passive thinking but high flexibility on design without neglecting the use of newest construction technologies.

“Very hot climate” definition for designers.

The term "hot climate" is often too general in western and European cultures. Wladimir Köppen defined "hot desert climate" as Bwh, where “B” meant a climate defined by little precipitation, “W” indicating an extreme arid one with annual precipitation under a certain threshold, and “h” meaning low latitude climate with temperatures average annual temperature above 18ºC, which basically means hot arid weather. This term covers all Saharan Africa, Arabia, south of the United States and the center zone of Australia. However In this classification not all countries undergo the same need to use air conditioning, specially the countries of the Arabian Peninsula and around the Red Sea and the Persian Gulf, where record-breaking temperatures are often measured. In 2004 the ASHRAE and IECC (International Energy Conservation Code) agreed to create a common classification more accurate, standard 90.1.: Zone 1: very hot and wet (1A)/very hot and dry (1B). A climate is rated 1B "very hot and dry climate" if it has more than 5000 Cooling Degree Days (CDD) at a temperature of 10ºC.

By this method, the city of Riyad with 6026 CCD at 10ºC would be largely in this category. However with the same criteria, a city like Karachi in Pakistan with 6119CDD to 10ºC would be in the same category of hot climate even if it does not represent a climate as severe as the climate of the cities of the Arabian Peninsula. A higher temperature threshold would be more judicious to establish criteria to classify cities in extreme desert climates.

If we consider that heat discomfort starts at 26º, under relative humidity conditions around 50%, and most of the air conditioning equipment starts also at 26º, then CDD26º is a good reference to classify the “hunger” for energy on active cooling of a climate. The choice of 26ºC is an arbitrary one and it depends on cultures and lifestyles. Cultural and social factors can have strong influence on the accepted “hot temperature” that we will not study in this paper.

Based on this method, Table 1 shows a classification on cooling energy needs based on a start of the cooling needs at 26º (considering that most of the existing air conditioning systems do not consider relative humidity parameters). It is clear that the GCC countries (Saudi Arabia, UAE…) are way far ahead on cooling needs that any other zone in the world.

Classification of a city climate by using the concept of “Climatic Seasons”

The approach of the climate of a city by a designer is not systematic and it is frequently neglected in projects of private houses and small collectives. In order to classify a site from the point of view of bioclimatic strategy we defined three simple situations that represent the broad majority of cases, and imply very different bioclimatic design strategies. These generic situations are described as follows:

Situation 1 - It is cold outside, and the vector [temperature, humidity] is unpleasant: users prefer to close doors and windows and reduce exchange with the outside. They try to get as much as possible of sun inside of the house.

Situation 2 - It is temperate outside, cool or warm, the vector [temperature, humidity] is pleasant: users prefer to open doors and windows to generate cross ventilation.

Situation 3 – It is hot outside; the vector [temperature, humidity] is unpleasant: users prefer to close doors and windows and reduce exchange with the outside. The sun-rays are blocked as much as possible.

Several of these three situations can arrive during one same day, making appear different day-types: 1-1, 1-2-3, 1-2, 2-3, and 1-3. The designer will then need a passive strategy for different day-type. The impression of cold, cool, warm and hot, can vary a lot depending on cultures. We chose the most usual range in Europe of 19ºC to 26ºC, but it could be adapted to any culture. With this range of comfort temperature and these three situations, we define a new concept named “CLIMATIC SEASON”, which are periods that can last several months with the passive strategy remains the same (fig.1)

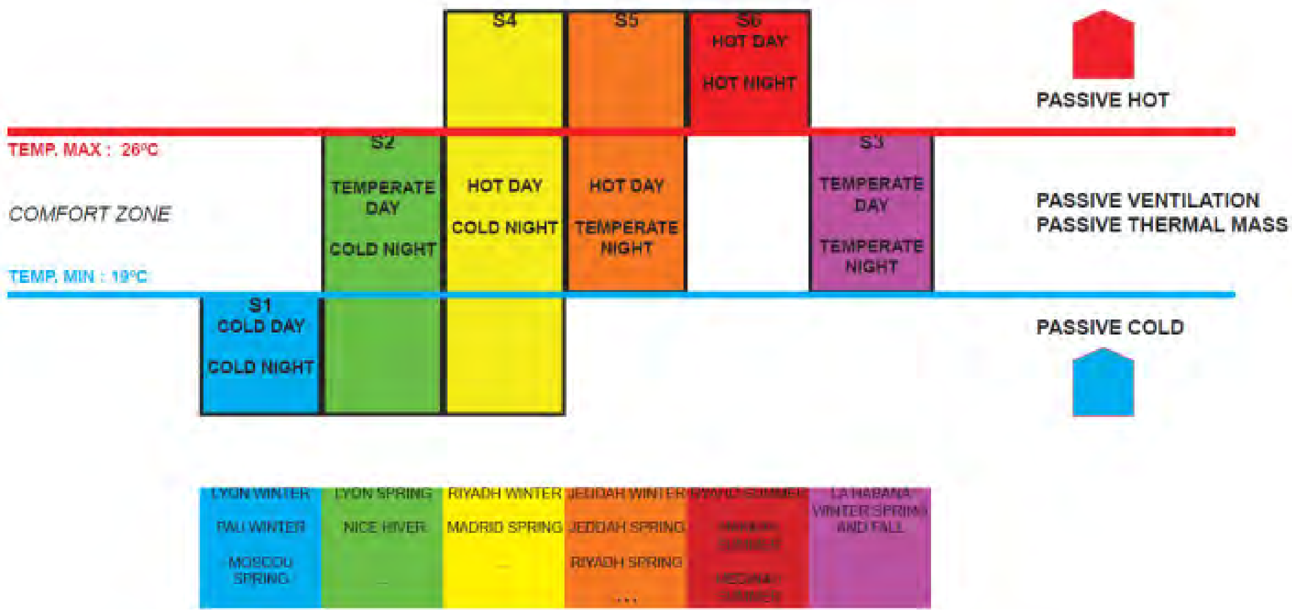

Figure 1. Diagram of “climatic seasons” with some examples of cities and their seasons.

These “climatic seasons” are defined as follows:

Climatic Season S1: cold days and cold nights. This season is the coldest of all, and it is characteristic of many cities in Northern Europe during winter. The temperatures are low, and even though they may not be extreme they are permanently under the cold temperature threshold. People do not want to have exchanges with the exterior.

*Climatic Season S2: cool days and cold nights.*This season combines daily temperatures that are comfortable and night temperatures that are below the comfort threshold.

Climatic Season S3: temperate days and nights. This season is always comfortable in terms of temperature, because the maximum temperature and minimum daily remain always within the thresholds of comfort. These conditions are often associated with tropical cities close to the sea with high relative humidity values and a low daily temperature fluctuation.

Climatic Season S4: hot days and cold nights. Daily maximum temperatures are above the upper threshold of comfort and the daily minimum temperatures are below the low threshold of comfort. An important part of the day temperatures are comfortable but at peak hours we either feel too hot or too cold.

Climatic Season S5: hot days and warm nights. Daily maximum temperatures are above the upper threshold of comfort and daily minimum temperatures stay in the range of comfort. A large part of the day exterior conditions are uncomfortable and late in the evening they become confortable for some hours.

Climatic Season S6: hot days and hot nights. This is the hottest season of all, temperatures are high all the time, and even though they may not be extreme they are permanently over the high threshold of comfort temperature. It is characteristic of many cities in the Middle East during spring, summer and fall.

Degrees-days for architectural passive strategy

To be able to organize the year of a city in Climatic Seasons we will use a widespread and relatively accessible index in all the bibliographies and websites: the heating degree-day (HDD) and cooling degree-day (CDD). We will use two values associated with the high temperature threshold of 26ºC: HDD26 and CDD26, and two values associated with the low temperature threshold of 19ºC: HDD19 and CDD19.

In order to determine to which Climatic Season (S1, S2,... S6) belongs a particular month of the year of a city, we need to establish criteria based on a established threshold:

Season 1: HDD19>0 CDD19=0 heating- no air conditioning- no exterior
Season 2: HDD19>0 CDD26=0 heating- no air conditioning- some exterior
Season 3: HDD19=0 CDD26=0 no heating- no air conditioning- lots of exterior
Season 4: HDD19>0 CDD26>0 heating- air conditioning- some exterior
Season 5: HDD19=0 CDD26>0 no heating- air conditioning- some exterior
Season 6: HDD26=0 CDD26>0 no heating- air conditioning- no exterior

However we need to allow a certain overtaking on these values to dismiss extreme values: it will be enough in a very cold day (S1) with an outside temperature of one degree over the comfort level to consider it as a temperate-cold season (S2). To allow this over threshold we will use a percentage of the “monthly comfort allowance”, MCA, representing the total degree-day located between the comfort thermal range. For a 7º degrees range the MCA value is 217, for a 31-days month, 210 for a 30-days month and 196 for the 28-days month. We will consider that if the DD value divided by MCA is less than 5%, it will be consider as 0 in terms of Climatic Seasons classification.

Figure 2 shows the comparison between the Climatic Season classification and the maximum and minimum daily temperatures of a average journey in Dubai in 2005 climate data, the result shows that from May to October the temperatures are too high to open the windows at night time, as shows the Season 6 with the “Climatic Season” method. In January, the temperatures are low, especially at night time, so a Season 2 strategy can be carried out.

Figure 2. Comparison of Climatic Season method with a temperature-humidity values of 2005 for Dubai.

The climatic year

The combination of the Climatic Seasons of a particular city over a year is named 'Climatic Year', the diagram in figure 3 shows all the different combinations of climatic seasons for different cities. These combinations allow us to define several types of Climatic Years:

-Temperate cold Climatic Year: S1 + S2 + S4 (Paris, Bordeaux)
-Temperate hot Climatic Year: S1 + S2 + S4 + S5 (Madrid, Valencia, Sevilla, Jericho)
-Very hot and dry Climatic Year: S2 + S4 + S5 + S6 (Riyad, Medinah)
-Very hot and humid Climatic Year: S2 + S3 + S5 + S6 (Dubai) and S2 + S5 + S6 (Doha)
-Extreme hot Climatic Year: S5 + S6 (Jeddah, Makkah)

Architectural strategy based on Climatic Seasons

Both, hot/cold, bioclimatic strategies have similar approaches organized in five general axes:

1-External hot/cold protection

2-Inner heat management
3-Heat evacuation/capture
4-Cold/heat production
5-Heat/cold adaptation

Figure 3. Climatic year of different cities by combination of climatic seasons

Once a site is classified in Climatic Seasons, we must combine (fig.4) Architectural Actions to clearly define the spirit of the passive strategy for each Climatic Season. An Architectural Action is a decision taken by the designer having an impact on the architectural shape of the building to bring down the energy consumption of the building,

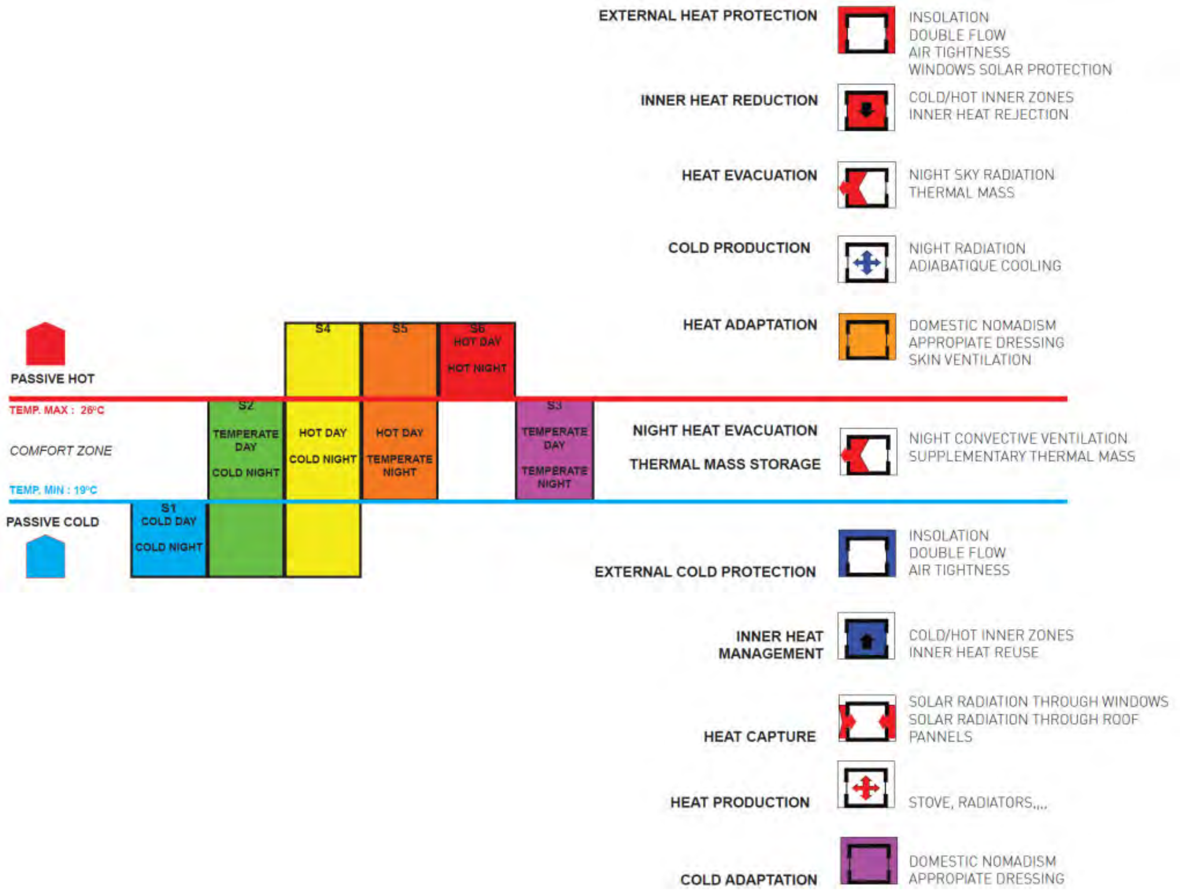

Figure 4. Strategic directions and the most common architectural actions

Classification of architectural Actions (AA) for a very hot climate

We classified all the Architectural Actions extracted from the scientific literature of the last 50 years and real practice in contemporary construction under hot climates fig.6. They are grouped by five main axes, and several sub-groups:

AXIS 1: External hot protection

1. Heat reduction coming through glazed openings in housing: Reduction of glass surface exposed to the sun. Reduction of the surface of glass-not-exposed-to-the-sun. Preferably N-S orientation. External brise-soleils. Inner opaque curtains. 2. Heat reduction coming through the opaque parts: Strong thermal insulation. No thermal bridges. Low emissivity on exterior walls. Ventilated double skin. Albedo reduction by peripheral shading. 3. Reduce the heat entering the house through ventilation: high-performance air sealing. Double flow thermal exchanger. Partial cooling of the air by underground pipes.

AXIS 2: Inner heat reduction

1. Energy efficiency label, position and management of the cooking appliances in the kitchen, thermal zoning of the area of the kitchen that produces a strong residual heat (fire and oven). Specific air extraction in areas with strong heat production. 2. Energy efficiency label of the computers, small appliances and lighting. Electrical switches for complete disconnection of appliances out of charging periods. 3. Position and management of domestic hot water in the bathroom and distribution: Extraction of water steam with strong latent heat storage.

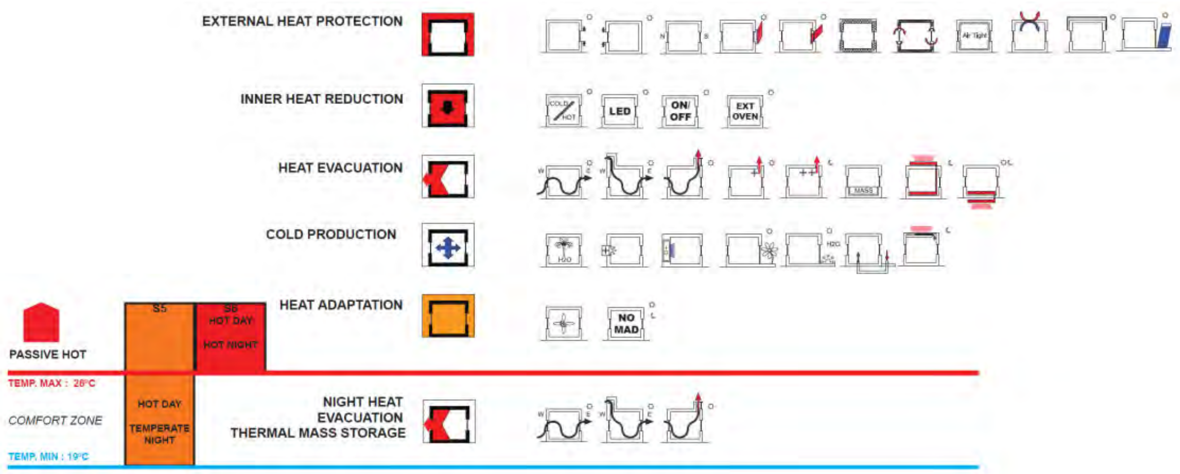

Figure 6. Architectural Actions associated to a very hot climate year as Jeddah or Makkah

AXIS 3: Inner heat evacuation

1 - Convective Evacuation by air: natural cross-ventilation air currents. Wind catcher towers. Thermic gradient towers or walls. 2. Night radiant heat discharge of thermal load by the facades and roof with specific thermal mass storage. 3. Heat storage in the thermal mass of the building. Delete ground insulation to facilitate the evacuation of heat to the ground.

AXIS 4: Cold production

1 - Adiabatic cooling: Direct or indirect adiabatic cooling. 2. Radiant night sky cooling with specific thermal mass storage. 3. Night recovery of the lower temperature air under radiant plate orientated towards the sky.

AXIS 5: Heat adaptation

This axis is to identify all architectural, social and cultural elements that can improve the comfort, without involving measures that change the inner temperature:

1 - Facilitate the natural mechanisms of regulation of the human body: no air-conditioned mechanical ventilation, fans.

2. The use of space: nomadism inside and outside.

3. Wearing appropriate clothing that helps other measures to work well.

Discussion

This simple method can be carried out by anyone having a low internet connection to get the degrees-day data, a simple worksheet program, and some basic principles on bioclimatic architecture. Thus, any young designer can understand the main bioclimatic challenges of a project site and propose a solid bioclimatic based project to their clients. However, the choice of an Architectural Action is associated with logic of investment and a pay-back period, which is associated with three factors: 1. The contribution of the Architectural Action to decrease the energy consumption. 2. The cost of construction and maintenance over the years of the Architectural Action. 3. The price of energy. The first and second factors, the energy saving and the price of the action will depend on climate and the geographical context of the site. According to local context, energy prices and the construction cost will depend on factors such as the hourly cost of labor, the lack of access to electricity, the cost of building materials. The combination of these values must create a hierarchy in the possible Architectural Actions based on the pay-back period of each that will invite the designer and clients to implement it or not

To quantify these parameters we modeled on Design Builder model with a hot climate house-type, and created a digital model by different architectural action variants. We quantified the influence of each action per day. In parallel we have evaluated the additional cost of each one of these actions on the cost of construction of the House. These elements define the payback period in function of the electricity cost and allow a hierarchy on the choice according to local context.

[3]Faculty of Built Environment, Universiti Teknologi Malaysia, Skudai, Johor Bahru, Malaysia.

Abstract: This study investigates the effects of proposed energy-saving modifications for urban houses in hot-humid climate of Malaysia through full-scale experiment. The effects of the proposed modifications were investigated under the two different cooling strategies, i.e. structural cooling strategy (night ventilation) and comfort ventilation strategy (full-day ventilation). Then, the thermal comfort level of indoor spaces with the proposed modifications is evaluated based on operative temperature (OT) and SET* indices. The results show that the resultant indoor air temperatures of the master bedroom were successfully reduced by the structural cooling strategy during day and night after the application of the proposed modification strategies. Meanwhile, the reduction could only be seen during the night-time in comfort ventilation. It was found that the application of attic fan at night did not contribute in lowering the nocturnal air temperature in the master bedroom. The evaluation of thermal comfort shows that the indoor condition of master bedroom with the proposed modifications in comfort ventilation strategy was found to be preferable for hot-humid climate of Malaysia when the evaporative heat loss was taken into consideration.

Keywords: Passive cooling, Energy-saving, Natural ventilation, Hot-humid climate, Modification

Introduction

Energy consumption for space cooling in buildings has been increasing rapidly especially in the warm, developing regions such as Southeast Asia. Due to the rapid economic growth and urbanization, the energy demand in this region has increased more than 50% between 2000 and 2013 (IEA, 2015). In Malaysia, for example, it has been reported that the number of households having air-conditioner has increased about sixth-fold during the last two decades (1990-2010) (Mahlia et al, 2004). Therefore, passive cooling should be considered wherever possible to reduce the energy demand caused by the growing use of air-conditioning. Passive cooling in the building scale can be divided into two methods, i.e., 1) removing indoor heat by natural ventilation and 2) blocking the heat entering the building by solar radiation controls and heat transmission through building envelopes (Lee et al, 2017).

Natural ventilation is a basic technique for creating a comfort indoor climate and for reducing the cooling load of the building. Natural ventilation strategies that are commonly suggested for building in hot-humid climate is night ventilation and full-day ventilation. Night ventilation (or structural cooling) is based on the circulation of the cool ambient air to decrease both the temperature of the building's structure and the indoor air (Santamouris et al.,2010). According to Kubota et al., the application of night-ventilation in the urban terraced house in Malaysia could provide better thermal comfort for the occupants in term of operative temperature compared to the other ventilation strategies (Kubota et al., 2009). In the study of Jamaludin et al., the application of night ventilation was also found to be the most effective natural ventilation techniques for residential college building due to lower mean temperature values compared to other ventilation strategies (Jamaludin et al., 2014). However, when the night ventilation is adopted in a hot-humid climate (windows are closed during daytime), relative humidity tends to be high during the daytime, though the air temperature is reduced (Kubota et al., 2009). Meanwhile, full-day ventilation (or comfort ventilation) is a common method for achieving indoor thermal comfort in a hot-humid climate especially for the lightweight building. However, Givoni has demonstrated that continuously ventilated thermal mass can significantly lower indoor maximum temperature (Givoni, 1994). Wang and Wong investigated the impacts of various ventilation strategies and façade design on indoor thermal environment for naturally ventilated apartments in Singapore (Wang and Wong, 2007). In term of natural ventilation approach, they concluded better indoor thermal comfort can be achieved by the application of full-day ventilation than the other ventilation strategies. In general, by full-day ventilation, indoor air temperature would be increased with the increases of indoor wind speed but with a lower humidity level. Based on the reviews, though there are two different approaches of natural ventilation in the tropics, the most effective ventilation strategy that can provide better thermal comfort and indoor air quality is still uncertain.

Meanwhile, there are various strategies for solar radiation control and building's thermal modulation such as shading devices, building insulation, increasing of the reflectance of building's material and the application of high thermal mass structure (Lee et al, 2017; Gupta and Tiwari, 2016; Santy et al, 2017). The strategy of heat reduction for the roof is also important in the hot humid climate since the main thermal energy absorbed for habitable space is due to the heat fluxes crosses the roof (Givoni, 1994). Recent studies showed that the solar radiation control for the roof can be achieved by the implementation of reflective and radiative approaches in roofing systems (Obaidi et al, 2014), green roofs (Mahmoud et al., 2017) and hydrodynamic cool roof system with energy recovery (Chávez et al., 2016). However, most of these studies have been conducted in laboratory settings or to be applied with air-conditioning system. The scientific studies on the effects of the above-mentioned strategies to improve thermal performance of buildings under natural ventilation condition remain few especially by night and full-day ventilation strategy.

Therefore, the objective of this paper is to investigate the performance of passive cooling modification strategies under natural ventilation strategies of night and full-day ventilation by full-scale field measurement in the experimental houses. The aim of this study is to develop the comprehensive energy-saving modification techniques through passive cooling for existing urban houses in Malaysia.

Full-scale experimental houses in UTM campus

The full-scale experimental houses (two adjacent terraced houses) were constructed in the main campus of *Universiti Teknologi Malaysia* (UTM), in the city of Johor Bahru (1°29'N 103°44'E) in December 2015 (Figure 1). The experimental houses were designed to represent typical floor plans of Malaysian terraced houses. Each of the houses measure approximately 6.7 m by 9.8 m with a total floor area of 127 m^2. Meanwhile, the height of each floor is 3.1 m from the floor to ceiling. As shown, the building is oriented towards North. Each house has two master bedrooms on the first floor, facing North and South, respectively. The ground floor consists of living hall, dining hall and kitchen.

The houses are constructed of brick and concrete and had single glazing windows. In addition to the original plans, small slit windows were added onto the upper and lower parts of the main windows, partition walls, and doors. Moreover, exhaust fans were installed in the attic spaces, master bedrooms and staircase halls for experiments. The houses are not insulated except for both end walls that were insulated to eliminate the thermal influences from the outdoors.

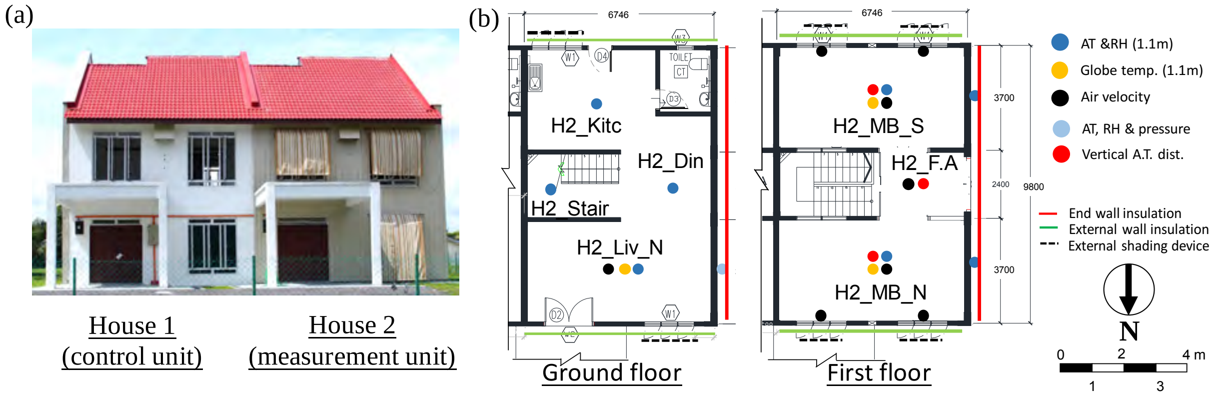

Figure 1. Energy-saving experimental houses in UTM campus. (a) Front view (b) Floor plans of the experimental houses. H2: House 2, MB: Master bedrooms, N: North, S: South, F. A: Family area, Liv_N: Living hall on North side. Din=Dining; Kitc=Kitchen; Stair=Staircase

Methods: Full-scale experiment

The full-scale experiment was conducted in two units of the above-mentioned experimental houses from June to September 2016. In the field measurement, one of the houses (House 2) was equipped with the proposed modifications (i.e. measurement unit), while the other house (House 1) was remained unchanged as a control unit. The proposed modifications include i) roof insulation, ii) external wall insulation (outside), iii) external shading devices, and iv) forced ventilation (for the whole house and for attic spaces). To be noted that the modifications were selected based on the results of previous study that examine the optimum combinations of the modification techniques for the urban houses through numerical simulations by using TRNSYS and COMIS (Kubota et al, 2017). Roof insulation was installed underneath the roof board of north- and south-facing master bedrooms of House 2. Meanwhile, the external wall insulation was installed on the outer surfaces of the external wall of the master bedrooms. Both insulations were of 100 mm thick rock wool form with a thermal resistance of 3 (m^2K)/W. Furthermore, the external shading devices were installed on all windows in House 2 except for the window located in the washroom. The shading factor was set to be 0.75. The windows were shaded during the daytime (8:00-20:00) and unshaded during the night-time (20:00-08:00). As for the forced ventilation, a large exhaust fan was utilized at 30 air change rate per hour (ACH) for the entire house, while the attic fan was at 40 ACH. Both of the forced ventilation were applied only during the night-time to reinforce the effect of night ventilation (structural cooling).

The main variables for the thermal comfort assessment were measured in the master bedrooms (first floor) of the two units at 1.1 m above the floor. The measured variables were air temperature, relative humidity, wind speed and globe temperature. In addition, air temperature and relative humidity were measured in the attic spaces and at the other spaces located on the ground floor, i.e., dining halls, kitchens and staircases of both units. The outdoor weather data were recorded by a weather station located in an open space approximately 40 m away from the units. The conditions for the experimental cases (Cases 1-6) are described in Table 1.

Table 1. Study cases

Study cases	Natural ventilation	House 1 (control)	House 2
Case 1	Night ventilation	• Opening: All windows • Techniques: No	• Opening: All windows • Techniques: Building insulation + external shading
Case 2	Night ventilation	• Opening: All windows • Techniques: No	• Opening: All windows • Techniques: Building insulation + external shading + whole house fan
Case 3	Night ventilation	• Opening: Main windows • Techniques: No	• Opening: Slit windows • Techniques: Building insulation+ external shading + whole house fan + attic fan
Case 4	Full-day ventilation	• Opening: All windows • Techniques: No	• Opening: All windows • Techniques: Building insulation + external shading
Case 5	Full-day ventilation	• Opening: Main windows • Techniques: No	• Opening: Main windows (day)/ slit windows (night) • Techniques: Building insulation + external shading + whole house fan
Case 6	Full-day ventilation	• Opening: Main windows • Techniques: No	• Opening: Main windows (day)/ slit windows (night) • Techniques: Building insulation+ external shading + whole house fan + attic fan

Results and discussion

Effects of proposed modifications in structural cooling (night ventilation)

From this section on, we compare the results of measurement unit (House 2) with that of control unit (House 1) in terms of indoor thermal environments in the master bedrooms. Figure 2 shows the temporal variations of measured air temperatures and relative humidity (RH) in Cases 1-3 that analyze the effects of proposed modifications under the night ventilation condition (see Table 1). As shown, the outdoor air temperature during the measurement period ranges from 23.8-34.5°C, while the corresponding RH ranges from 50-100%.

Case 1 shows the effect of roof insulation, external wall insulation (outside) and external shading (Figure 2a). As shown, the air temperature of the master bedroom of the measurement unit (House 2) was lower than the control unit (House 1) by approximately 0.5-0.8°C during daytime. Meanwhile, there was almost no air temperature reduction during the night-time. This is simply because all of the above three techniques are effective in reducing the effect of direct solar radiation on the building during daytime. The RH in both rooms is almost the same, ranging from 70-90% during daytime and about 80-90% during the night-time.

In Case 2, the whole house ventilation was adopted at night in addition to the above-mentioned three techniques (Figure 2b). As a result, the air temperature reduction can be seen not only during the daytime but also during night-time. The air temperature reduction by the modifications is about 0.8°C during the day and night-time. This indicates that the application of the whole house ventilation is effective in reducing nocturnal air temperature, but the resulting indoor temperatures are still higher than the outdoors by about 2°C. Furthermore, the RH in House 2 is found to be increased accordingly after the modifications by approximately 3% compared with that of House 1 for the whole day.

In Case 3, the attic ventilation was applied at night in addition to all the techniques of Case 2. As shown in Figure 2c, the air temperature of the master bedroom in House 2 is lower by up to 1.4°C during daytime and night-time compared with those of House 1. The air temperature reduction was slightly larger than the previous two cases. However, it should be noted that the maximum and minimum outdoor air temperature were slightly lower than that of Case 2. In this case, the RH level was always higher than the control unit by about 6-7% during the whole day.

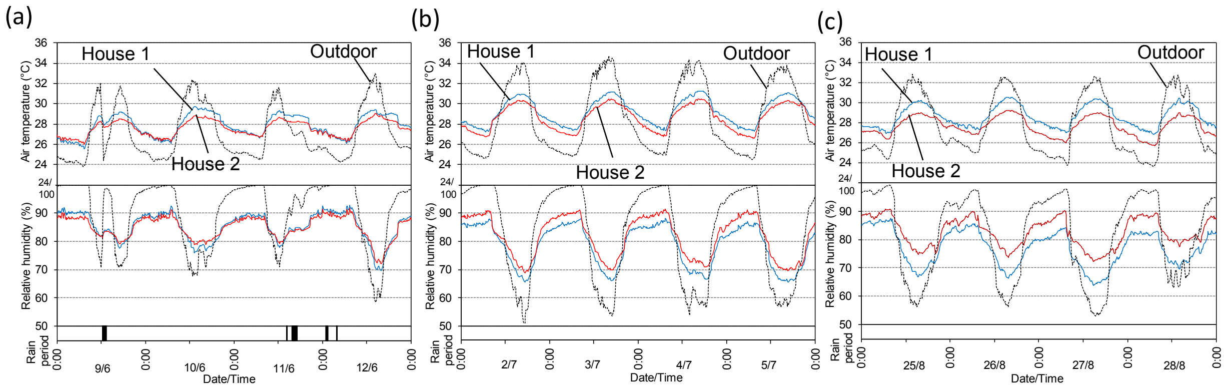

Figure 2. Temporal variations of air temperatures and RH in the master bedrooms of House 1 (H1_MB_S) and House 2 (H2_MB_S). (a) Case 1 (b) Case 2 (c) Case 3.

Effects of proposed modifications in comfort ventilation (full-day ventilation)

The same experimental cases were conducted under the full-day ventilation condition. Figure 3 shows the temporal variations of air temperatures and RH in the master bedrooms in Cases 4-6. As shown, the outdoor air temperature during the measurement period ranges from 23.0-34.0°C, while the corresponding RH ranges from 50-100%.

In Case 4 in which roof insulation, external wall insulation and external shading were applied, it was found that almost no air temperature reduction observed in the master bedroom of House 2 at daytime (Figure 3a). This is simply because the inflow of warm air into the room. Meanwhile, the nocturnal air temperatures were increased by about 0.2°C on average. This is probably because the thermal insulation on the building prevented the heat from releasing to the outdoor spaces. In this case, RH level between both rooms were almost the same for the whole measurement period. Indoor RH was reduced to as low as 53% during daytime and increased by up to 90% at night.

In Case 5, the nocturnal air temperature in the master bedroom of House 2 was reduced by up to 0.7°C when the whole house ventilation was applied (Figure 3b). However, it was found that the structural cooling effects did not result in reduction of daytime air temperatures. The daytime RH in both rooms is about 55-65%. In night-time, RH in the master bedroom of House 2 is about 8% higher than that of House 1. This is probably because the humid outdoor air entered the room by the whole house ventilation.

Meanwhile, unlike the previous Case 3, there is no significant reduction in the nocturnal air temperature in the master bedroom in Case 6, even when the attic ventilation was added to the previous case (Figure 3c). The reduction of nocturnal air temperature in the master bedroom in House 2 is almost the same as that in Case 5 (0.7°C). This implies that the air temperature reduction seen in Case 3 is not due to the effect of attic ventilation but due to outdoor weather condition. This indicates that the attic ventilation did not contribute in lowering the nocturnal air temperature in the master bedroom. This is probably because the cooling effects by ventilation through window was larger than that of the attic fan.

Overall, the air temperature reductions during daytime in Cases 4 to 6 (i.e. comfort ventilation strategy) are smaller than those of previous Cases 1 to 3 (i.e. structural cooling) as expected, mainly because the windows were opened during the daytime. Nevertheless, indoor RH in the master bedrooms maintained lower values ranging from 53-92% in Cases 4 to 6 instead in the case of comfort ventilation strategy.

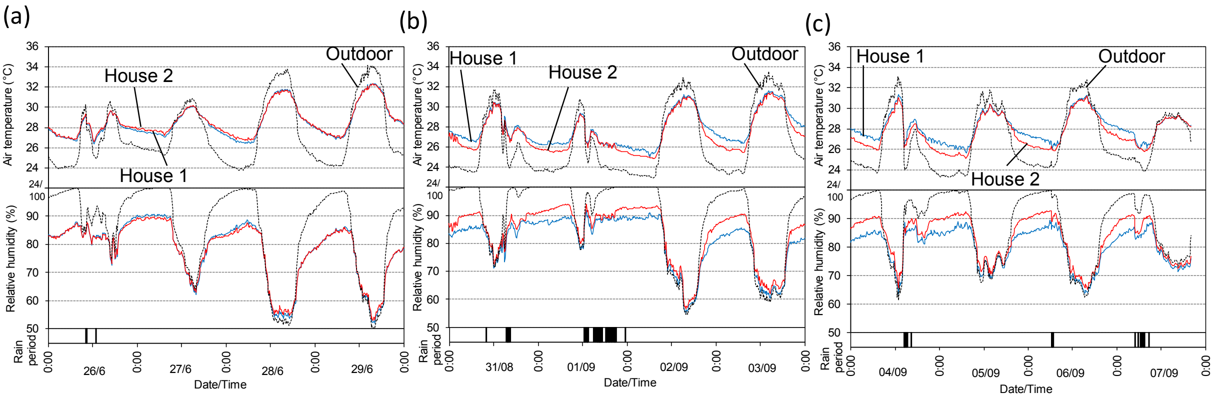

Figure 4. Temporal variations of air temperatures and RH in the master bedrooms of House 1 (H1_MB_S) and House 2 (H2_MB_S) (a) Case 4 (b) Case 5 (c) Case 6.

Thermal comfort evaluation in the master bedrooms

Figure 5 shows the daily average of indoor thermal environments in the master bedroom and the living hall under the two cooling strategies equipped with the proposed modifications (i.e. roof insulation, external wall insulation, external shading and whole house ventilation).

In the case of structural cooling (night ventilation), the air temperature in the master bedroom and the living hall tend to be lower than the corresponding outdoor temperature by up to 4.0-4.5°C during the daytime (Figure 5a). Meanwhile, in the night-time, the air temperature in both spaces are about 2°C higher than the corresponding outdoor temperature. In this case, the RH is always above 75% for the entire day.

In the case of comfort ventilation (full-day ventilation), the reduction of air temperature during daytime in the two spaces is smaller than those of the previous strategy (Figure 5b). The air temperature of the master bedroom and living hall are about 2°C and 3°C lower than the corresponding outdoor temperature. Nevertheless, it should be noted that the RH of the indoor spaces is lower than that of the previous strategy as expected, which is as low as 65% in the daytime. Meanwhile, the air temperature difference between indoor and outdoor during the night-time is almost the same as that of the former strategy, which is about 2°C higher than the corresponding outdoor temperature.

Operative temperature (OT) and SET* are used as indices to evaluate thermal comfort in the master bedroom and the living hall. As for the OT, the thermal comfort is evaluated based on adaptive comfort equation (ACE) developed for naturally ventilated buildings in hot-humid climates (Toe and Kubota, 2013). The 80% adaptive comfort upper limit from ACE is used for the evaluation. Meanwhile, a metabolic rate of 1.0 met and a clothing value of 0.4 clo are applied in the calculation of SET*.

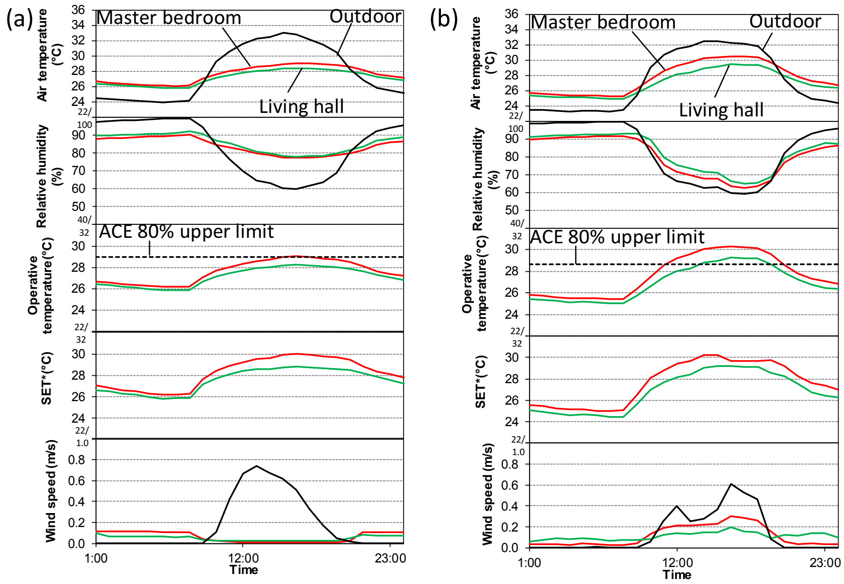

Figure 5. Indoor thermal environment of master bedroom of the proposed energy-saving strategy. (a) Structural cooling strategy and (b) comfort ventilation strategy.

As presented in Figure 5, the calculated OT of the master bedroom and the living hall in structural cooling record lower values (28.0 to 29.0°C) than those in comfort ventilation (29.0 to 30.0°C) during daytime. The OT of master bedroom and living hall in structural cooling generally fall within the limits, while those in comfort ventilation exceed the limit over 30% of the measurement period. Nevertheless, when SET* is used for the evaluation, those in the two spaces in the two cooling strategies show almost the same values during daytime (approximately 30.0°C and 30.3°C SET*). This indicates that if the effect of sweat evaporation is taken into account by using SET*, the resulting thermal comfort levels in the two cooling strategies are considered almost equal.

On the other hand, it can be said that the relatively lower RH in comfort ventilation is more tolerable than that in structural cooling since constantly high humidity condition (>70%) would cause mold growth (Johansson et al, 2012) and health related problems (Sterling et al, 1985). Hence, it can be concluded that the cooling strategy of comfort ventilation is probably preferable than that by the structural cooling for the hot-humid climate of Malaysia.

Conclusions

- The application of proposed modifications, i.e. roof insulation, external wall insulation, external shading and whole house ventilation successfully reduced indoor air temperatures by about 0.8°C during the day and night under the structural cooling strategy. Meanwhile, in the comfort ventilation strategy, the temperature reduction could only be seen during the night-time where the resultant air temperature reduction is about 0.7°C. Nevertheless, the whole house ventilation was not able to reduce the nocturnal indoor air temperatures as low as outdoor in both cooling strategies.
- It was found that the application of attic fan at night did not contribute in lowering nocturnal air temperature in the master bedroom. This probably because the cooling effects provided by the attic fan is smaller than that of ventilation through the windows.

- The resultant indoor thermal comfort of two different cooling strategies, i.e., structural cooling and comfort ventilation was evaluated by using OT and SET*. Although the OT in the master bedroom and living hall in structural cooling showed lower values than those of comfort ventilation, the SET* of these spaces in both cooling strategies was almost the same during the daytime (approximately 30.0°C and 30.3°C SET*). Considering not only indoor thermal comfort but also indoor air quality, the comfort ventilation (full-day ventilation) strategy was found to be preferable for the hot-humid climate of Malaysia.

Multi-objective window optimization of school buildings for thermal and daylight performance in the cold climate of China

Anxiao Zhang[1], Qiong Huang[1], Yanchen Sun[1] and Qi Zhang[1]

[1] School of Architecture, Tianjin University, Tianjin, China

Abstract: The objective of this study is to provide a methodology for optimizing the window design parameters of school buildings with respect to the triple objective of energy use, summer thermal comfort and annual daylight conditions. The optimized variables are window-to-wall area ratio (WWR) and window type characterized by visual and thermal characteristics. The adaptive thermal comfort model of ASHRAE 55-2010 was used to evaluate summer thermal conditions since most schools in the cold climate of China are naturally ventilated in summer. The sum of energy demand for heating and lighting (EDHL) was used to assess energy use. The Useful Daylight Illuminance (UDI_{avg}, between 100 and 2000 lx) was adopted in this research for daylight evaluation purpose. Energy use and thermal comfort were calculated using the software EnergyPlus, and the UDI_{avg} was computed using DAYSIM. A multi-objective optimization based on genetic algorithm was performed in order to balance the antagonistic effects of the window variables on different objectives. Moreover, a definition of the “overall best” solution for further screening was proposed. This method offers the advantage of quickly providing the optimal solutions to the problem at early design stages, providing guidelines for designers in making decisions.

Keywords: School building, window design, multi-objective optimization, thermal performance, visual comfort

Introduction

Environmental comfort and energy efficiency are important issues in school building design since schools accommodate children for long periods of time. A discomfort indoor environment will negatively affect the health and performance of students and teachers (Corgnati et al., 2007). In the cold climate zone of China, the coldest mean monthly temperatures are between -10°C and 0°C, while the average temperatures in July range between 18°C and 28°C (GB51078-93, 1993). Such continental climate presents a big challenge to both architecture design and human activities from the view of an entire year: during winter, huge energy consumption is required to maintain constant indoor temperature of schools, while in summer most school buildings are free-running buildings without cooling system, leading to serious heat stress. Furthermore, a high level of daylight condition in classrooms is generally required to meet students' reading and writing demand.

Windows in school buildings characterize both thermal performance and visual comfort patterns. The size and physical properties of the window determine the availability of solar radiation entering building, which directly influences the energy demand of buildings or indoor thermal comfort through heat transfer process. On the other hand, the visible part of solar irradiation, namely daylight, affects the illuminance level of classrooms and changes lighting schedule, and thus indirectly influences lighting demand. Furthermore, it becomes even more complicated for buildings in the cold climate of China, where in hot summer solar radiation needs to be blocked outside the buildings, while in winter it is more inclined to absorb heat from solar radiation. For example, apparent window sizing contradictions occur when maximizing thermal comfort in summer but minimizing heating demand in winter.

In this paper, a method for optimizing the window of school buildings based on thermal performance and taking into account daylight was proposed. Three objectives, namely the sum of energy demand for heating and lighting (EDHL), summer thermal comfort and visual comfort, were optimized in the process. Window-to-wall area ratio (WWR) and window type were chosen as the design variables. The Pareto approach was applied to find the equally optimal solutions for the problem. The results will be used to improve facades design for school buildings in the cold climate of China.

Optimization methodology

In this research, the 3D graphic software Rhinoceros and its plug-in Grasshopper were applied to control the geometric parameters. The plug-ins Ladybug and Honeybee were used to add physical properties of building envelopes and connect to the energy simulation software EnergyPlus, and also the daylight simulation program Radiance. To evaluate energy consumption, annual EDHL was calculated as a main objective. Moreover, since most school buildings are naturally ventilated in summer in the cold climate of China, the adaptive thermal comfort model of ASHRAE 55-2010 was used in this study. The standard is based on the database compiled from several countries worldwide and has been proven more reliable than the standard Predicted Mean Vote (PMV) index in free-running buildings (De Dear et al., 1998). The summer thermal discomfort hours was then calculated. For visual comfort, the dynamic daylight metric Useful Daylight Illuminance (UDI) (Nabil et al., 2006), namely annual occurrence of illuminance at a given point that falls within a given range was applied. To describe classroom space, the average Useful Daylight Illuminance (UDI_{avg}) was calculated averaging the values of all the measurement points in the classroom. The threshold of UDI_{avg} was set at 100 lx and 2000 lx as a proxy indicator for both sufficiency and glare.

Furthermore, Octopus, an evolutionary multi-objective optimization component, was applied to perform the optimization. The Octopus is based on SPEA-2, an improved multi-objective evolutionary algorithm, which has shown to have advantages over NSGA II in multi-dimensional space (Zitzler et al., 2001). In this study, design variables are treated as genes and objectives as fitness values. In the multi-objective optimization, the Pareto approach was used, which provides a trade-off method among the objectives energy demand, thermal comfort and visual comfort. The Pareto front is mathematically defined as follows: Consider a system with function $f:\mathbb{R}^n \rightarrow \mathbb{R}^m$, where *X* is a compact set of feasible decisions in the metric space $\mathbb{R}^n$, and *Y* is the feasible set of criterion vectors in $\mathbb{R}^m$, such that $Y=\left\{y\in\mathbb{R}^m : y=f(x), x\in X\right\}$. We assume that a point $y''\in\mathbb{R}^m$ is preferred to another point $y'\in\mathbb{R}^m$, written as $y''\succ y'$ and called y'' dominates y'. Thus the Pareto optimal is $P(Y)=\left\{y'\in Y:\left\{y''\in Y: y''\succ y', y''\neq y'\right\}=\varnothing\right\}$. Pareto's simple idea of optimality can be verbally described as follows: "A solution is Pareto-optimal if it is dominated by no other feasible solutions, which means that there isn't any other solution, that is superior at least in case of one objective function value, and equal or superior with respect to the other objective functions values'' (Pareto, 1964). None of the Pareto solutions are better than the other, with respect to all of the objective functions. For a problem with multiple objectives, a set of Pareto-optimal solutions are obtained rather than a unique optimal solution, providing multiple choices for architects and policy makers. After a finite number of iterations in Octopus, non-dominated solutions, namely best trade-offs between those objectives, are produced and visualized.

Reference model

The reference model consists of a classroom of 10.0 m x 8.0 m with a height of 3.80 m, situated in the city of Tianjin in the cold climate of China. Four main orientations, namely south, west, north and east, are considered (Figure 1). It is assumed that the room is located on the third floor of a 5-storey building. The thermal transmittance from ceiling, floor and the partition walls that separate one classroom from other classrooms are set to adiabatic. The external wall is defined as a 0.30 m thick concrete-brick structure insulated with 50 mm board, with a U-value of 0.46 W/m^{2}K.

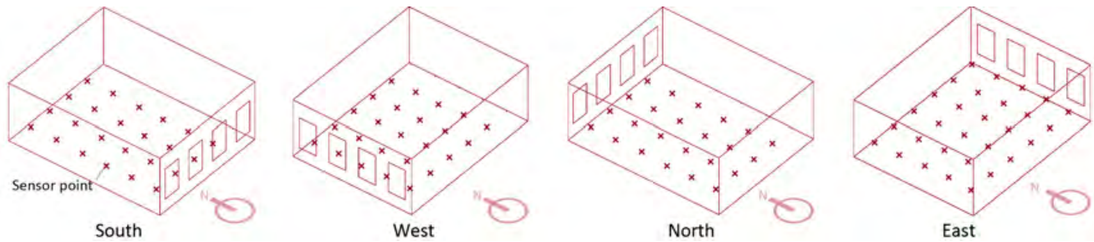

Figure 1 Three simulated classroom models. Lighting zone sensor points are placed based on a grid resolution of 2.0 m x 2.0 m at 0.8 m from the floor plane.

The school building is open from 8:00 AM to 5:00 PM during workdays. Typical Chinese school holidays accounting for 95 days annually are considered, which include holidays during the hot summer days and cold winter period. The lighting schedules for energy calculation are the results from daylight simulation by DAYSIM. In addition, the target illuminance value was assumed to be 300 lx for the classroom. A dimmed lighting system with an occupancy sensor is assumed. The photocell dims the activated lighting until the total work plane illuminance (daylight and electric light) reaches the minimum illuminance threshold. The Radiance calculation parameters are as follows: 6 ambient bounces, 1500 ambient divisions, 100 ambient sampling, an ambient resolution of 300, an ambient accuracy of 0.1, a limit reflection of 6, a direct threshold of 0, and a direct sampling of 0. The ideal loads air system is selected as the HVAC system in EnergyPlus, which is most suitable at the early-design stage considering calculation time cost. The heating set point is set at 18°C for classrooms. Internal gains (people, lighting density, etc.) comply with the requirements of local norms.

Design variables and objectives

The influence of window size is investigated with different window types for four main orientations (south, west, north, and east). The window size is estimated as WWR from 0% to 95%, with four glazing materials included in the window types, namely single clear glass, double clear glass, double low-e glass and triple low-e glass. More specifically, the details of the glazing materials are shown in Table 1.

Table 1 Characteristics of different window types

Type	Description	U-value (W/m^2K)	Solar heat gain coefficient	Visible transmittance
1	[Sgl: Clr 6 mm]	5.78	0.82	0.88
2	[Dbl: Clr 6mm/13mm Air/6mm]	2.67	0.70	0.78
3	[Dbl_LoE (e2=0.1): Clr 6mm/13mm Arg/6mm]	1.49	0.57	0.75
4	[Trp_LoE (e2=0.1): Clr 6mm/6mm Arg/6mm/6mm Arg/6mm]	0.78	0.47	0.66

Since Octopus can only solve minimization problems, the values of UDI_{avg} (100-2000 lx) need to be multiplied by -1. Similarly, summer comfort was evaluated using the percentage of discomfort hours. For energy evaluation, EDHL was applied. It is calculated as the annual energy consumption per unit of floor area (kWh/m^2) of the model. The objective is to minimize EDHL and maximize summer thermal comfort time and UDI_{avg} (100-2000 lx). The parameters of optimization algorithm are set as follows: elitism of 0.500, mutation probability of 0.010, mutation rate of 0.900, population size of 50 and maximum generation of 30.

Optimization results

The optimization was run for four times for different orientations with the above parameters. Each run took approximately 30 h on a computer with 4-core 2.70 GHz processor and 4G RAM. Figure 2 shows all the Pareto front solutions for the south-oriented and north-oriented classroom models in the objective-function space. These non-dominated solutions have one object-function out of the three that is lower than other solutions, being equally optimal.

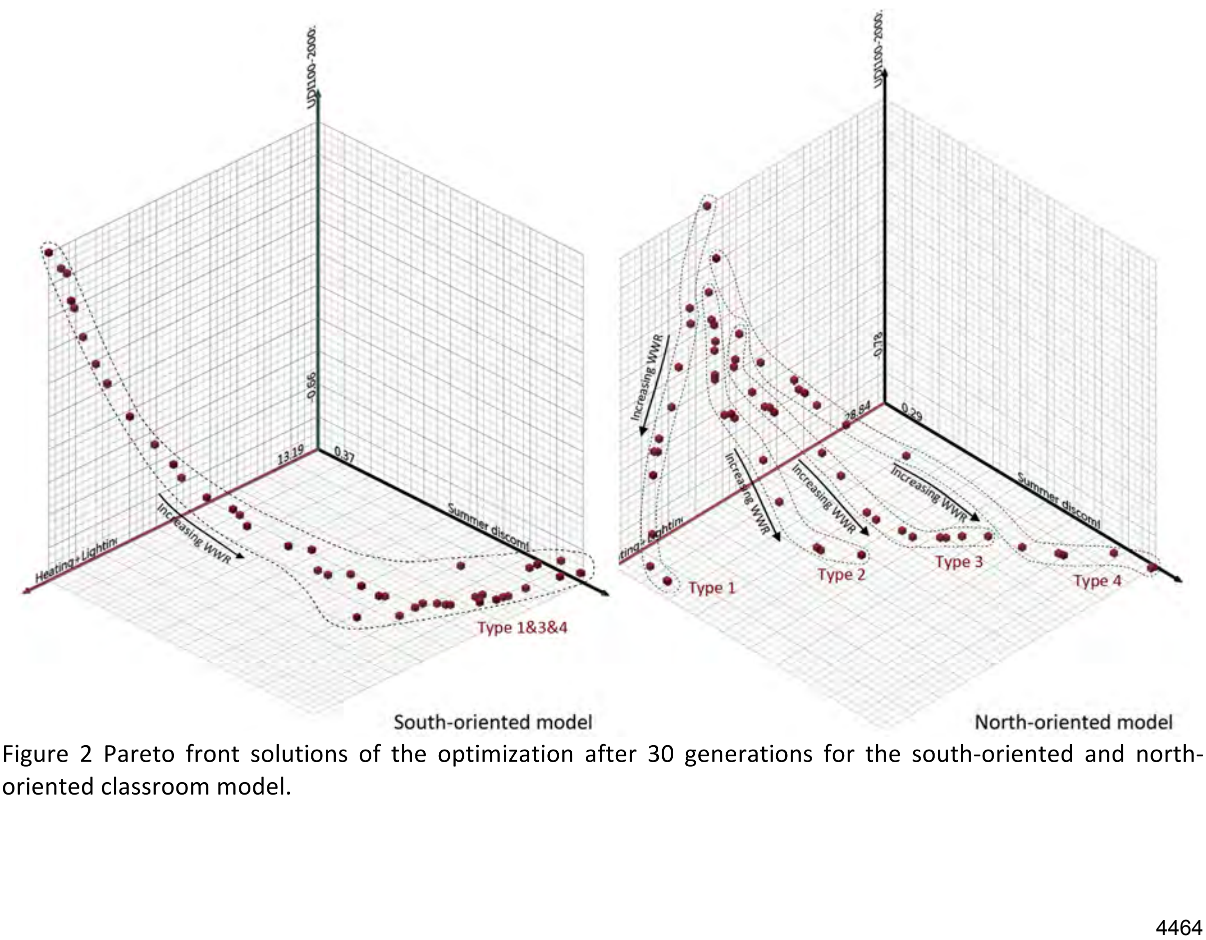

Figure 2 Pareto front solutions of the optimization after 30 generations for the south-oriented and north-oriented classroom model.

As can be seen, both of the Pareto solutions run from the upper left corner to the lower right corner. However, the Pareto solutions of the south-oriented model gather together into one line, while the solutions of the north-oriented model are grouped into four lines. Each line corresponds to a window type, and each point of the line corresponds to a WWR. Actually, the west-oriented and east-oriented classroom models exhibit similar grouping phenomenon (which is not shown here due to length limits). This indicates that window type has less impact on south-oriented classroom than the other three models, particularly for large WWRs. For better analysis of the non-dominated solutions, they were summarized in terms of their design characteristics and performances.

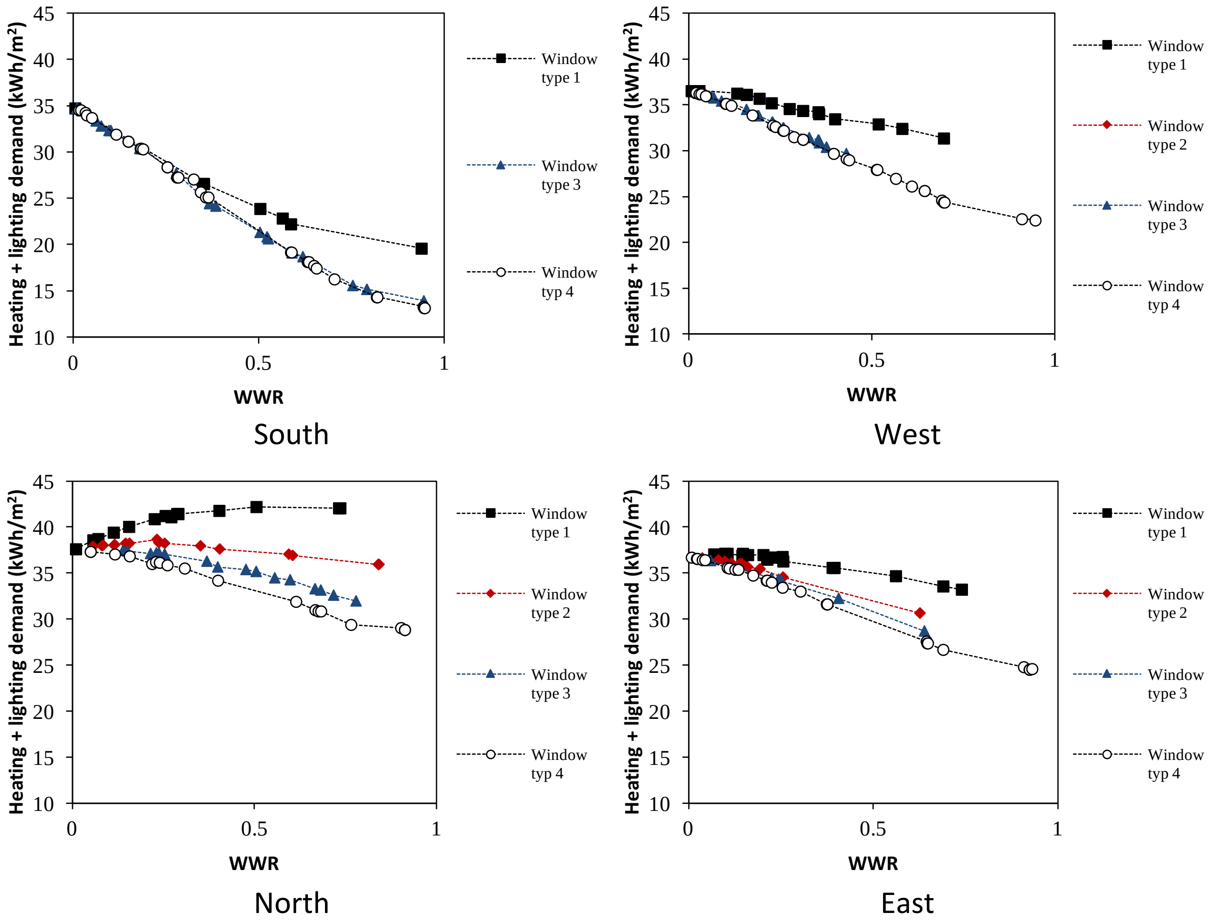

Figure 3 The energy performance for the Pareto solutions of four differently-oriented classroom models.

Figure 3 shows the energy performance for the Pareto solutions of four differently-oriented classroom models. It can be observed that almost all window types have a wide range of WWRs except window type 2, which is never optimal for the south orientation and only appears once for the west orientation. The EDHL decreases with the rise of WWR in most cases. The reason is that the increase of WWR results in more radiant heat and daylight penetrating into classroom, leading to the reduction of both heating and lighting demand. Furthermore, window type 4 shows maximum energy reduction for all the orientations when WWR increases, of which the U-value is the lowest ($0.78W/m^2K$), preventing heat loss to the greatest extent. On the other hand, window type 1 shows the least reduction, and there is even a slight increase in the north-oriented model as WWR increases. In this case when the U-value of window is high ($5.78W/m^2K$), the heat dispassion variation of the room due to the increase of window size is relatively larger than the sum of increased radiant heat and varied lighting energy. It is particularly obvious for the north orientation where there isn't any direct solar radiation, thus leading to the increase of energy demand as WWR increases. In addition, the energy demand shows the greatest reduction for the south-oriented room due to the large amounts of solar radiation. In high WWRs, south-facing room can reach a value of 13.3kWh/m^2, while for the other models the lowest energy demands are around 25kWh/m^2.

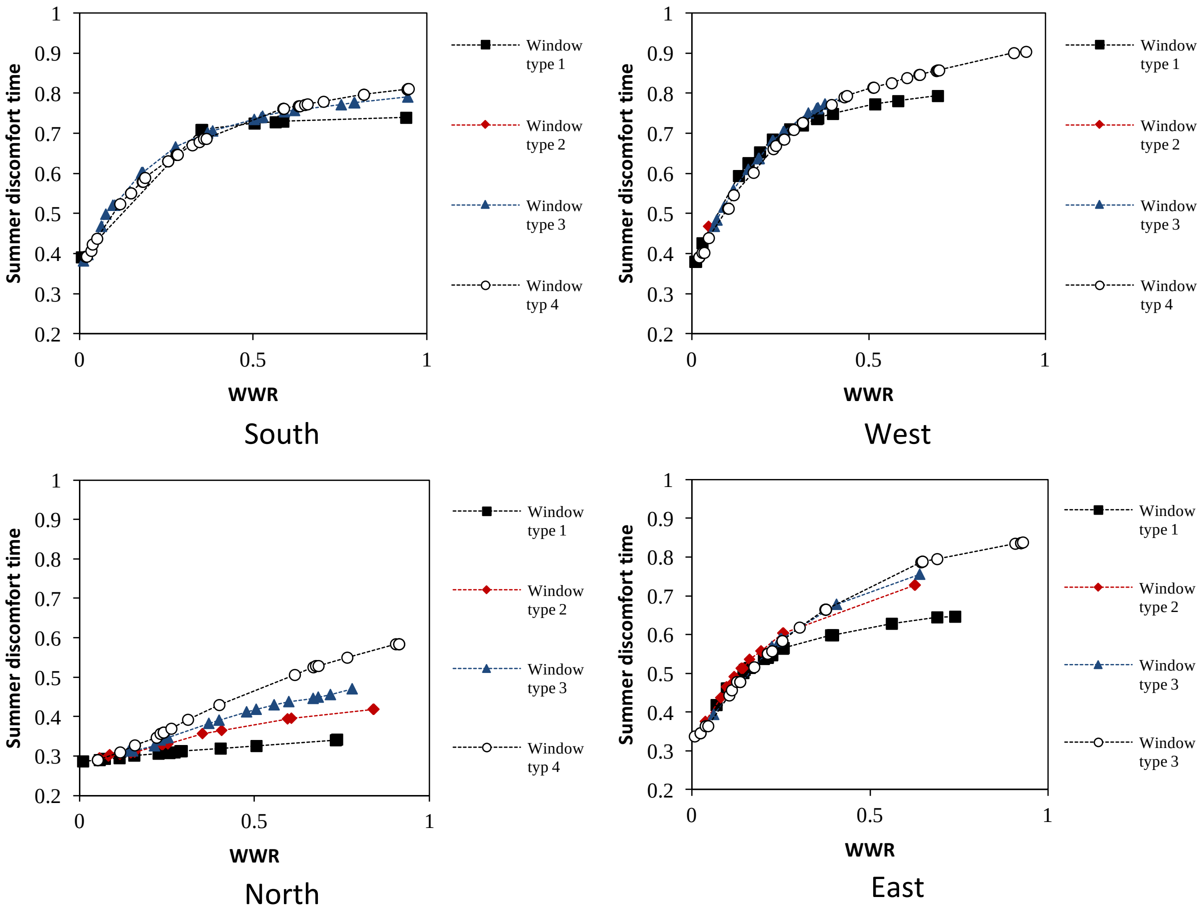

Figure 4 The summer discomfort time for the Pareto solutions of four different oriented classroom models.

The Pareto solutions for four differently-oriented classrooms were then summarized in terms of summer discomfort time, as shown in Figure 4. The discomfort time increases for all orientations as WWR increases due to the increased radiant heat entering the room. For a given WWR, window types with high U-values (e.g. type 1) lead to low summer discomfort time, particularly for large WWR models. In this case, the types with low U-value are not optimal for indoor thermal comfort since they prevent heat from going out and lead to overheating. Moreover, it can be seen that north-oriented room exhibits relatively lower summer discomfort time than other orientations because of no direct solar radiation.

Considering visual comfort, models of all the orientations show similar situations (Figure 5). UDI_{avg} (100-2000 lx) increases rapidly when WWR rises until approximately 50% when the UDI UDI_{avg} (100-2000 lx) remains at a stable level afterwards. A closer look at the four orientations when the WWR is large, the north-oriented model has maximum UDI_{avg} (100-2000 lx) (around 80%), while the south-oriented model has the lowest values (around

60%). The reason is that large WWR leads to excessive daylight penetrating into the south-oriented room and results in illuminance at some senor points above 2000 lx. Additionally, since the difference of visual transmittance of windows are smaller (maximum 0.22), the UDI_{avg} (100-2000 lx) exhibits similar patterns for all window types.

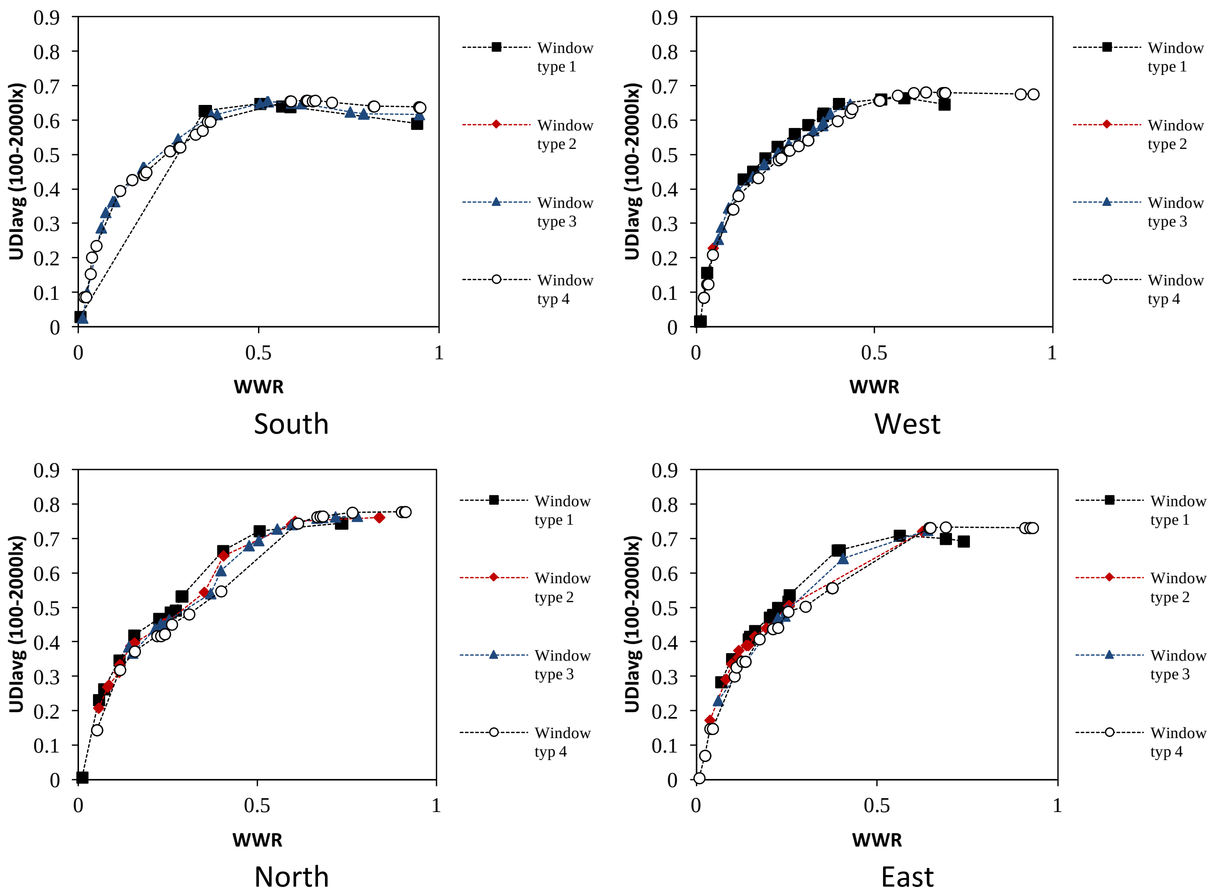

Figure 5 The UDI_{avg} (100-2000 lx) for the Pareto solutions of four different oriented classroom models.

Architects can choose any solution from the above Pareto front solutions. However, some extreme solutions might perform the best in some aspects irrespective of the other two performances. Thus a definition of the “overall best” solution is presented here for the reference of designers. It is the design nearest to the origin in the figure with the Pareto front which is calculated as follows (Eq. (1)).

$$OA_{best} = Min\left(\sqrt{\left(\left(\frac{(EDHL_i - EDHL_{min})}{EDHL_{min}}\right)^2 + \left(\frac{(STD_i - STD_{max})}{STD_{min}}\right)^2 + \left(\frac{(UDI_i - UDI_{min})}{UDI_{min}}\right)^2\right)}\right) \quad (1)$$

Where EDHL = heating + lighting energy demand, STD = summer thermal discomfort time, UDI = UDI_{avg} (100-2000 lx), I = result of iteration, min = minimum value in the set, max = maximum value in the set.

The final four chosen overall best solutions for each orientation are shown in Table 2. It can be observed that different oriented classrooms have different window “adaptation” methods to balance the three objectives. South-facing room has the highest WWR (74%) with window type 3, while north-facing room has relatively lower WWR (40%) with type 2. Moreover, both west-oriented and east-oriented rooms use small windows (10% and 11% of WWR respectively) with the highest U values.

Table 2 Summary of four overall best solutions for different models of orientation

Orientation	WWR	Window type	Energy demand (kWh/m^2)	Summer discomfort time	UDI_{avg} (100-2000 lx)
South	74%	3	15.6	77%	62%
West	10%	4	35.2	51%	34%
North	40%	2	37.6	37%	65%
East	11%	4	35.5	46%	33%

Finally, it is worth noting that decision-maker can choose site-specific solutions in terms of the relative importance of individual objectives on site. For example, allocating a weight to an objective-function or setting some constraints by eliminating some solutions according to on-site situation can help make better use of the Pareto solutions.

Conclusion

This paper proposes a method to simultaneously optimize three objectives, which are energy demand, thermal comfort, and visual comfort. The adaptive thermal comfort model and UDI_{avg} (100-2000 lx) were used in the evaluation of thermal comfort and visual comfort respectively. The design variables of the problem are window-to-wall area ratio, and the window type. The set of potential solutions was computed using Ladybug and Honeybee coupled with EnergyPlus and DAYSIM. Lastly, the Pareto approach was applied using Octopus to optimize the three conflicting objectives.

The results show that the increase of WWR will decrease energy demand, while increase both summer discomfort time and UDI_{avg} (100-2000 lx) in most cases. South-oriented room is more inclined to have lower energy demand whereas north-facing room has generally less summer thermal discomfort hours. Furthermore, some window types are rarely optimal in specific-oriented rooms, e.g., Type 2 is not suggested to be used in south-facing and west-facing rooms. High U value of window is beneficial to the decrease of energy demand but has negative effect on summer thermal comfort particularly for large WWRs. In addition, window types exhibit similar effect on the UDI_{avg} (100-2000 lx). Finally, a definition of the “overall best” solution to balance the multiple objectives is proposed for the reference of designers. This multi-objective optimization method offers the advantage of quickly giving the optimal solutions to the problem, providing guidelines for architects. The approach can also be used for other optimization problems in a design procedure.

Place Making and Wellbeing: The Story of Forbidden Space

Sahera Bleibleh

United Arab Emirates University , Al-Ain, The United Arab Emirates

Abstract: People mostly appropriate, and reappropriate, everyday spatial practices in time of peace as well as in time of conflict. In so doing, the "practice of everyday life" conveys much about place making and wellbeing. In wartime, home becomes a forbidden space where life is considered a collateral damage; therefore, people lose their memories and a life they once had. Place making fundamentally creates rightful environment that supports undisturbed everyday practice and equally empowers place attachment. This paper explores the ways in which people experience space disorder in warfare time when they were/are forced to evacuate and seek shelter in a temporary place not knowing when, or if they will ever be able to return home. It investigates the consequences of sudden blowing up home and its significant attributes. Following an ethnographic approach in the old town of Nablus and Jenin Refugee camp between 2010-2014, this paper discusses the spatial and behavioral disorder of war and displacement. It focuses on the impact of Israeli occupation military continuous assaults that transform the entire space of Palestinian life into a theater of war. Homes are no longer secured. The very intimate space and social life is dehumanized as the Israelis turned the Palestinian urban fabric into landscape of and for war. It also disturbed the essence of the daily life and created a "forbidden space" that contradicts the fundamental meaning of home. Such military strategy in the domestic space is meant to annihilate the everyday tactic of resistance under the occupation, which creates further struggle over the meaning of space/place thus questions the essence of place making, well being and trauma. In conclusion, peoples' narrative of place making helps us reimagine the spatial politics of emancipation in the aftermath of each attack. The resilience of space of enjoyment that arises against spaces of annihilation is a positive appropriation and transformation of forbidden space into place making. At this point, the assembling of everyday pieces into a collective space resonates with insurgent practices of temporary pleasure and create a space of joy and dominance.

Keywords: Place making, forbidden space, everyday life, wellbeing, Palestine.

Introduction

This paper attempts to discuss the responsiveness of the urban fabric of two compacted sites in Palestine to the social and socio-economic needs while continuously experiencing political struggle under the Israeli occupation. Drawing on ethnographic research among Palestinians whose homes were destroyed during the 2002 *Edjteyah*, in the old town of Nablus and later in Jenin Refugee camp. I explore the impact of Israel's *invisible* warfare upon the physical and social meaning of place, community, identity and "building with change." Interviews, focus groups and participant observations were conducted in Nablus from 2009 to 2011, and from 2012 to 2014 in Jenin refugee camp. These interviews were carried out with residents, refugees and institutional representatives. The inhabitants' experiences after their homes were invaded and bombed, and the ways in which they took care of themselves and worked to repair the damage, tell a story of resilience and agency that is critical to understanding the breadth of the "everydayness." Moreover, the inhabitants' interactions with the local institutions and established local committees that were involved in the repair process during the post-reconstruction presented, and presents, a significant example of people collective commitment to rebuild their homes based on the foundation of its historical legacy and their hopes for future that preserves their culture and identity. This effort not only reflects colonial power but also the humanitarian aid control over people's sovereignty.

According to Weizman (2007) in *Hollow Land,* during 2002 Israeli invasion "soldiers avoided using the streets, roads, alleys, and courtyards that define the logic of movement through the city, as well as the external doors, internal stairwells, and windows that constitute the order of buildings; rather, they were punching holes through party walls, ceilings, and floors, and moving across them through 100-metre-long pathways of domestic interior hollowed out of dense and contiguous city fabric." This maneuvering makes everyday life activities invisible where outside movement becomes the inside and people have no control on their domestic space anymore. The political dynamics create flexible medium where the inside is borderless against the external imposed control. The political space created by Israel's colonial occupation from the deep profound spaces of the West Bank (and Gaza) to their militarized airspace, Weizman unravels Israel's mechanisms of control and its transformation of the Palestinian land into a theoretically constructed artifice, in which natural and built features function as weapons and shells with which the conflict is waged. In exploring Israel's methods to transform the landscape itself into a tool of total domination and control, *Hollow Land* lays bare the political system at the heart of this complex and terrifying project of late-modern colonial occupation. Warfare delineates both internal and external spaces where public and private become a space of tactics and control where typologies no longer represent the real function of spaces in ways where the meaning of space is distracted. To reflect on such policy one of the interviewees mentioned that women, while inside, remained dressed up and wearing their veils in case of any unpredicted invasion of their living space, following the Israeli newly introduced military strategy of "walking through walls". These images intersect with de Certeau's argument on the mixed use of space between names and practices, "[t]he presence and circulation of a representation … tells us nothing about what it is for its users. We must first analyze its manipulation by users who are not its makers. Only then can we gauge the difference or similarity between the production of the image and the secondary production hidden in the process of its utilization." This notion might also be debatable when the *utilized* space is threatened by external forces that contribute to manipulate its perception.

The "walking through walls" strategy represents the logic of reorganization of the built urban syntax because it manipulates or ignores the existing pattern of streets or movement and replaces it with another more damaging circulation system. By liquidating urban structure, it becomes easier to control on-site planning where paths are determined in response to opportunities. It is, Eyal Weizman (2007) states, meant not just to occupy but also to reorganize the space of colonized cities, so that modern warfare with its high-tech weapons and surveillance systems can work to the colonizer's best advantage. Describing it as "design by destruction," Weizman asserts, "contemporary urban warfare plays itself out within a constructed, real or imaginary architecture, and through the destruction, construction, reorganization and subversion of space" (Misselwitz & Weizman, 2003, pp. 272-275). In this sense, military strategic thinking has been developed to overcome the complexity of the city; thus, war has evolved from being "in the city but for the city, by the city. The city has become no longer the locus, but the apparatus of warfare" (Misselwitz & Weizman, 2003, p. 279; Weizman, 2006, 2007). This unexpected penetration of war into the private domain of the home was also carried out in Iraq by the U.S. military. The strategy, based on joint military training between the United States and the Israeli armies, has become the most profound form of humiliation and trauma for the invaded communities (Misselwitz & Weizman, 2003).

The newly introduced Israeli military technique of “walking through walls” not only affected the significance of this hierarchical relation, but also the household members were left in fear and insecurity within their own “nuclear” space, and thus the “nuclear” space is no longer as private nor safe anymore; rather, it is a “forbidden space.” Space is forbidden for the participants to live freely, and allows for the Israelis to brutally invade their privacy and *normal* life. The bombing and the “walking through walls” military technique had turned their homes, possessions, and lives inside out. Several participants, like Um Raed, Um Jehad, and Um Jamal and her daughters, needed to remain dressed up with their head scarfs in anticipation of any possible future attack to their homes. The compacted urban fabric allowed for some flexibility to move between homes in time of the attack, which in some cases enabled the neighborhood to act as one family. As Um Jehad stated, “During the *Edjteyah* time, we were always dressed up and ready to leave … I was mostly concerned about my eighteen year old daughter. I didn’t know what to do except protect her with my body.” In similar context Um Jamal’s daughter said, “We slept wearing our *jilbabs* and *esharbs* [long dress and head scarfs]” and Um Raed stated with distress, “*Wallah ya binti* [With God’s name my daughter], we had tough days. Our inner space and privacy had been invaded, *enkashaf halna* [literally, “our situation had been exposed” to indicate an invasion of privacy]. ”

Furthermore the Israelis’ gave no consideration to the possible health impacts destroying walls that released toxic dust and other hazardous materials. Although Abu Ridha continues to live in the basement to be close to his assassinated son’s memories, he affirmed,

> “Since the day of the *Edjteyah* till now my livelihood was cut off, and I got sick, I have asthma because of the weapons and the tear gas used by the Israelis, later I had a stroke in the brain, a heart attack and nerves break down… [Looking around the basement, it is a small place with little furniture, the smell of mold, peeling paint, and a small window below the ceiling. It was dark and the light was turned on despite the daylight outside, and therefore the door was kept open].”

While the compacted urban fabric supports everyday urbanism in both sites, the political hybridization affects its vernacular resilience. When the “inside” is redefined to mean “invisible”, and “outside” is redefined to mean “visible”, patterns of movements are not governed by the order of space; rather the movement itself produces space around it. This metaphor introduces another perspective on understanding patterns of movement within the urban complexity strikingly leads scenarios to defeat the city’s customary space. The “outside” space metaphorically becomes Bhabha’s “third space” or de Certeau’s “site of resistance” and both represent the resilience of not only survival of people but also history and culture. The “inverse geometry” that was conceived to turn the city “inside out”, shuffling its private and public spaces, would now transform and re-conceptualize the sense of security and the meaning of space under pressured situations.

Lefebvre’s description of space as being a social product varies between the perceived space, the conceived space, and the lived space. All these categories make “as if the sum of the individual parts do not equal the whole”. The argument that people have influence over shaping their spaces, and that they are in turn shaped by them is valid; however, there are external forces that also contribute to shaping both spaces and people. Such forces are sometimes out of control, mainly when they are related to politics and conflict where their influence is either hard to ignore or predict. Though danger and fear are not physically represented, their implications are reflected on the physical urban structure the same way they are reflected on people. Therefore, the indirect unforeseen danger becomes a force of hybridity that shapes spaces the same as direct forces do. This correlates with Lefebvre's argument of space as social product, and also a political product, and here it's worth reconsidering Lefebvre's concept "the right to the city". How we will reflect on this concept when a place is destroyed, yet gaining more meaning and stronger memory?

Methodology

Building on ethnographic research in the old town of Nablus between 2009-2012 and in Jenin Refugee Camp in 2013-2014, to collect stories of people whose homes were destroyed during the 2002 *Edjteyah*, this article explores how the Palestinians encountered, and encountering, the aftermath of the Israel's invisible warfare upon the physical and social meaning of place, community, identity and "production of illegitimate social space." Interviews, focus groups and participant observations were conducted in both sites. The interviews were carried out with residents, refugees and institutional representatives. The larger research focuses on the peoples' experiences after their homes were invaded and bombed, and the ways in which they took care of themselves and worked to repair the damage, tell a story of resilience and agency that is critical to understanding the breadth of the "everydayness" and human well being. Also, their interactions with the local institutions and established committees that were involved in the repair process during the post-reconstruction of the historical town of Nablus and Camp presented, and presents, a significant example of people collective commitment to rebuild their homes based on the foundation of its historical legacy and embraces their distinguished sense of place and connectedness.

Production of Illegitimate Social Space and Wellbeing

Besides the damage caused by the "walking through walls," several buildings were totally destroyed in the old town of Nablus, and a complete neighborhood (Hawashin) in Jenin Refugee Camp. The municipality of Nablus steered the reconstruction in the old town of Nablus, and the UNRWA took care of the camp. During the 2002 Israeli invasion *Edjteyah* neighbors joined each other for refuge. Therefore, the interior space has been divided to accommodate gender privacy for those who were forced to stay together. For example, in a basement of one family of seven households has to accommodate fifty persons during the invasion. The basement was divided with a blanket and a hole was excavated to provide a toilet to avoid any embarrassment for women who want to have some privacy. This experience offered the opportunity to understand the space layout in time of danger. Consequently, the distribution of the interior layout was considered for amendments in the reconstruction phase.

While confined inside, most households learned more about what they considered "vulnerable areas" in their homes thus reconsidered the distribution of the internal space and introduced spatial modifications. These changes varied according to the use of space and the households' particular experience, for example, entrances, either by material, location, size, or additional entrance; interior layout and exchange of room use to distance bedrooms from the outside; new building materials and construction technique rather than the traditional one; opening size and location; increasing roof parapets height; external facades alignment; and street widening. Although committees of the local communities were established to share responsibilities in reporting on damages and needs, in several cases, it was the municipality decision based on case-by-case evaluation. The committees in Nablus and Jenin were jointly formed of those whose houses were damaged. Although women representation was limited on the official level, none of them were included from those who experienced the "walking through walls." Um Alaa's narrative explains the situation, "Imagine you and your family are sitting in your living room, watching television and chatting together after the evening meal … suddenly, you hear a tremendous roar and the wall disappears. The room fills with dust and rubble, and the soldiers, one after the other either with masked or painted faces, show up through the wall. The children are screaming, panicking … not knowing what to do or where to go when submachines guns pointed everywhere. It is like a nightmare!" Um Jamal, who lives in the old town of Nablus, was content to convey her needs to her son who was following up on the reconstruction of their damaged home. She states, "My son, Allah yerdha 'leih [God bless him] decided we need an external stairs as a second entrance, so we use it in times of emergency. It was constructed against the Municipal law [limitations on making any changes in the historical site], but we need it. As you see, the old town is so compact and we need a way out in case something happened. My son was checking the progress of work during the construction time, his approval was taken for any changes, we [as women] were not allowed to interfere, but we were fine with the outcome." Although Um Jamal expressed satisfaction of the overall reconstruction work, she and her daughter, similar to the case of most women, were excluded from the rebuilding process.

Perhaps one of the most tragic memories for some of the women of the *Hawashin* neighborhood in Jenin Refugee Camp was the loss of their sons, in top of the loss of their homes. Women were compounding the loss of their beloved and their homes. This double loss for Um Mohammed resulted in her inability to remember her son properly since much of their lives together emerged within the space of their home, which has been damaged. She affirms, "I swear by God that I can't recall this period [when my home was destroyed]. I remember myself standing in front of my home and I was shocked. I couldn't go inside the home because of the strength of the trauma. It was great loss: the loss of my son, my home and the memories where I raised Muhammad."

Rula was one of the camp residents relocated to a new quarter after the reconstruction. The new site, however, left her feeling alienated both from the memories of her son and the lives they built as part of the neighborhood. According to her, the destruction of the *Hawashin*, her home, and her son left her feeling in a state of extreme estrangement.

> "I still feel a tremendous loss. I lost my house, my neighborhood, and my neighbors with whom I lived for more than 20 years, with whom I gave birth to my children and raised them. I lost all the memories of those who have perished. Because of that, I am incapable of coping or adjusting to this new place."

Manar expressed similar feelings of loss and estrangement as a result of her son's death and the destruction of the *Hawashin*. "Whenever I remember these events, I feel sick with emotional stress. Bad dreams attack me day and night. Yesterday, I got up from my nap shouting that I had lost Imad. I screamed his name loudly. No matter what happens, a mother never forgets. I shall never forget, never." Like Rula, the link between her son's death and the destruction of the neighborhood complicated the present experience of the camp. "Honestly, I no longer see the camp as something beautiful even though it is much prettier and the infrastructure is much better. Many of the youth were either killed or imprisoned [during the attack], like my sons. Memories of a house are linked with its owner and, nowadays, when I walk through the camp and see the houses without their owners, I feel bad. I lose my interest to continue walking in the camp."

Obviously, contribution of women in the reconstruction of their homes was limited, if not eliminated. Husbands, sons and brothers steered most of the committees to communicate and follow up on the reconstruction. The pain of loss women were suffering kept them isolated from any crucial contribution in the reconstruction. They, later, have to live the hostility of living in a" cold and empty place" of their precious memories that were lost twice. Surprisingly, their contribution during the *Edjteyah* contradicts with theirs after. While they demonstrate heroic stories of steadfastness and resistance by supporting and feeding those who were fighting the Israelis during the invasion, their presence was eliminated during the reconstruction.

Conclusion

This article presented the accounts of Palestinian women who survived the Israeli Edjteyah of the old town of Nablus and of Jenin Refugee Camp. These representations offer a critical insight into the way some women experienced the Israeli assault. It argued that the memories of these women illustrated the complex intersections of voice in which individuals and the collective are deeply intertwined. Thus Palestinian women recalled the violence of Edjteyah from viewpoints that combined their own perspective on events with those of others in both sites. In this sense, Palestinian women offered a collective memory of the attack in ways that not only highlighted their solidarity with others but also positioned themselves within a larger social body. Their perspective was a shared one in which individuals and community were deeply imbricated. Moreover, women's accounts underscored particular forms of agency rooted in their social location as women. Motivated by their deep concern and love for their children, Palestinian women took great risks and defied the Israeli assault in ways that can be described as heroic. There actions, however, did not conform to the ideological constructions of the Palestinian nation. Rather, their accounts suggest an understanding and experience of agency grounded in their own social perspective as women who aid and support a resistance that they're never quite a part of.

Reinventing the Historic Townscape – a Guanshan Story

Yun-Shang Chiou[1], Yu-Hsi Hsieh[1] and Yu-Hsiang Huang[1]

[1] Department of Architecture, National Taiwan University of Science and Technology, Taipei, Taiwan, email: ychiou@mail.ntust.edu.tw

Abstract: Situated in the Huatung Valley in eastern Taiwan, Guanshan Township was established in 1915 by the Japanese colonial government to control aboriginal Taiwanese and to develop the valley's nature recourses. Grid-pattern streets, government institutions, public education system, agricultural and forest industries were carried on after WWII by the Taiwanese Government. It was not until 1980s when the eastern and western railways connected that Guanshan's population started to decline. Today, Guanshan is aging yet many old structures still stand. In the summer of 2016, a team led by the authors took initial steps to reinvent the townscape of Guanshan. The cultural corridor and the historic railway corridor were proposed to break the spatial pattern of homogeneity. With local residents' participation, three ill-managed sites in the corridors were transformed into highly popular public spaces with art installations. Several shopfronts were renovated. A series of events was hold in an old house to evaluate the feasibility of converting historic structures to public cultural facility. Precious lessons were learnt in the reshaping of public and private spaces of Guanshan.

Keywords: Guanshan, urban artefacts, direct experience, townscape, place making

Introduction

Covered by stone-filled land and lack of stable water supply, up till early 19th century, few human settlements can be found in the vast area over the 150 km strip of Huatung Valley. Occasionally, Bunun tribe in the Central Mountain and Amis tribe in the Coastal Mountain descended to the valley for hunting. This territory was not even on the map of Chin Empire. The first permanent settlements in Huatung valley were established in mid-19th century by Pinpu tribe. The Pinpu was displaced from the homeland in southern Taiwan due to territory expansion of Han-Chinese. Thanks to Pinpu's knowledge in rice farming, waterways were opened, land parcels were cleared, the food production was finally enough to sustain permanent population. Both Pinpu and Amis started to settle in the valley. By late 19th century, there are eight Pinpu settlements scatting across the valley, Guanshan (old name "Riran") was the southernmost of them. In 1895, Japan took over Taiwan from Chin, the Pinpu settlement of Riran was shown on the the 1902 and later maps (Fig. 1). In 1896 census of Riran, the population of Pinpu was 300 whereas that of Han-Chinese was 39 (Hsu, 2007).

Figure 1. 1902, 1924, 1944 Historic Guanshan (Riran) maps (Centre for GIS, Academic Sinica)

In 1915, the Japanese colonial government established Guanshan Township to control aboriginal Taiwanese and to develop the valley's vast nature recourses. On 1924 map (Fig. 1), the grid plan has replaced the original one-road settlement and guided the development of Guanshan in the following 90 years.

The grid plan of the Japanese Guanshan was centred on the east-west railway station – police station axis, signifying its role as the power of authority and the hub of transportation. Along the axis are the buildings for regional political- commercial activities. North of the central axis is the daily life axis evolved from the old Pinpu settlement. Public school, market, local shops, theatre, and Mazu (Sea Goddess) Temple all sit in this district. South of the central axis is the residential sector for government officials. The area was outside the original Pinpu settlement and mostly occupied by Japanese. On the north-south direction, supporting facility such as warehouses, railway dormitories were built along the railway whereas government and police officer's residences and supporting facilities were built along the front road of the police station (Fig. 2).

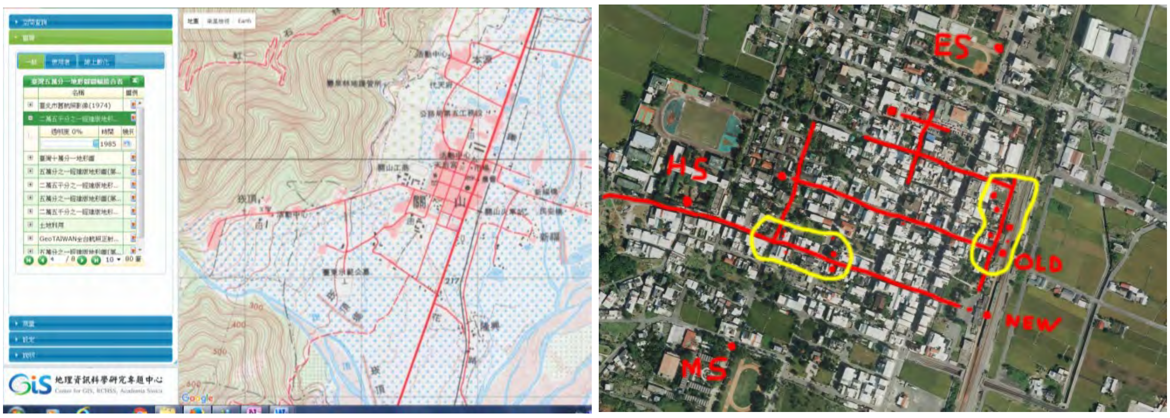

Figure 2. Guanshan 2009 Aerial Map (Centre for GIS, Academic Sinica) notation by the authors

The plots in the grids were divided into private lots. There was no room for public spaces. Different demographic groups lived in different sectors of the town and were highly segregated. A quick survey of the elders has found that most people only familiar with a small segment of the old town, they grew up together yet hardly sharing memories beyond their school life. It was a town of authority, a reflection of the mind-set of the colonial government. The life style of Guanshan continues long after Japanese left. While Guanshan is aging and losing young population to big cities since the connection of eastern and western railways in 1980s, segregated history of different demographic groups still left invisible barriers among town residents.

In the 2016 government commissioned project "Guanshan cluster of culture and creativity enterprises", the authors, who have been documenting the historic structures of Guanshan, led a team of NTUST students to reinvent the townscape of Guanshan according to modern values. The scope of work includes three public spaces and eight private shopfronts. Rossi's notion (1984) that the quality of urban artefact, like sound and smell, often can only be felt through "direct experience" is applied in many aspects - especially in the involvement of stake holders in the process of design creation. The project serves as an aspiration of the redevelopment of Guanshan in 21st century.

While the project itself is a great success with applauses from locals and publicities in news media, its limitation was also observed. Even if the town becomes people and business-friendly, local residents feel that without quality healthcare and education systems, it would still be difficult to attract young and senior families to settle down in Guanshan.

Design analysis – Guanshan in evolution

The scope of the project includes art installations in public spaces and renovation of shopfronts, exact locations were up to the design team. In approaching a cohesive philosophy in site selection and design intervention, the evolution of Guanshan townscape was first analysed.

Since established by the Japanese, the image of Guanshan is defined by two visual elements: the homogeneous street grids and the axis-based urban function districts. By choosing walking along or walking across streets of main axes, the sequences of urban artefacts that represent either similar or different urban functions will give very different tastes of and provide orientations to the grid-plan Guanshan (Fig. 3).

Figure 3. Street scenes of three functional district (official's residence, centre, Mazu temple)

The economy and population of Guanshan has faced continuous decline since 1980s. Out of the five functional axes previously described, only the regional political- commercial street axis and the "daily life" street axis still maintain their vitality. As a result, the image of grid-pattern now overtakes the image of axis-based urban function and gradually erases the sense of orientation of the historic Guanshan.

The change from an agricultural settlement to a political-commercial centre in 1915 also changes the pattern of interactions among the residents. In Taiwan's agricultural settlements, residents are bounded by their shared identity and it is quite common seeing clusters of people chatting in someone's front yard for pastime. Although surrounded by rice field with population around 3000, such scene was never observed in Guanshan. Privatization of properties and the invisible divisions among people of different demographic groups is also observed. It is likely a lingering influence from Japanese "class" specific policy that often seen in colonial ruling.

Guanshan's identity as an urban centre rather than a rural settlement indicates a need of public facilities for community bounding. It is interesting however, there was not such place in the official zoning of Guanshan during Japanese ruling. The only exception is the front court of Mazu temple in daily life street axis. It is not surprised because Guanshan was established to control local people at the first place.

Design strategy - Guanshan re-orientation

Rossi (1984) saw a city either as "a gigantic man-made object, a work of engineering and architecture" or "urban artefacts, which like the city itself are characterized by their own history and thus by their own form." Rossi describe the core presence of the urban artefact as "one is struck by the multiplicity of functions that a building of this type can contain over time and how these functions are entirely independent of the form. At the same time, it is precisely the form that impresses us; we live it and experience it, and in turn it structures the city." While Lynch (1960), point out the five elements that construct the image of a city, Rossi's emphasis on the importance of direct experience give a more intimate view on how the quality of a city is apprehended.

This project attempts to revitalize Guanshan townscape of grid plan and functional street axes and to create places that facilitate events to unite people. Rossi's notion of urban artefacts provides design guidelines to approach such objectives. The design solutions of new urban artefacts need to meet following criteria: 1. connecting past and present in visual context while its function can be free from historic reference, 2. maximizing stakeholders' direct experiences, especially "experience to share", of the quality of the urban artefacts.

Due to limitation of resources, the project team focuses only on "railway facility street" axis (the railway corridor) and old "residential sector for government official" street axis (the cultural corridor). The former was chosen because of its visibility to people in and out of Guanshan as the edge of a city, the latter was chosen because of its role as the corridor of education (district) and the connector (path) to the nearby village of Bunun tribe. The shopfronts were selected from a pool of volunteer business owners, based on the historic characteristics of the building and the contribution of the business to the vitality of daily life.

To expand the "direct experience" as shared memory, we intentionally invited different sectors of people to be involved in the project, including the initial discussions and the approval of design scheme in the town hall meeting, shopfront selection jury with local opinion leaders and the detailed design and construction with local artisan, carpenter, metal work, plumber, electrician and high school students and teachers.

Design implementation

a. The railway corridor

The old Guanshan railway station was built in 1936. For four decades, the railway station corridor has been the centre of town activities. Along the east-west main street facing the train station, there are shops, restaurant, hotels, and all kind of business. Along the north-south direction parallel to the railway, there are open water channel, linear garden, station chief's residence, dormitories for railway worker's families and the warehouses of farmer's association. The corridor carries the collective memory of Guanshan (Fig. 4).

Figure 4. Historic photos of the railway corridor (dormitory, old station, Jabin Hotel, vendor by the waterway)

The railway station corridor faces a steady downturn since late 1970s. . The connection of eastern and western railway drew people to cities. Local business started to decline. In 1980, a big fire burn down half a street block of the wooden structure facing the old station, a new station of concrete structure was erected 100 meter south and the old station was converted to warehouse. In coming years, the north-south water channel were covered and garden was removed to make motorway, the railway workers moved out and the dormitories fell into shambles. In 2015, most historic structures were gone; leaving only gravel ground and a few old trees from the past era. Government funded the restoration of the old station and station chief's residence in early 2000s. It brought back some memory but a sustainable business model was never developed. Today, three government registered historic buildings stand on the site, the old railway station, the station chief's residence and the Jabin Hotel. They are empty most of the time. In additions, a big old tree stands on the side of the old station. The small garden between them was in a mess and became a breeding ground of mosquitos.

The project team introduced new urban artefacts (Fig. 5) in the railway corridor (right "yellow box" in Fig. 1) to 1. Create a sequence of visual events (landmarks) that echoes to the collective memory of the "edge" of Guanshan (Lynch, 1960). 2. Make the corridor approachable and create visual sparks to attract people. The functions of the artefacts, however, are not limited to the historic use of this area.

Figure 5. Dormitory mural and old railway station side garden (before and after)

The most pertinent issue in the corridor is the uncomfortable condition of the railway side garden. Its sanitary condition indicates local people no longer have the capacity to maintain the greenery. Instead of replanting it, the project team chose to change it from wet-based to dry-based landscape and keep only four trees on the site. A line of sleepers was laid on the new gravel bed to give the garden a taste of an obsolete railway track. This newly created urban artefact not only solves the sanity and maintenance issues. It also introduces "direct experience". By stepping upon the sleepers, or by using it as a platform for train photography, the new function of the garden provides a connection to what the corridor was built upon.

The clean-up of the side garden exposes the view of Jabin Hotel across the road from the passing trains. In past 20 years, Jabin Hotel has been covered by sheet metals to protect its aging wooden exterior. The hotel has not been in commercial operation since the first-generation owner passed away in 2012. Once famous lines of roses along hotel perimeter now all died out. Rusts started to grow on the doors, exterior stairs and window trims. Without the fund for structure restoration, this project took two simple steps to make it friendly with surroundings again. First, the rusted surfaces were cleaned and repainted with historic green colour; second, the empty flower beds were removed and replace by long chairs with rose decoration pattern. The colour rearrangement makes this hotel in harmony with the nearby old train station. The street furniture provides a view of train passing by. It offers direct experience associating the hotel to the history of railway development.

Local high school students with architectural major were invited to take part in the implementation of the side garden and hotel exterior maintenance. They were also invited to take an in-depth survey of the hotel. The hope is that the younger generation will carry on the memory of the historic Guanshan to the future.

Back in the heydays, passengers on the train approaching Guanshan from the north would have seen a sequence of urban artefacts from the Japanese era: warehouses, dormitories, big trees, single residence of the station chief, Jabin Hotel and eventually the old train station. Travellers' description of the uniqueness of Guanshan experience was often started with the description of such visage. In order to recreate the linear experience of arriving Guanshan, the project renovated the naked cemented wall behind the gravel ground where the dormitory structures once stood. The wall is the exterior wall of the supermarket of farmer's association. Several public toilet entrances and a mud sink are attached to it. After reaching the conclusion that these functions are needed, the project team focused on how to change the perception of the wall. A cage was installed to seal the view of the mud sink. A famous local artisan was invited to paint a mural representing the railway worker's dormitory on the wall. The mural was painted in a section view according to historic colour scheme. Its proportion was purposely tweaked for selfies and for being seen afar. Individually, the mural attracts people approaching and staying around. Collectively, the dormitory mural, the single residence of the railway station chief, the big old tree, Jabin Hotel and the old train station reconstruct the historical visual experience of arriving Guanshan (https://www.youtube.com/watch?v=XCqyzr_2-bQ).

The mural turns out to be the most successful new urban artefact. Residents around the area constantly talk about how it reminds them the old days and changes the quality of the place. The visitors to the supermarket have increased. And the mural becomes a very popular scene of selfies in Guanshan.

b. The cultural corridor

The project team proposes to reinvent the steer axis of the government official's residences as the cultural corridor of Guanshan. From the functional aspect, it is a major deviation from the past. From the viewpoint of urban form, however, a change of use ensures the buildings carrying the memory of the town, will collectively find their place in the future.

After the Japanese left, a middle school and a vocational high school were established along this street axis by the Taiwanese government. At one end of the east-west running street is the new railway station. At the other end is the public vocational high school. The school is the highest education institution among the neighbouring counties. Further ahead, the mountain village of Bunun tribe is not far away. For decades after WWII, generations of students walking between the new train station and the schools, the official's residences they passed by every day, once the symbol of segregation, have long become the collective memory of Guanshan.

The function of the street as the official's residential sector has deteriorated overtime. Government policy changed and no longer provided housing for new public servants. Existing residents are reaching their eighties. Many wooden houses from the Japanese era are empty and in need of major renovation. Yet, no action has been taken since government finds no return for such investment.

By re-orienting the street axis to cultural activities, the project changes the purpose of the street from serving a diminishing population of former government employee to serving future generations in this region. Three steps were taken in this corridor: 1. An Art installation on an open space reflecting multi-racial culture and history of this region. 2. Renovation and utilization of an empty house from Japanese era to hold cultural events. 3. The renovation of several shopfronts to reinforce the historical image of the street.

The very reason for the creation of Guanshan Township was to control native Taiwanese. Bunun people living in the Central Mountain were the Japanese government's primary target. Over the years, Bunun people were displaced from their deep mountain settlements and forced to settle in the shallow mountain village nearby Guanshan. The relocation of Bunun people also brought their culture to Guanshan's daily life. The art installation, a woodwork composition representing the stretching clouds and the serpentine, was designed by the team and built by a Bunun artisan and high school students. It was placed on the open space in the mid-section of the street. Function wise, the art installation serves as benches in the park. They are designed to allow people to sit, to lie down, to chat face to face or even to picnic together. Icon wise, serpentine carries the meaning of friendship in Bunun culture and the stretching cloud by the hill is ubiquitous in Huatung Valley. The open space was there only because the old buildings standing on it deteriorated and fell apart. It created a breathing space, similar to Geddes's notion of "conservative surgery"(1915), to the development of the town. The new urban artefact, an art installation created from indigenous elements of Guanshan, is to give a sense of prestige and permanency to the open space. Hoping the open space will eventually become a permanent existence in Guanshan's townscape (Fig. 6).

Figure 6. Art installation in the open space of the cultural corridor

Figure 7. Events and actives in the cultural hub (renovated Japanese house)

Figure 8. Examples of shopfront renovation (signage, semi-open space and street furniture)

Across the street from the open space, an empty house managed by the town office was renovated. The house was constructed during the Japanese era. Later on, several spaces were added to the Japanese-styled structure. The exterior wall was installed with signboard for posters of events. Semi-open front yard was furbished with lights and benches for woodworking. The wall of entrance hall was painted as black board and furnished with desks and chairs for meeting and discussion. The front Japanese room was cleaned and stocked with toys for children while their parents take part in the house's event. The rear Japanese room was furnished with mattress to accommodate temporary stay. The original kitchen and dining space was placed with rows of chairs and a projector for lecture up to 20 people. Neighbours, artisans, teachers and students were invited to take part in the events hold in this renovated house (Fig. 7). The facility functioned well and the reaction was very positive.

Finally, several privately-owned buildings were chosen for government sponsored storefront renovation. Their typologies all bear significance to Guanshan's history. The objective of the renovation is to create a holistic image of Guanshan. The project did so by renovating storefront based on historic images, introducing storefront furniture and redesigning the business signage (Fig 8). Recent research (Zheng, 2014) has shown that street furniture give visitors more places to rest, resulting in longer stay. All the renovation works were carried out by local craftsmen - another kind of “direct experience”. The shop owners were very happy with the end products of the renovations.

Conclusions

In a time of drastic societal changes, many historic buildings can no longer be sustained by its original use. There are cases where the historic event is extremely important that the artefact associated to it should be kept at all cost. There are far more cases where such significance cannot be found. It is always a debate if there is a coherence approach to treat these everyday historic structures.

In this project, Rossi’s view of city as urban objects was taken as guidance. The creative forms were associated with the historic context yet their functions were allowed to change. It was the “direct experience” offered by the new urban artefacts reconnecting people with the memory of the past. The appreciation to people’s memory and the convenience of modern amenities of the renovated spaces bring high regard from people of all demographic groups in Guanshan.

In months after the completion of the project, the limitation of the townscape improvement is gradually surfaced: 1. Local civic groups do not have enough capacity to operate and maintain the cultural hub (the renovated house). And the government regulations would not allow business entity, even cultural related ones, to operate in it. It results in low utility rate of the space. 2. Local residents like the changes of townscape. Yet, people think, for any long term effect, the concern on local healthcare and education infrastructure need to be addressed. Good design can help community revitalization. But it is people that make changes. In addition to a quality built environment, sound regulatory environment and social infrastructure are still needed to make the changes sustainable.

Acknowledgements

Spatial study of Guanshan is funded by National Taiwan University of Science and Technology “DMUST” grant and by the Ministry of Science and Technology of Taiwan (Project No: MOST 105-2410-H-011-027 -). The design implementation presented in the paper is part of the “2016 Guanshan cluster of culture and creativity enterprises” project commissioned by Taitung County. The authors wish to acknowledge the valuable contributions of Petr Danda and Takanori Kodama, both international exchange students of NTUST, to the development of the design of the cultural corridor’s art installation and the railway corridor’s train station side garden.

The Integration of Urban Agriculture and the Socio-Economic Landscape of Future Cities

Andrew Jenkins[1], Professor Gregg Keeffe[1]

[1] School of Natural and Built Environment, Queen's University Belfast, Belfast, Northern Ireland, ajenkins02@qub.ac.uk/g.keeffe@qub.ac.uk

Abstract: Cities rely upon the provision of imported foods in order to feed their large populations. As a result, the ecological footprint of cities is far greater than their geographical areas. Through the integration of facade and roof-based food systems, agriculture within urban environments has the ability to grow vast amounts of food upon some of the most underused and undervalued areas of the built environment. Such large-scale agricultural systems would not only reduce a city's ecological footprint by reducing the need for imported foods, but they would also engage with the city at an economic and social level. The following paper aims to understand the additional positive impacts of urban agriculture - such as reduce air pollution, decrease depression, promote healthy lifestyles and create jobs - and postulates how such impacts might affect the physical health, mental well-being and financial security of urban populations. Urban agriculture is a viable driver of environmental change, but it is also a catalyst for social and economic reform.

Keywords: Urban Agriculture, Ecosystem Services, Social, Economic, Architecture

Introduction

Urban agriculture is capable of producing large volumes of crops upon the surface area of cities through the integration of horizontal and vertical based food systems (Jenkins, et al., 2015). In doing so, a multitude of supporting services are created such as air filtration, psychological restoration, and the creation of jobs. The following paper aims to understand the role these supporting services play in the physical, psychological and financial well-being of urban populations, and forms an overview of the different ways in which urban agriculture can benefit cities. The research, in most cases, does not aim to quantify these impacts but instead discusses the linkages between prevalent issues within cities and the additional services provided by urban agriculture. Although the research discusses the economics of urban agriculture, it is not the role of this paper to develop robust economic models. Instead, the paper aims to use simple methods of analysis to calculate the impact on local economies and the number of jobs created.

Global Food Demand

At some point during 2010 and 2011, the world's population surpassed 7 billion people for the first time in human history (ESA, 2015). As a result, a single hectare of agricultural land will need to supply enough food for 6.7 people per annum by 2050, whereas the same area of land in 1970 had only to produce enough food for 2.6 people (FAO, 2012).

The relationship between agricultural land share and food production is not always a direct one however. Due to increased economic prosperity and changing dietary habits, it is estimated that food production will need to increase by 70 per cent in developed countries and 100 per cent in developing countries by 2050, when referring to production values of 2005 through to 2007 (Bruinsma, 2009). If these estimations are correct, the increase in production will have to be met regardless of changing climates and concerns over energy security, without the cultivation of additional land and without further damage to essential ecosystem services (The Royal Society, 2009).

Ecosystem Services

Ecosystem services are described as the benefits that people obtain from ecosystems (Millennium Ecosystem Assessment, 2005). These include, but are not limited to, food, natural fibres, purification of water, air filtration, regulation of pests, pollination, microclimate regulation, medicinal substances, noise reduction, carbon sequestration, nutrient cycling, open space, and protection from natural hazards such as floods.

Since the inception of the first cities, the dependence on ecosystem services has not changed. The city of Uruk, founded by the Sumerians in 3500BC, was dependent on the flooding of the River Tigris and River Euphrates to enhance the fertility of their soils. However, this flooding was unpredictable and so led to unpredictable harvests. To combat this, the city constructed the first artificial landscapes; building large levees to contain the river and constructed sophisticated irrigation systems to distribute the water evenly to outlying farms (Steel, 2013). By moulding the natural world to suit their needs the Sumerians could predict their harvests more accurately, enabling them to hold a larger static population and in doing so, establish the basic ground rules of urban civilisation.

In 3500BC, city and nature combined to form the ‘city-state’, exemplifying the connection between prosperity and ecosystem services. Since the invention of global trade, however, these ecosystem services have been displaced well beyond the civic boundaries of today's cities. This disconnection not only shields urban populations from the vital role nature plays in their lives, but it also separates the very processes that are needed to keep people alive, happy and healthy from where they are most needed; cities.

Urban Health

Urbanisation is a process closely linked with economic development, but its impact on health and wellbeing can, in some instances, be dramatic. Non-communicable diseases (NCDs) - mainly cardiovascular diseases, chronic respiratory diseases, cancers, and diabetes - are the world’s biggest killers. More than 36 million people die annually from NCDs accounting for 63 per cent of global deaths each year (WHO, 2013). The primary causes in most cases of premature death from NCDs are tobacco use, an unhealthy diet, physical inactivity and the excessive consumption of alcohol. Although urban development cannot be held responsible for these risk factors, the urban context is associated with the adoption of lifestyles that favour the development of NCDs (Van de Poel, et al., 2009). This is due in part to increased exposure to outdoor air pollution, overcrowding, crime, stressful work and social isolation, as well as the increased consumption of salt and high sugar foods, reduced physical activity, and increased tobacco use. All of which increase the risk of hypertension and obesity, leading to increases in heart disease, strokes, certain cancers and diabetes (Mendez et al., 2009).

Depression and Anxiety

Psychiatric disorders, including stress and anxiety amongst other conditions, are one area in which the urban context can dramatically affect the wellbeing of an individual. Peen, et al., (2009) discovered that the presence of psychological conditions, on average, were 38 per cent higher in urban areas than in rural areas. This also included for depression and anxiety, which were 39 per cent 21 per cent higher respectively. Within the UK, the total cost of depression and anxiety in 2007 was £16.4 billion. These psychological disorders, as a result of city living need addressing to help increase the mental well-being of urban populations, reduce the economic strain brought about by these conditions, and to reduce the number of those affected developing more serious physical conditions.

Air Pollution

Another factor affecting physical wellbeing within cities is exposure to air pollution; compromised of particulate matter, ozone, nitrogen dioxide and sulphur dioxide. Urban air pollution can be responsible for such problems as Chronic Obstructive Pulmonary Disease (COPD), which is a collection of lung diseases including chronic bronchitis, emphysema and chronic obstructive airways disease. Within the UK, air pollution is estimated to reduce life expectancy by seven to eight months (Environmental Audit Committee, 2010) and within Europe, over 100,000 deaths are recorded per year as a direct result of exposure to fine particulate matter (WHO, 2003). The total direct cost of COPD to the National Health Service in the UK is over £800 million per annum, with the indirect cost of lost productivity to employers and the economy estimated at £3.8 billion a year (NHS Medical Directorate, 2012). The total cost of health problems related specifically to particulate matter is even higher; estimated to be between £9.1 and 21.4 billion per annum (DEFRA, 2007).

High levels of air pollution can exacerbate symptoms found within asthma sufferers and in some cases, can lead to fatal asthma attacks, which currently accounts for approximately 250,000 annual deaths worldwide. (Bousquet, et al., 2007). It is expected that urban air quality will continue to deteriorate globally with air pollution projected to become the top cause of environmentally related deaths worldwide by 2050 (OECD, 2012).

Obesity and Diabetes

Although not necessarily exacerbated within urban areas, (Peytremann-Bridevaux, et al., 2007; Befort, et al., 2012) obesity is quickly becoming a global problem. Diabetes, on the other hand, is projected to increase globally as a result of urbanisation (Wild et al., 2004). In 2012, an estimated 62 per cent of adults were overweight in England; 24.7 per cent of which were obese, with 2.4 per cent noted as severely obese (Public Health England, 2014a). In 2013, 2.7 million adults were diagnosed with diabetes in England; an increase of 137,000 people from the previous year (Prescribing and Primary Care Team, 2013). Within the UK, 10,000 premature deaths per annum are linked to obesity (Faculty of Public Health, n/d) with type 2 diabetes accounting for 23,300 deaths per annum in England alone (Public Health England, 2014b). Obesity costs the UK £4.2 billion pounds per annum and type 2 diabetes and its related effects on healthcare and the economy account for expenditures of £13 billion per year (Public Health England, 2014b). Only through challenging the risk factors associated with NCDs - specifically physical inactivity and poor diets - will the prevalence of obesity and diabetes start to decline, bringing with it healthier populations who live longer.

The Impact of Urban Agriculture

Due to the linkages between lifestyle choices and the primary risk factors of NCDs, the majority of premature deaths are largely preventable by tackling the associated risks (WHO, 2013). Although it can be argued that these risks cannot be directly resolved through urban agriculture, the integration of agriculture within urban environments can promote alternative lifestyles to those currently offered to help reduce their impact.

Human well-being consists of security, the basic materials for a viable livelihood (food, shelter, clothing, energy, etc., or the income necessary to purchase them), freedom, choice, good health, and good social-cultural relations (Millennium Ecosystem Assessment, 2005). Ultimately, all aspects of human life are defined by the access to ecosystem services such as food, clean water and fresh air. It can, therefore, be argued that the wellbeing of mankind is directly proportional to the health of the biosphere.

If the above factors of human well-being are combined with the primary causes of NCDs, three distinct categories emerge with which the impact of urban agriculture can qualified; physical health, psychological well-being, and financial security. The following will discuss how urban agriculture can benefit society in these three key areas.

Physical Health - Food Production

The most prevalent way in which urban agriculture can affect physical health is through the improved access to organic foods. In an effort to quantify city-wide food production, the authors of this paper designed and constructed a working elevated aquaponic food system in 2012/13. This system was constructed within a disused mill in Manchester, England and was capable of producing 16,500 crops per annum (Jenkins, et al., 2015). As part of this experiment a food producing facade prototype was also developed to explore the possibilities of vertical growing upon buildings (Jenkins, et al., 2014). Taking the crop production metrics of these two systems - 26.66 crops/m2 and 15 crops/m2 respectively, it was possible to calculate city-wide food production, using the city of Manchester, England as a case study. Through the use of three-dimensional modelling, an annual city-wide daylight study was produced and the vertical and horizontal data from the elevated aquaponic food system and façade prototype was applied. The resulting data concluded that the city centre of Manchester was capable of growing an estimated 180.4 million crops per year upon its vertical and horizontal surfaces (Jenkins, et al., 2015). Such production levels of organic foods would at the very least promote an increase in fruit and vegetable consumption, leading to improved urban diets.

Physical Health - Air Pollution

To progress this research further the same area studied for the daylight analysis of Manchester was investigated further to analyse the provision of green space within the city. It can be seen that the current proportion of green space within the city is particularly low (see Figure. 1). The city centre of Manchester covers an area approximately 402.3 hectares in size, of which green space accounts for only 24.2 hectares; approximately 6 per cent. Urban green space is key to improving air quality as it not only helps sequester carbon and produce oxygen, but also aids in the reduction of particulate matter, and can in some cases absorb ozone, nitrogen dioxide and sulphur dioxide

Taking into account only horizontal food systems upon flat roofs in Manchester, urban agriculture would add an additional 76 hectares of green space to the study area; increasing total green space by 314 per cent (see Figure 1). If vertical growing was also taken into consideration another 94 hectares of green space would be added - taking into account the reduction in crops/m2 compared with horizontal systems. Therefore, the total cumulative addition of green space within the city through the integration of urban agriculture would be 170 hectares; an increase of 702 per cent - making the city eight times more efficient at processing air pollution. The improvement of air quality within urban environments will not only better protect those suffering from respiratory diseases but it could also lead to the reduction in the development of respiratory diseases within cities.

Figure 1. Current green space within Manchester city centre (left) with possible green space (right)

Psychological and Physiological Wellbeing

Natural environments are said to have restorative qualities, which help the human body recover after periods of stress. This theory suggests that humans evolved a positive psychological response to unthreatening natural environments to allow fast and effective recovery from the stress response. It is believed that modern humans retained this positive response to natural environments and it is still as crucial today as it was many millennia ago (Ulrich, 1993). In this context, restoration is defined as 'the process of recovering physiological, psychological and social resources that have become diminished in efforts to meet the demands of everyday life' (Hartig, 2007). These restorative qualities include, but are not limited to, the reduction in blood pressure, levelling of heart rate, reduction in muscle tension, reduction in stress hormone levels and the strengthening of the immune system (Hartig, et al., 2003; Park, et al., 2010). This natural connection between humans and ecosystems is so strong, that restoration can even be achieved through non-tangible experiences - i.e. when viewed through a window - allowing people the opportunity for 'micro-restoration' in their everyday indoor environments. Although brief, these micro-experiences can combine to form measurable cumulative benefits (Kaplan, 1993).

The introduction of urban agriculture to the city of Manchester, England would add an additional 170 hectares of restorative infrastructure to the city. Although the majority of this newly created foliage would be inaccessible to most, the views out from buildings within the city would be transformed into a sea of vegetation spreading across rooftops, spilling down facades and engaging with the public realm. This in itself would bring with it a multitude of opportunities for micro-restoration throughout the day as well as opportunities for full psychological restoration through the creation of vegetative social spaces and centres for commerce.

Physical activity, although primarily linked with physiological well-being, has a profound effect on the psychological wellbeing of an individual. Exercise is key part of mental health but within urban environments, exercise in the traditional sense is hard to fit into daily life. However, even brief five-minute spells of green exercise can lead to large benefits (Barton, et al., 2010). Consequently, green exercise projects are increasingly seen as a valuable form of treatment for mental health problems.

Financial Security

It is estimated that the city of Manchester can grow approximately 180 million crops per annum, achieving a sale value of between £360 million and £720 million per year (Jenkins, et al., 2015). Such massive levels of crop production would require a substantial workforce. For the proceeding approximation of job creation within the city of Manchester the lower of the two estimates will be used for annual turnover; i.e. £360 million. This value is the sum of profit, human capital and running costs, which are extremely sensitive to external pressures and complex to calculate. Hence, simple existing information will be used to inform this data.

Tesco is a large supermarket chain in the UK and reported operational profits of 9.2 per cent in 2015 (Tesco, 2015). If this is applied to the projected turnover of urban agriculture in Manchester, approximately £33 million would be set aside as profit for future investment. The percentage spent on human capital by larger companies is approximately 70 per cent (Human Capital Management Institute, n/d); i.e. £229 million per annum. The remainder would cover utility costs, cost of repairs etc. at a cost of £98 million per annum. If the cost of human capital is compared to the average distribution of wages per 1 per cent of population within the UK (HMRC, 2015) the job creation of urban agriculture within Manchester can be calculated. For example, the 1st percentile of the labour force in the UK earns, on average, £8,370 per annum and the 99th percentile of the workforce earns, on average, £150,000 per annum (HMRC, 2015). By using the same proportions of wage spend per 1 per cent of population and applying it to the workforce of urban agriculture within Manchester, it can be calculated that 8,385 jobs would be created within the city at varying levels of importance and income. For the purposes of this exercise a sample of the data has been provided indicating 84.7 jobs are created for every one per cent of workforce, equalling 8,385 jobs in total (see Table 1). It should be noted that the top one per cent of earners have been removed from the study due to extremely high wages.

Table 1. Sample data of job creation when applied to percentile earnings in UK (UA=Urban Agriculture)

Percentile	Annual Wage	Percentage of wage bill	Money for UA Job Creation	Jobs created in UA
1st	£8,370	0.31	£708,949	84.7
50th	£21,000	0.78	£1,778,726	84.7
99th	£150,000	5.55	£12,705,188	84.7

Conclusions

By the year 2050 it is expected that 66.4 per cent of the world's population will be living in cities (ESA, 2014). Although cites are primarily man-made, techno-centric environments, they depend entirely on ecosystem services well beyond their civic boundaries. If cities are to become more sustainable and resilient to change it is likely that they will have to engage with ecosystem services at increasingly localised levels. Urban agriculture, in most respects, provides a solution to producing food where demand is highest. Although the food produced by urban food systems through non-intensive farming techniques (i.e. natural lit polytunnels and facades) will never be able to meet the full demands of urban populations, it can help reduce the need for imported foods, as well as reduce the need to cultivate natural environments elsewhere.

Air pollution, poor diets, physical inactivity, depression, anxiety and financial insecurity are all issues which affect the wellbeing of urban populations and urban agriculture can help remedy these issues to varying degrees. The integration of urban agriculture can greatly increase vegetation within the city, improving air quality and reducing the probability of urban populations suffering asthma attacks or developing chronic obstructive pulmonary diseases. Additional green vegetation within cities, even if not entirely accessible by the public can aid in reducing depression and anxiety through the restorative healing power of natural landscapes, and can aid in promoting exercise through the use of green corridors and the provision of engaging public spaces. Finally, urban agriculture can produce vast quantities of fresh organic food, promoting healthier diets, reducing obesity, and creating thousands of new jobs within greener, more engaging cities.

PLEA 2017 EDINBURGH
Design to Thrive

Empowering local people through the planning process: The emerging practice of 'Place Planning' and its contribution to community well-being in Wales

Matthew Jones[1], Amanda Spence[2]

[1] Department of Architecture and the Built Environment, Faculty of Environment and Technology, University of the West of England, Bristol, UK, matthew32.jones@uwe.ac.uk;
[2] Design Commission for Wales, Cardiff, UK, amanda.spence@dcfw.org

Abstract: The past twenty years has seen UK Government aspiring to put greater power in the hands of local people. In England, the 2011 Localism Act and 2012 National Planning Policy Framework have created new opportunities for local people to influence development. The Welsh Government has taken its own stance: the Planning Act 2015 (Wales); the Well-being of Future Generations (Wales) Act 2015 and the Active Travel (Wales) Act 2013 commit local authorities to improving social, economic, cultural and environmental well-being. Alongside these top-down processes, there is an emerging strategy to further engage local people in influencing the quality of their places and the well-being of their communities. A critical review of two tools designed to facilitate the Place Planning process in Wales is presented. Both tools help to increase opportunities for local people to have a voice in the planning process, and for the people who know places best to influence their well-being. However, questions are raised about the capacity and aspirations of communities to help deliver Place Plans, and assess the pressures on overburdened, under-resourced local authorities. Importantly, the increasing role of community-led initiatives has consequences for the role of designers and the skills they can contribute to place-making and well-being.

Keywords: Place, planning, well-being, community, Wales

Introduction

This is a critical point in time for our communities, with drastic reductions in local government spending placing greater levels of responsibility for the future of communities in the hands of their inhabitants. Increasingly stretched Local Authorities across the UK are focused on providing essential and statutory services, while planning and development services have faced cuts of 46% between 2010 and 2014 (National Audit Office, 2014, p4).

While in England the *Localism Act (2011)* has created new opportunities for local people to influence development, in Wales the *Planning (Wales) Act 2015*, the *Active Travel (Wales) Act 2013* and the *Well-being of Future Generations (Wales) Act 2015* have committed local authorities to improving social, economic, cultural and environmental well-being. Alongside these strategic policies, there is an emerging approach to further engage local people in influencing the future of their built environment through the development of 'Place Plans', led and authored by local communities and adopted as Supplementary Planning Guidance. These policies present a unique opportunity to redistribute knowledge and decision-making power to local people, offering the opportunity for communities to 'reclaim the initiative' and for the people who know their places best to inform their future.

In response to these agendas, this paper explores the emerging Place Planning process in Wales and its potential to empower communities to take control of their future and to increase community well-being. It is suggested that in order to enable local people to understand their place and make a tangible difference to it, new methodological approaches and tools are needed. The innovative 'Shape My Town' method of analysis, designed to enable community-led plan making in Wales and beyond, is critically reviewed. Developed by Coombs Jones Architects and Design Commission for Wales (DCFW), it is the first Place Planning tool to be developed and tested in Wales. It offers an approach founded on the need to construct an evidence base, created through analysis of the built environment, to inform community-led decision-making. Two iterations are discussed: 'Shape My Town', a freely available web-based toolkit giving local people the tools, resources and inspiration to help shape the future of their built environments; and 'Shape My Brecon Beacons', a bespoke evolution of the tool developed for the Brecon Beacons National Park Authority that extends the tool to include community well-being and cohesion.

We argue that these tools, founded on principles derived from urban design research, help to increase opportunities for local people to 'reclaim the initiative' in the planning process and for the people who know places best to influence their future and well-being. We conclude by discussing the opportunities and challenges of transferring plan-making to local communities and the impact of this on the role of designers in contributing to place-making and well-being. While the complex interplay of localism and austerity present *"an opportunity for progressive urban design and a rupture in business-as-usual urban development"* (Gray, 2016, p.4), these challenges have significant consequences for how designers conceive the urban environment and the skills they can contribute to place-making.

Community-led planning and well-being

Recent policy in the UK has seen a shift toward increasing participation in decision-making. The UK Government's 'Big Society' concept and the *Localism Act*, which gained Royal Assent in November 2012, is giving local people more decision-making powers and offering communities opportunities to shape their environment by developing local plans. Top-down is being replaced by bottom-up, with the aim of "*reinvigorating the most local forms of government – parish, town and community councils – allowing them to take control of key local processes, assets and services tailored to the needs of local residents*" (RIBA, 2011, p.7).

The devolved Welsh Government has taken its own approach. Welsh Government's '*Regeneration of Town Centres'* report recommends that within the framework of a local authority's Local Development Plan (LDP), individual communities should have a comprehensive plan in place developed by a partnership of stakeholders and the community (National Assembly for Wales Enterprise and Business Committee, 2012). The *Planning (Wales) Act 2015* similarly requires increased participation and public engagement in development planning. Alongside the accompanying *Positive Planning Implementation Plan (2015),* the Act introduced the notion of 'Place Plans' as Supplementary Planning Guidance, led and authored by local communities. Welsh Government's *Planning Policy Wales* states that, *'Selective use of Supplementary Planning Guidance (SPG) is a means of setting out more detailed thematic or site specific guidance on the way in which the policies of an LDP are to be interpreted and applied in particular circumstances or areas'* (Welsh Government, 2015 p.21). This represents a shift toward greater emphasis on place and community engagement in the plan-making process, giving individuals and groups a greater and more meaningful impact on the future of the places in which they live, work and play.

Alongside the devolution of plan-making power, Welsh Government has placed Well-being at the heart of Government policy. The *Well-being of Future Generations (Wales) Act 2015* and *Active Travel (Wales) Act 2013*, commit local authorities to improving social, economic, cultural and environmental well-being. The *Future Generations Act* introduces seven well-being goals, creating a shared vision for public bodies to work towards to support individuals and communities to sustain and improve their health and well-being. The five 'Ways of Working' outlined in the Act encourage integration, collaboration and involvement and place well-being at the heart of regeneration policy (see table 1).

Together, these Acts create an environment in which local people can have an increased role in considering the well-being of their place. Taking control of the future of their place can empower communities to bring into consciousness the conditions that shape their place in their world; this self-determination is linked to an increased sense of well-being, purpose and community cohesion (Deci and Ryan, 1985).

Table 1: The seven well-being goals and five ways of working described in the *Well-being of Future Generations (Wales) Act 2015*

Seven Well-being Goals	Five 'Ways of Working'
A globally responsive Wales	Long-term
A prosperous Wales	Prevention
A resilient Wales	Integration
A healthier Wales	Collaboration
A more Equal Wales	Involvement
A Wales of cohesive communities	
A Wales of vibrant culture and thriving Welsh language	

The 'Shape My Town' method

In this context, this paper illustrates the use of the innovative 'Shape My Town' method (www.shapemytown.org), developed to encourage and enable community-led, local planning in Wales and beyond.

The method was developed to reflect the importance of understanding the built environment in creating successful places and to promote a move toward greater consideration of place-making and distinctiveness in new development. Welsh Government has identified *"the physical quality of the town and its rural area"* as a vital component in developing *"vital and vibrant places"* (Welsh Government, 2012 p.4). Research by CABE suggests 87% of people agree that the quality of buildings and public spaces have a direct impact on the way they feel (CABE, 2002), and research by Gehl (2004) has similarly linked the quality of public space to social use and liveliness. It has also been demonstrated that good quality design plays a vital role in enhancing the well-being of inhabitants, strengthening community, improving social and physical health, and increasing civic engagement (Knox & Meier, 2009).

Created by Coombs Jones and DCFW, 'Shape My Town' builds on a body of work understanding the physical character of a place, including DCFW's publication '*My Square Mile*' and '*Ruthin: Market Town of the Future*', an award-winning community-led town planning project. The method provides an accessible web-based toolkit of information, guides and ideas to inspire and support community groups who want to play a part in shaping the future of their places. The target audience is predominantly non-professional and the tool offers a simplified set of questions to provoke discussion and analysis of urban design issues. The method consists of five phases that lead participants through setting up a plan team, building an evidence base for decision making, developing a vision, delivering a place plan and monitoring progress, summarised in Table 2. Best practice case studies, downloadable guidance and resources to help facilitate workshops and activities supplement the analytical tool.

The methods of analysis promote an approach to the understanding of places that is focused on the built environment. The primary aim is to reveal the sense of place and the components that give a place its character; as Powe and Hart (2016) identify, gaining an understanding of how a place has been affected by history and geography is vital in planning for its future. The analysis prompts consideration of the built environment at a range of settlement scales. The method draws on research that is morphological (Lynch, 1960), historical and visual (Cullen, 1961 & Worskett, 1969), multi-scalar (MVRDV, 2002) and people oriented (Gehl, 2004). While the above approaches tend to focus on one aspect of place-making, the Shape My Town approach is a qualitative multi-dimensional analysis that gathers, processes and reconstructs evidence derived from experiential, photographic, graphic and statistical surveys. The tool encourages local people to build an evidence base for change in their community through analysis of urban design issues, sense of place and distinctiveness, by working at a variety of scales, each with a series of guidance notes and associated ‘questions to ask’:

- Landscape: Setting, views, skyline, edges, parks and green space.
- Townscape: Heritage and history, form and layout, buildings and scale, and materials and detail.
- Streetscape: Public spaces, Streets and lanes, Furniture and surfaces.

Through evaluation and analysis of the information gathered and comparison to other places, key strengths, weaknesses and opportunities for improvement are revealed and taken forward into a place plan.

Pilot projects: Increasing community coherence

The tool was tested through pilot studies in two communities in south Wales: Abergavenny, a relatively sizable and prosperous market town in Monmouthshire, and Ynysybwl, a village in the post-industrial South Wales Valleys. In a day-long workshop in each location, members of local community groups and councils came together to test the evidence-building phase of the toolkit. Feedback was collected through observation of the workshop in progress and use of a questionnaire to gather formal feedback from participants. This process revealed a number of key issues that were addressed in amendments to the toolkit.

The emphasis on built environment did not allow exploration of community facilities and the relationships between community groups in any detail. It gave a specific focus to the evidence gathered that excluded vital aspects of community cohesion and how the community functions within its environment. The well-being of a community - the way health, educational, cultural, housing, employment, leisure and social needs are met - are important considerations in the planning process and by neglecting these aspects the tool was limited in its application. In many cases what is needed is not new buildings or public spaces but a greater consideration of how people live in a place and how their social needs are catered for.

Table 2: Comparing the Shape My Town and Shape My Brecon Beacons process

Stages of the process	Shape My Town	Shape My Brecon Beacons
Getting Started	-Setting up a town team -Working with the Local Authority -Working with the community	-Set up a place plan team -Form a relationship with the local authority - Reach out to the wider community
Gathering evidence	- Landscape - Townscape -Streetscape	-Context and setting -People and place -Buildings and facilities -Life between buildings
Evaluating the evidence	-Analysing and comparing your town -Evaluating distinctiveness	-Drawing out findings -Engaging the wider community
Writing a plan	-Preparing a plan -Consulting planning policy -Identifying issues -Your vision -Developing a framework -Measuring success	-Preparing a plan -Working with the local authority -Developing a vision -Developing a delivery framework
Agreeing and implementing a plan		-Agreeing your action plan -Stakeholder agreement -Agreeing the plan as Supplementary Planning Guidance -Monitoring and review

Considering community well-being: Shape My Brecon Beacons

Following development of the tool and pilot testing, Welsh Government announced a shift in policy toward greater consideration of health and well-being. Subsequent development of the tool has reflected the changing aspirations and remit of local authorities and the need for greater consideration of well-being as part of the planning process. In 2016 Welsh Government approached local authorities in Wales to develop concepts for place planning in their locale in light of these changes to policy. Working alongside the Brecon Beacons National Park Authority, The Shape My Town method was used as basis for a bespoke version of the tool for use in the National Park. In response to the pilot projects and the changing policy landscape, the scope of the tool was extended to further explore the function and well-being of a community, taking the emphasis away from the built environment. A further step in the development of the tool was to link the outcome of the tool to planning policy and enable emerging Place Plans to be adopted as Supplementary Planning Guidance. To achieve this, the tool emphasised the importance of positive relationships with the local authority and identified the role of planning officers in guiding and steering the plan-making process. Here, local authorities act as facilitators and mediators working with local people rather than implementing top down policy and procedure. This further addressed a concern with monitoring the use and effectiveness of the original web based tool; due to being freely available, it had proved difficult to track use and application. Through the involvement of the local authority in the process, the number and location of communities undertaking place plans in the authority area can be tracked and their development monitored.

The three analysis themes (landscape, townscape and streetscape) were reorganised to integrate community and well-being concerns, resulting in four new headings: Context and setting; People and Place; Buildings and Facilities and Life Between Buildings. As table 3 demonstrates, this reorganisation embeds well-being within the analytical framework to a greater extent that the original Shape My Town web tool.

Table 3: Potential well-being benefits addressed in Shape My Town and Shape My Brecon Beacons

Shape My Town	Shape My Brecon Beacons
Landscape: - Ecology and biodiversity - Physical health - Mental health	Context and Setting: - Ecology and biodiversity - Physical health - Mental health - Coping with climate change - Cultural identity
Townscape: - Cultural identity	People and Place: - Inclusivity and accessibility - Employment - Education - Health - Cohesive communities
Streetscape: - Spaces for social interaction - Accessibility - Connectivity - Active travel	Buildings and Facilities: - Economy - Housing equality - Low-carbon living - Coping with climate change - Environmental sustainability
	Life Between Buildings: - Accessibility - Connectivity - Spaces for social interaction - Active travel

While still founded on principles of place-making and analysis that works across a range of scales, the reorganisation encourages greater consideration of demographics, employment, public services and community services. The revised themes give a broad picture of the social well-being of a place and introduce a further layer of analysis to the method using readily available statistical data. Similarly, consideration of housing provision and tenure, access and transport connections extends the scope of the analysis and aligns the outcomes of evidence building more closely to planning policy objectives.

Conclusion: Reflecting on the process

The emerging importance of health as a policy driver is leading countries to explore mechanisms for improving community well-being. Initially a top down process, governments are increasingly searching for ways to support communities to improve their own social, economic, environmental and cultural well-being.

Fully developed in England and emerging in Wales, localised planning processes will create the opportunity for communities to produce their own place-specific plans, manage services and build small developments. This empowerment of local people to lead regeneration processes could see plans being created by people who know their place best. Tools such as Shape My Town offer benefits of a strong foundation of evidence, built on local knowledge and understanding of local issues.

To succeed at plan-making and realise projects, communities need to be able to mobilise a range of skills and resources. While this puts communities in charge of their future, it requires activation of social capital, whereby community members become fundraisers, coordinators and 'champions'. Facing deep-cutting austerity measures, there exists a lack of capacity within Local Authorities to facilitate this and provide the necessary support to communities (Powe et al, 2015). There is currently limited financial support available for this type of community development and local people are being asked to shoulder the burden. Where there is no expert involvement, tools and resources such as Shape My Town provide a way to fill this gap and guide local people through a methodical process, enabling Local Authorities to do more with less.

However, with limited expert input, there is a risk that planning processes led solely by local people could result in narrowed vision and insularity (Powe, 2016). While local people arguably know their place best, external experts can act as mediator, provocateur, initiator and consultant and offer routes to wider participation and successful implementation (Petrescu et al, 2016). Additionally, experts can help to promote active citizenship, entrepreneurship and capacity building to achieve change (Herbert-Cheshire & Higgins, 2003). Built environment design professionals can contribute creative problem-solving skills and an innovative approach to place-planning which is likely to be missing from community groups and cannot be replaced by a toolkit. The long-term value which expert consultants can bring to plan-making should not be underestimated or compromised by short-term cost cutting.

In the context of an evolving planning system in Wales, the Welsh Government and Local Authorities have an opportunity to engage with local communities through Place Plans so that they can make a real difference to their own environment and well-being. Tools such as Shape My Town can enable this process to happen with stretched Local Authority resources, but to maximise the impact and long-term value of Place Plans, investment in professional design and planning skills should not be overlooked.

Toward an Asian Sustainable Urbanism: A Comparative Study of Model Eco-city Projects in Japan and China

Zhongjie Lin[1]

[1] Associate Professor of Architecture and Urbanism, Director of Master of Urban Design program, School of Architecture, University of North Carolina at Charlotte.

Abstract: Asia has seen rapid development of eco-city led by governmental initiatives. The Japanese government continues to expand its "Eco-Model Cities" program, while in China, hundreds of towns have laid out their plans to become an eco-city, inspired by the national directives and high-profiled demonstration projects. In both countries, the eco-city is promoted as innovative urban policy under the agenda of sustainable urbanization and restructuring post-industrial economy. This paper compares the planning and development of model eco-cities in Japan and China, using Kitakyushu and Tianjin for case studies to examine their common and contrasting approaches to ecological urbanism, their respective design strategies and technological measures, the relationship between the eco-city building and local economic development, and the roles played by the governments and the private sector in this effort. Through the analysis of the policies and implementations of eco-city in both countries, this paper aims to offer a critical insight into the changing ideas of urbanity in Asian society, and engage discussion of the global issues of sustainable urbanism.

Keywords: Eco-city, sustainable urbanism, Kitakyushu, Tianjin Eco-city, Asian urbanization

Introduction

Although the concept "Eco-city" has been discussed and promoted for several decades, it was in the last ten years that we started to see an increasing number of large-scale projects translating it into practice. Eco-city is now a global phenomenon, yet Asia shows particularly notable development with strong governmental intervention, and witnessed ambitious, systematic national initiatives to build exemplary eco-cities. In Japan, the central government launched the "Eco-Town Project" initiative in 1997, then turned it into a more comprehensive "Eco-Model Cities" scheme announced at the 2008 G8 Summit in Hokkaido. So far twenty-three cities have been designated as Eco-Model Cities, ranging from large cities like Yokohama to small towns like Minamata. Financial incentives are provided to undertake major urban restructuring, low-carbon developments, and sustainable industries.

Arguably the most ambitious eco-city program, at least in terms of the number of initiatives and scale of projects, is currently taking place in China, where more than 100 eco-new towns are under development and some 259 existing cities have declared their intention to become an "eco-city" or "low-carbon city" (China Urban Sciences Research Council, 2011). The central government has created a number of high-profiled eco-city demo projects, such as Dongtan Eco-city in 2004 and Tianjin Eco-city in 2007. Eco-cities are promoted as innovative urban policy strategies and practices under the overarching paradigm of "ecological modernization," which seeks to de-couple economic growth from environmental degradation by incentivizing low-carbon, low-waste economic development.

This paper studies the planning and development of model eco-cities in Japan and China, using a comparative method to examine their policies and programs, design and development strategies, and technological specifics. It aims to extract some of the characteristics of contemporary Asian urbanism and map its path toward a low-carbon society. The comparison will mainly focus on the data of two model eco-city projects, Tianjin Eco-city in China and Kitakyushu in Japan, and address a few key issues of eco-cities in order to enhance the understanding of Japan's and China's policies and practices including their common, and contrasting, approaches to urban sustainability, the relationship between the building of an eco-city and local economic and cultural development, and the roles played by the governments and the private sector in this effort.

The Rise of Eco-City Movements in Japan and China

Eco-city in Japan was formalized in 1997 in legislation with a financial plan to support it. Twenty-six cities had been designed as "Eco-towns" in this program. In February 2008, the government established a Cabinet-level Panel on Low-Carbon Society to study solutions to deal with global warming and a wide range of related issues. One of the decisions made by the panel was the creation of "Eco-Model Cities." The panel chose model cities in order to promote drastic reductions of greenhouse gas emissions and encourage local communities to promote integrated efforts that incorporate existing knowledge and information into social and economic systems and make good use of local characteristics. Consequently, six cities – Yokohama, Kitakyushu, Toyoma, Obihiro, Shimokawa, and Minamata – were chosen from 82 total applications as the first group of Model-Eco Cities, which was announced at the G8 Summit at Hokkaido in 2008. Both the Eco-Town program and the Model Eco-City initiative address particular issues of Japanese society such as shortage of natural resources and the aging population. The eco-city concept is also seen in Japan as an effective way to revitalize previously environmentally degraded cities, direct national government funding to the most effective areas, and deal with climate change in the face of the reduction of nuclear power as a result of the 2011 Fukushima disaster.

China, on the other hand, is experiencing rapid and large-scale urbanization, and its urban environmental is facing unprecedented challenges under the dramatic growth. The 17th National Congress of Chinese Communist Party (CPC) in 2007 put forward the low-carbon eco-city model as an important part of the overarching agenda of "eco-culture" calling for the building of "a harmonious world characterized by sustained peace and common prosperity." More recently, "urbanization" was highlighted in the 18th National Congress of CPC, when Premier Keqiang Li called for leading the country's mass urbanization toward a sustainable path to create new venues for jobs, consumptions, and investments, to balance mega-cities with small towns, to correct economic disequilibrium between coastal and inland regions, and to improve energy efficiency and air quality. These directives have encouraged local governments to pursue eco-city developments. By 2014, more than 230 cities have responded with initiatives to create eco-cities or low-carbon cities following the standards set by the Ministry of Environmental Protection and the Ministry of Housing and Urban-Rural Development (Ghiglione, 2015).

A comparison of the eco-city movements in Japan and China reveals both common approaches characteristic of eco-city development in Asia as well as fundamental differences in their respective policies and strategies toward urban sustainability. One of fundamental distinctions involves the models of retrofit versus new town development. Retrofitting existing cities appears to be the primary way of building low-carbon cities in Japan. It stands in contrast to China's approach of planning and building numerous eco-cities from scratch due to its explosive urbanization. Another issue to compare is the difference between a top-down approach and a bottom-up one toward the eco-city. Both governments took the lead and played an important role in eco-city development, and the projects were carried through public-private collaboration. Comparisons of the case studies of Kitakyushu and Tianjin Eco-city illuminate the policies, designs, and implementation of eco-city in Japan and China.

Kitakyushu and Tianjin Eco-city

Both Kitakyushu and Tianjin Eco-city have a comprehensive ecological agenda and have established detailed environmental performance indicator system. Both receive substantial governmental support and enjoy extensive international exposure – Kitakyushu was among the first to be included in the Eco-Town program as well as in the Eco-Model City Initiative, and Tianjin Eco-city originated from the inter-governmental collaboration between China and Singapore. Both have developed incrementally for a number of years and seen the result of ecological planning. Tracking the transformation under the eco-city agenda, analyzing their spatial components, and comparing their indicator systems would provide insights into the different paths of sustainable urbanism in the two countries.

Kitakyushu rose as one of the early industrial bases of Japan in the early 20th century, and continued to develop through the post-WWII period. The growing manufacturing power, however, also impacted the city from the other side, making it one of the heavily polluted placed in the country. In the 1960s, the Women's Association in Kitakyushu launched the anti-pollution campaign, which pushed the local government to enact a Pollution Control Ordinance and the private sectors to sign on a series of pollution prevention agreements. The grass-root organizations continued to play an important role in the city's drive for sustainability, particularly after the emergence of Local Agenda 21 in 1996 (Sustainable Cities International, 2012). Despite all the top-down policies and incentives that the city has been readily received, Kitakyushu's pursuit of urban sustainability remains pretty much bottom-up practices and involved different walks of the city.

On the other hand, the Sino-Singapore Tianjin Eco-City (SSTEC) is a brand new town built from scratch under the inter-governmental partnership between China and Singapore. The eco-city occupies a total area of 34.2 square kilometers and will be home to 350,000 residents when completely built in 2020. The choice of the site with its majority being saline-alkali land and wasteland indicates the governments' awareness of ecological challenges and shrinking land resources and determination to tackle these issues. Planned by the government and developed primarily by state-owned companies along with their Singaporean counterparts, Tianjin Eco-city followed a top-down approach although the joint venture is operated like a corporation. The primary economic driver of such project is not incentives for environmental improvement, but rather financial return from land development. Most eco-city projects in China follow this path. They looked to Tianjin as a model for standards and implementation of planning and building an eco-city. They framed their indicators based on Tianjin's EPI system, and many sought international partners for importation of know-how and, more importantly, added brand value.

Environmental Performance Indicators

The Environmental Performance Indicators (EPI) is an essential tool for planning and evaluating the eco-city. The EPI defines a series of threshold or target indexes of social or environmental quality that the city intends to reach within a certain timeframe as the goals of sustainability. The approach to selecting indicators generally falls into two general categories, top-down or bottom-up. The top-down approach means policy makers define the goals and accompanying indicators, and the data collected is usually highly technical and requires experts to interpret. The bottom-up approach is community-based and involves extensive consultation with stakeholders to select appropriate indicators. Kitakyushu and Tianjin Eco-city represent these two different approaches to controlling and measuring the development of eco-city.

Table 1. KPIs of Kitakyushu. Source: City of Kitakyushu, *Kitakyushu Eco-Future City Plan*, 2012.

No.	KPI Area and Detail	Indicative Value	Time Frame
I. Environment			
1	Carbon emission	11.8million ton CO_2 (25% cut based on 15.6 million in 2005)	2025
2	Generation of renewable energy	730,000KW (up from 40,000KW in 2010)	2025
3	Reduction of carbon emission with green Transportation system	2,362 ton CO_2 (29% cut based on 3,315 ton in 2011)	2025
4	No. of strategic international cooperation projects	10 (up from 3 in 2010)	2025
5	No. of international environmental trainees accepted	3,000 in 2021-2025 (up from 2,077 in 2006-2010)	2025
6	Bio-diversity	Zero loss of species in protected area	2025
7	No. of people participating in eco-tours	1 million (up from 100,000 in 2010)	2025
8	Amount of lithium-ion battery recycled	25,000 ton (25% of Japan, up from zero in 2010)	2025
9	Solar panel system recycled	80MW (up from zero in 2010)	2020
10	Household waste generation and recycling rate	450g/household (down from 506g in 2009), 40% recycled (up from 30.4% in 2009)	2025
II. Responses to Aging Society			
11	Citizens who feel the efforts of health promotion have been enhanced	30% (up from 26.7% in 2010)	2025
12	Citizens who feel the efforts of regional medical (home care, etc.) have been enhanced	20% (up from 15.9% in 2010)	2025
13	Proportion of elderly people feeling their own health as "good"	50% (up from 38% in 2010)	2025
14	Employment of elderly people	25% (up from 20% in 2010)	2025
15	Citizen feeling the increase of a network of mutual support	25% (up from 20% in 2010)	2025
16	No. of schools supported by the business community	All elementary and middle schools (up from zero in 2011)	2025
17	Proportion of parents feeling support by people in the region	70% (up from 52.2% in 2010)	2025
III. Others			
18	Support of reconstruction of Great East Japan Earthquake disaster area using the outcome of Kitakyushu smart community	Consultation is being conducted	immediate
19	Total floor area of the data center facility	50,000 m^2 (up from 15,000 m^2 in 2011)	2025
21	No. of contracts of international business projects at Asian Low-Carbon Center of Kitakyushu	A total of 100 by 2025 (only 1 in 2010)	2025
22	Technology and know-how related to water supply and sewage to be exported abroad	6% share of the projected 31 trillion yen business of water treatment	2025

Kitakyushu's indicators system is based on the so-called DPSIR (Driving forces, Pressures, State of the Environment, Impacts, Response) System, a framework for organizing information about the state of environment. It is adopted by the European Environment Agency to assess and manage environmental problems by describing the interactions between society and environment (SCI, 2012). It is composed of the following components:

- Driving forces of environmental change (e.g. industrial production)
- Pressures on the environment (e.g. discharges of waste water)
- State of the environment (e.g. water quality in rivers and lakes)
- Impacts on population, economy, ecosystems (e.g. water unsuitable for drinking)
- Response of the society (e.g. watershed protection)

Kitakyushu city has revised the DPSIR into a more community-driven system by adding new elements that reflect the changes in the environmental systems and making it more relevant for the local conditions of Kitakyushu itself as well as the Asian cities that were included in the Kitakyushu Initiative. The result is a set of indicators reflected in the table 1.

Table 2: KPIs of Tianjin Eco-City. Source: http://www.tianjinecocity.gov.sg

No.	KPI Area and Detail	Indicative Value	Time Frame
I. Natural Environment			
1	Ambient air quality (days meeting National Ambient Air Quality II Standard)	> 310 / Y	Immediate
2	Quality of water bodies	Grade IV of China's national standards	2020
3	Quality of Water from Taps	Potable	Immediate
4	Noise Pollution Levels	Satisfy the stipulated standards	Immediate
5	Carbon Emission Per Unit GDP	< 150 ton/ $1 million	Immediate
6	Net Loss of Natural Wetlands	0	Immediate
II. Man-made Environment			
7	Proportion of Green Buildings	100%	Immediate
8	Native Vegetation Index	70%	Immediate
9	Per Capita Public Green Space	>12 m^2/person	Immediate
III. Life style			
10	Per Capita Daily Water Consumption	<120 L/day	2013
11	Per Capita Daily Domestic Waste Generation	<0.8 kg	2013
12	Proportion of Green Trips	90%	2020
13	Overall Recycling Rate	60%	2013
14	Access to Free Recreational and Sports Amenities	< 500 meter	2013
15	Treatment of hazardous and domestic waste	100%	Immediate
16	Accessibility	100% barrier-free access	Immediate
17	Services Network Coverage	100%	2013
18	Proportion of Affordable Public Housing	>20%	2013
IV. Developing a Dynamic and Efficient Economy			
19	Usage of Renewable Energy	>20%	2020
20	Usage of Water from Non-Traditional Sources	>50%	2020
21	Proportion of R&D Scientists and Engineers in the Eco-city Workforce	> 50 /10,000 workforce	2020
22	Employment-Housing Equilibrium Index (residents employed in the Eco-city)	> 50%	2013

Tianjin Eco-city's Key Performance Indicators System was developed in April 2008 based on the current Chinese national standards and best practices in Singapore. The framework includes 22 quantitative indicators and 4 qualitative indicators, as presented in table 2. The qualitative indicators appear to be general expectation without operational guidelines such as "maintain a safe and healthy ecology through green consumption and low-carbon operations," while the quantitative ones contain concrete criteria. The quantitative KPIs are grouped into four categories: natural environment, man-made environment, life style, and economy.

These Indicators were incorporated into the Kitakyushu Green Frontier Plan. Among other goals is a clear target of 50% CO_2 reduction by 2050 compared to the level in 2005, expecting 40% economic growth in the same period. The plan also calls for the reduction of CO_2 in the entire Asian Region equivalent to 150% of Kitakyushu's own emission. The mid-term goal, aiming for 2030, is to reduce the city's carbon emission by 30% based on the figure in 2005.

Within these KPIs are some standards that represent notable improvement from existing practice, such as preserving wetland, making tap water potable, and demanding all constructions to meet China's Green Building standards. It is also commendable that the eco-city set a concrete carbon density of 150-ton carbon emission per million dollar GDP, and a goal of 90% green transportation. There are, however, some mediocre numbers. For instance, the renewable energy would account for only 20 percent of the total energy consumption by 2020, compared to China's national plan that requires 15 percent for renewable energy by 2015. Another KPI call for 20% of residential development to be subsidized affordable housing, but the number of affordable housing units in Tianjin has been around 50% of the total new housings since 2011.

It is neither simple nor very meaningful to compare the individual indicative values of the two cities' indicators system due to their different stages of economic and social development and the different emphases of eco-city agendas. However, it is illuminative to compare the set of data they chosen to include in their respective evaluation system as they indicate their understanding of the eco-city from their respective social contexts. Kitakyushu's system emphasizes reduction of carbon emission and economy of recyclability. Not only is there a firm target of carbon emission for the city in general, each district and many manufacturers have set a mission of carbon emission (Kitakyushu Green Frontier Plan, 2011). In addition, a subset of the indicators is dedicated to the goals of dealing with issues related to the aging society, which is not only a challenge to Kitakyushu, but one facing Japan in general. The populations in many Japanese cities, including other eco-model cities like Kobe, are declining, with young people moving to the country's few mega-cities (Tokyo and Osaka) for better job opportunities and the elderly left without sufficient care. A major objective of the eco-cities in Japan is to strike a balance between creating dynamic economy, through the development of recycling industries among other strategies, and enhancing social sustainability through redistribution of resources. The fact that the evaluation of social sustainability is based on the survey of degrees of satisfaction among residents also demonstrates that bottom-up force plays an important part in shaping the eco-city agenda.

In contrast, the indicators and means of evaluation characteristic of Tianjin Eco-city's KPI system appears to be more objective and technical, indicating characteristics of a top-down approach. As a brand new city, SSTEC focuses on attracting population and businesses through promoting a higher standard of living environment and unique opportunities. Even though urban population in China is growing dramatically, SSTEC is still facing fierce competition with many other new cities across the nations as well as those established urban centers. Economy assumes a high priority in the eco-city development as the administration shrewdly chose the indicators that could help most in enhancing the eco-city's competitive advantage without committing to some high-expense sustainable items. Some scholars also noted that the real estate sector has a lot of say in the direction of eco-city development. Developers view the concept of eco-city as a selling point and associate them with such values as "luxury" (Springer, 2012). Social equality is marginal in SSTEC's agenda, and it is not surprising the affordable housing accounts for much lower percentage than the average level in the city of Tianjin.

Conclusion

The concept of eco-city is changing the way cities are being built and resulting in new urban landscapes in Asia. It is applied in projects of different scales and in different urban setting such as greenfield projects or retrofit of existing cities. There is no one-size-fits-all formula. Differences in political system, economic conditions, and geographic characters necessitate different approaches to eco-city, as this comparative study reveals.

Japan and China represents two important models of implementing an eco-city. Eco-cities in Japan have a grassroots origin. Organized around national government's legislation and incentives, efforts within Japanese towns and cities are often driven by the local government, industry, and citizens, and involve support of the NGOs. As a result, Japanese eco-cities have a clear focus on citizen involvement and initiatives, as well as strong awareness of recycling and other environmental practices. The "Three R's: Reduce, Reuse, Recycle" is the principal theme for most of Japan's eco-town projects. In contrast, eco-cities in China are characterized by a top-down process. The central government made the policies and created the standards of eco-city, and the local governments and state-owned corporations took charge in implementing the large-scale projects, expecting financial returns from the development of land. Participation takes place amongst political and economic elites but does not involve communities. There seem to be an assumption that a sustainable lifestyle could be built into the city along with the introduction of recent technologies, which often turn out to be a naïve conception.

There are things that these two different models can learn from each other. Japanese cities could benefit from some experience of Chinese counterparts in stimulating economic vitality through the eco-city initiatives. Chinese governments, on the other hand, should investigate the means to bring the communities into this effort as a stakeholder, and enhancing the measures of sustainability with micro-scale interventions. As other scholars noted, Tianjin represents a unique position and possesses many advantages as a demo-project that other cities do not have. For example, government-sponsored low-carbon industries, such as film animation and environmental technologies, are encouraged to relocate to Tianjin eco-city. Other eco-cities will not have the same level of investment or national government support, and their success will depend much more upon how the market perceive a potential environmental premium (Flynn, 2012). In addition, the urban sprawl and massive new town building that have been going on in China for decades will likely slow down in a few years as land resource becomes limited and cities becomes too large to be efficiently manage. Should this be the trend, Japan's approach to retrofit eco-development within the existing cities would represent more valuable experience for Chinese governments that continue to pursue forms of eco-city.

Sustainable and Green Design in Villages of Rural Southwest China

Adrian Pitts[1] and Yun Gao[1]

Abstract: In recent Chinese development the focus for improving sustainable building design has been on urban development. However, a large fraction of the country's population continues to live in rural areas (approximately 600 million); therefore providing and encouraging sustainable development in those areas is important too. This has been recognised in Chinese government initiatives commencing in 2005. Research has been undertaken to record and analyse village development in China's Yunnan Province. Villages vary considerably from cities including ownership of land and buildings, and local cultural influences. The redevelopment and sustainability outcomes also vary. Factors identified as affecting potential success include: village management and the level of enthusiasm of residents to participate in the development process; types of redevelopment encouragement offered (such as support for tourism and craft industries); the degree to which villagers themselves, have knowledge/interest in, sustainable/green design; the ways by which architects and planners are involved in the process; and the level of existing skills/knowledge available. Research has entailed visiting a range of villages and discussing sustainability issues with residents and also with architects and planners. Building surveys have also been performed. Outcomes of the research suggest optimum ways in which sustainable environmental development in villages can occur.

Keywords: China, rural, villages, sustainability, vernacular

Introduction

This paper presents research concerned with sustainable development of rural villages in China. The rapid urbanisation which has taken place in China since the 1990s is now well-known and there have been many investigations and proposals on how to improve the outcomes of that process so as to create greater sustainability. At the same time the number of rural villages has been reducing rapidly with approximately 25% being lost between 2000 and 2010 (ecns.cn, 2016). In the 11th 5-year plan set out in 2005 (www.gov.cn, 2012), the Chinese Government began to introduce changes that recognised the importance of rural areas: the so-called "New Socialist Countryside" (Watts, 2006). These plans defined policies to rebalance urban-rural divergences and included: the development of more modern agriculture industry; the increase of rural incomes; improvements to rural education and skills; improved investment policies; and improved appearance of the countryside along with infrastructure, environmental protection, healthcare and sanitation. Given that more than 600 million people live in rural China, some in very remote locations, policies to create change have taken time to implement. There is currently serious concern that of the 5,000 traditional villages identified for conservation, many are at risk (ecns.cn, 2016). As a result in recent years there has been a renewed urgency to effect change, but there is a risk that in a potentially more frantic rush for such change, some decisions are taken hastily or with incomplete knowledge and understanding. Some serious concerns have been expressed, such as by Lin (2012) that the process is causing “a wholesale shift from regionally specific building types to generic, concrete, brick and tiled buildings. Within this scenario of potentially extreme changes to the social and built landscape, the architect is wholly absent.” It is against this backdrop that the current research has been formulated; it questions whether varied traditional vernacular village dwellings delivered an optimum form of passive or low energy design, and whether their replacement creates a new vernacular, and indeed whether it can be optimized in contemporary village redevelopment.

Background

In cities land ownership is within city and government hands with extensive leasehold development and the development process has been described by many including Chen et al (2011). This has offered much potential in recent decades to leverage finance for major development, and this has also underpinned the remarkable economic performance of the People’s Republic of China. However as with a number of western countries, this does not always result in production of buildings in which environmental sustainability ranks high on the priority list, though some interesting examples do exist (Jiang et al, 2016). Also recognised by some researchers (for instance Pitts and Gao, 2014) has been the method of development which leaves the final stage of completion or of refurbishment to the occupant. Whilst this allows avoidance of complying with certain detailed regulations applying to full construction processes, it also offers potential for residents to improve the sustainability of their dwellings above the basic norms through informed choice and personal investment. Enhancing enthusiasm for sustainable or green outcomes can be supported by capitalising on socio-cultural influences and exchanges of understanding amongst groups. It is also true that there have been significant positive changes at government level leading to greater sustainability potential (energyinnovation.org, 2016).

By contrast, in villages (which are the 5th and lowest level of administrative division in China) much of the land continues to be owned by the villagers, but in general and until recently, they have lacked opportunities to access funds for redevelopment. In any case many original residents are absent having left to work in cities, and since land/property values are much lower than in urban areas there has been less impetus for improvement. Some encouragement can be provided through external support (financial and professional guidance) in a top-down manner though this often happens without a good and detailed knowledge of local circumstances. Villagers themselves can also effect bottom-up change but without some of the necessary expertise, this may also not provide optimum solutions (Gao, 2016). There is need for research in the current critical scenario; a need which this paper aims to aid and so achieve optimised outcomes for village redevelopment. Such redevelopment should respect the beneficial aspects of passive and low energy vernacular design; which is area in which good expertise seems to exist (Sun, 2013). In recent years there has been a renewed ‘push’ for more rapid redevelopment and the authors of this paper perceive an immediate need, and over the next 5 years, not only for research but also for dissemination of information on practical outcomes that can influence development to be more sustainable. Southwest China has been chosen as the focus because of: its often assumed remoteness from development in the East; the representation within the populations of a wide range of China's ethnic groups (half of China's 56 recognised groupings); and also because of the variety of techniques being used to encourage redevelopment. It was also clear that research was required to aid and optimise choices and decisions being made by non-expert stakeholders. Such choices and decision were clearly impacting on effectiveness of construction techniques, resource use, energy demand and the environments to be found inside and around rural dwellings.

The Rural Village

There are perhaps 600,000 administrative villages in China and they come in many shapes and sizes. The 'administrative' village may in fact comprise of several smaller 'natural villages' of which there are more than 2 million. In the more remote and less populated areas of the southwest of they may have a population from several hundred to sometimes several thousands. Natural villages may in contrast have just a few houses and a small number of residents barely in double figures, but most have nominal populations of a few hundred. Natural villages are also often comprised of residents predominantly from a single ethnic group and within which there might exist a clan-like and interlinked familial structure. The detailed explanation of village structure is beyond the scope of this paper but what is clear is that close groupings provide strong social and cultural ties.

The attraction of greater earning potential in major towns and cities has caused a significant exodus of working-age village residents (often male) leaving behind the elderly, women and children. The buildings of de-populated villages are often in a poor state of repair, and though water, electricity and electronic communication systems may well be provided there can be serious deficiencies in other aspects of infrastructure. There are however a number of villages which have retained the majority of their population and which are flourishing. Some of these have succeeded because of the strength of clan leadership or the refocusing of employment around such themes as tourism and traditional crafts. Liao and He (2015) have carried out research into potential outcomes for villages and identified three problematic scenarios which can be summarised as:

- Villages which have become depopulated with many buildings in a state of decay or abandoned with poor basic services, and potential for environmental contamination;
- Villages in which construction has not been well-designed or controlled with consequent poor levels of building and environmental quality;
- Villages in more affluent areas using design features adopted from urban areas such as concrete block construction and large areas of glazing.

In addition to understanding and supporting the sustainable development of villages in rural areas, there is also potential to extend the findings to more urban based villages. These villages often have a specific ethnic bias and may be linked to a particular industry or craft, and may therefore have similar experiences and needs to those in more remote rural areas.

Research Methods

This paper reports findings at a significant stage in the overall project. A variety of research techniques have been employed, including both quantitative and qualitative; it also involves different components ranging ontologically from realism (based around the physical principals that influence dwelling environments) to idealism (based around the complex and changing social and cultural interpretations). Methods therefore also vary from positivism to interpretivism. Evidence used to inform this paper arises from a number of techniques for village investigation: visits to dwellings and interviews with occupants/owners; meetings with architects and planners; collection of visual and measured evidence on construction and environmental performance; discussions with members of Design Institutes involved in the redevelopment processes; and meetings with other researchers. Villages that have been visited are not all individually identified and were often chosen for different reasons and are found around the Province of Yunnan; their locations are spread across several prefectures with a range of ethnic minorities: Kunming (Yi and Yi Sani), Lijiang (Naxi and others), Chuxiong (Zixi), Dali (Bai), Honghe (Hani and Yi), Dehong (Dai and Jingpo), and Xishuangbanna (Dai). Ethical procedures have been adopted in each research interaction.

Mechanisms of Rural Redevelopment

Investigations have been carried out to examine at the local village level what mechanisms are being employed in rural village redevelopment and the reactions of stakeholders. One of the key initiatives discovered has been that which encourages rural villages located in more scenic areas or places with some historical importance, to become tourist developments. Local crafts have also been supported as a means to enhance local economic developments and local infrastructure and services have been improved (see for example Gao et al, 2014).

Since 2015 funding has been made available directly to the inhabitants of some of most vulnerable and important villages; however it seems this has meant the owners of individual dwellings taking decisions to spend funds with less control. This has led in some reported situations to builders from other areas arriving to offer services and constructing buildings with lower standards and less aesthetic appeal, though meeting immediate needs for a modern, watertight and wind-proofed building of large dimensions (often covering almost the total plot area). A further impetus for redevelopment in the southwest quarter of China has come from the recent extensions to the high speed rail network and also the inclusion of even some of the most remote areas in telecommunications networks. Old trading routes are being encouraged linking the Greater Mekong area through established routes to the south (Vietnam/Thailand/Laos/Cambodia) and also through the promotion of the 'Southern Silk Road' in the direction of India via Myanmar (Burma) and Bangladesh.

Village Management

The organisation and management of villages has undergone some major revisions since 2000 and has been linked with removal of agricultural taxes and changes to distribution of centrally controlled income. This has also been encouragement to develop local industries, enterprise activity and income sources. Research carried out by the authors by meeting professionals and village residents has revealed current practices. Externally produced masterplans are now created by architects/planners sometimes with limited connection to the locality. Not all villages have plans at the present time and not all of those plans which do exist may be realizable in practice. A key factor is the relationship with the local village communities acting through a mixture of party officials and the family clan-like social and economic structures. The management of the redevelopment process and the enthusiasm and knowledge of the local inhabitants (in particular their knowledge of green/sustainability issues) plays a very important role in achieving success. From observations made and interviews carried out there is a need to create the correct mix of top-down support and bottom-up participation to achieve appropriate outcomes. Some villages achieve this better than others such as those in which one or more clan groups has particular technical understanding that contributes beneficially to group decision making.

Construction and Materials

The villages of China exhibit a very mixed set of construction techniques and materials usage (stone, timber, concrete, mud bricks, etc). Not only are there regional variations but also differences because of both historic and contemporary restrictions on materials choice. There are also differences superimposed by ethnic grouping and by the intrusions of current styles. The photographs shown in Figures 1 to 4 illustrate the differences between older and modern style dwellings in several villages that were visited in association with the research documented here. Whilst older buildings have a certain 'quaintness' due to local style and materials; occupants interviewed also expressed their dissatisfactions. Research identified that older buildings may have structural problems and allow rain ingress, as well as offering poor control of air flow and temperatures through leaky elements. The openings may not be well-distributed around the buildings and natural light admission can be very poor; washing facilities may also be poorly incorporated. As a result it is not difficult for a resident to be persuaded to opt for a modern building even if it is made from concrete and factory produced windows and roof tiles; and which may overheat and require air conditioning.

Figure 1. Comparison of old and new style dwelling construction in the village of Damoyu, near Kunming.

Figure 2. Comparison of old and new style dwelling construction in the village of Nuohei, Shilin County.

Figure 4. Comparison of old and new style dwelling construction in the village of Manzhang near Jinghong.

Environmental Performance

In order to establish a baseline of relevant data measurements of internal and external temperatures, humidities and natural lighting levels have been carried out for old and new dwelling types in different villages. Visual surveys of design and construction factors that would impact on environmental performance were also carried out. Space does not permit reporting of the full analysis but the key findings can be summarised as:

- Significant variations in temperatures were observed between old and new dwelling types in the same village and perhaps more interestingly the diurnal cycle of variation showed a different pattern between building styles.
- Orientation of older buildings often determined by Feng Shui or local traditions in relation to topographic features, leading to defined roads patterns; modern buildings may respect the road frontage but have less relationship to environmental needs.
- Both older and newer dwelling are likely to have majority of windows facing in one direction, but windows much larger in size were used for modern designs and with some variety in orientation. Older dwellings often had limited daylight penetration and window location was not well planned with respect to interior features
- Ventilation openings were poorly distributed, particularly in some older dwellings.
- Little or no use of insulation materials exists in modern dwellings; older dwellings also had no insulation materials though some traditional materials may have such benefits.

- Solar shading was often present in older styles but was used inconsistently in modern.
- Though some forms of environmental assessment techniques have begun to appear for rural buildings (Wan and Ng, 2014), these are not yet considered for use in development of the contemporary designs observed and reported here.

Opportunities to Improve Passive Design and Operation

Following from the investigations carried out and observations of design and use of dwellings discussions were held with local Chinese researchers and with local design professionals. This resulted in the authors identifying a need to provide local stakeholders with support mechanisms to optimise design and construction of new dwellings of whatever type in village locations. Relevant start points for consideration are the usual passive design techniques found in many locations and climates of: thermal insulation; use of passive solar gain and linked to daylight; thermal mass; natural ventilation (including night-purge techniques); and evaporative cooling. These have previously been assessed in an exercise evaluating components of buildings that can be modified in local design implementation: orientation; choice of windows; and main construction techniques (Pitts, 2016). This provided a basic sensitivity test. Also considered was the potential to actually introduce change or variations (some options are not possible because of unavailability of technology or materials or technical understanding). Taking all aspects together the authors determined the practical 'potential to improve' and this indicated two prime features which should be provided with better design support/advice for non-expert stakeholders. Table 1 summarises and shows the summarised findings with the key evaluation in the final column. The techniques which are indicated to have the best opportunity in terms of impacts and potential for use to improve environmental conditions are: solar heat gain and daylight admission through choice of windows and orientation; and provision of natural ventilation linked to windows and openings and their orientation/positioning within the dwelling.

Table 1. Impact of selected building elements on dwelling passive design performance (after Pitts, 2016).

Passive Design Feature	Building Element			Potential to use/improve
	Orientation	Windows	Construction	
Restrict thermal heat transfer	low	medium	high	low
Solar gain/natural light	high	high	medium	high
Thermal mass	medium *	medium *	high	low
Natural ventilation	high	high	low	high
Mass + night purge ventilation	medium	high	medium	medium
Direct evaporative cooling	medium	medium	low	medium
Indirect evaporative cooling	low	medium	low	low

* Orientation and windows relate to thermal mass because of control of solar heat ingress.

Conclusions and Recommendations

Rural villages in China represent an enormous opportunity to improve sustainability as part of major redevelopment programmes already taking place. There are multiple influencing factors but there are reasons to be concerned that less optimal outcomes might ensue. The following recommendations and advice are offered:

- Encourage discussion amongst all stakeholders to establish better understandings and prioritisation of opportunities and needs.

- Develop understanding of how villages operate and how best to support them to achieve beneficial environmental design and sustainability
- There is a need for a quick and easy technique to help with energy/environmental design and assessment (with potential for more sophisticated systems in the future).
- In the immediate future there is a need to be realistic about what styles can be used and what changes are possible – design must meet occupant expectations.
- There is future potential to (re)develop traditional skills to meet modern requirements.
- There is a need for more research into how awareness and knowledge about design and construction is gained/used: a research network involving stakeholders is required.

Abstract: Social housing often aims to provide sheltering for people on low incomes or with particular needs. This results in a constraints-dominated context where environmental and social sustainability find little room. Neglecting environmental and social issues, however, risks to further impact those already at the margins of our society, and for whom the social housing was meant to be a life upgrade. Yet, challenges can be transformed into opportunities if intelligent and collaborative planning is utilised. Such a holistic approach has characterised the project discussed in this paper, which has met the design aims whilst placing environmental and social sustainability at its core. Passive strategies have minimised the energy consumption whilst maximising the opportunities that the surrounding natural environment had to offer. Social needs have also been included throughout the various design phases. The result is a plan for a neighbourhood where utterly different users are brought together under the same roof, and social interactions are not just possible but in fact encouraged. Local trade is embedded in the social spaces to incorporate principles of economic sustainability. This case study can be adopted in and adapted to different contexts thus handing back to architectural design the honour and the moral responsibility to produce spaces in which humans as well as nature can thrive.

Keywords: social housing, low energy architecture, passive architecture, social sustainability, local communities.

Introduction and background

Social housing is often primarily seen as providing sheltering to people on low incomes or with particular needs. This frequently results in a constraints-dominated operating context where environmental and social sustainability find little room. This has led to growing concerns with respect to the social and environmental sustainability of housing programmes (Goebel, 2007).

However, low-energy and low-carbon housing is necessary to transition towards a sustainable future (IPCC, 2007, Kellett, 2011) and social housing makes no exception (Moore et al., 2016). This is true across the whole triple bottom line (Brundtland et al., 1987), not just for environmental and social sustainability. Indeed, hosing costs represent – in most countries – a noteworthy proportion of average salaries and therefore changes in the cost of housing inevitably has a noticeable impact on the standards of living (Whitehead, 2007).

Moore et al. (2016) have shown that policy makers often look at social housing primarily through a cost-benefit lens thus undervaluing or overlooking other – equally important –

aspects related to the housing as well as the householders. For instance, social housing developments that are not financially viable can be nonetheless characterised by positive social outcomes as well as improved health of the householders (Moore et al., 2016).

Whilst financial viability is certainly an important aspect to consider in any building project, it is now clear that a building and its intended users cannot be regarded to as two separate clusters any longer. This is because users' behaviour influences – and is influenced by – the building, its energy systems, and the technologies used (Berry et al., 2014). In other words, building users play a crucial, yet "poorly understood and often overlooked role in the built environment" (Janda, 2011 p.15).

Being often handled through a top-down approach, social housing policies and programmes take different forms in different countries and are frequently driven by governments' views and agendas. van Beckhoven and van Kempen (2003) investigated the social effects of urban restructuring in Amsterdam and Utrecht, in the Netherlands. Despite an ambitious intention to replace a "monoculture of low-income households by a thriving neighbourhood, characterised by lively social contacts between different groups and fresh opportunities for local amenities such as shops and schools", in reality the new residents live most of their lives outside the neighbourhood and the interactions with the old residents are sparse (van Beckhoven and van Kempen, 2003 p.854).

Taking into account the intended users and their needs in a social housing programme is a pivotal step towards a project's success, and architectural and social quality have been identified as the two preferential targets to aim for in light of development and regeneration of Italian's neighbourhoods (Boeri et al., 2011a). A further key aspect of social housing development to be taken into account is the area within the city where the development is planned. If in the suburbs, for instant, marginalisation should be carefully evaluated to avoid a fracture from the urban fabric and to enable access to services and facilities of the city (Boeri et al., 2011b).

Such challenges of social housing, however, challenges can also be transformed into opportunities if intelligent planning and collaboration strategies are put in place. Such a holistic approach to social housing has been the case of the project described and discussed in this paper, which has successfully met the design aims whilst also placing environmental and social sustainability at its core. The following sections present in detail the case study and discuss the passive and low-energy solutions implemented along with the elements of social cohesion and local trade. The paper concludes with a reflection on the lessons learned and how the case study presented can be adopted in and adapted to different contexts.

The case study

Teramo is one of the four provinces of Abruzzo, a region in central Italy. Figure 1 shows the geographical location of the province within Italy as well as a zoom in over the area related to the social housing development (shaded red area).

As the right-hand part of the figure shows, the social housing redevelopment happens to be east of the river Vezzola which marks the eastward boundary of the city centre. Therefore, the area of the project is located in the suburbs of Teramo. Furthermore, the morphology of the terrain creates a strong difference in height (+10.6m) between the site and the city, and this has been a challenge for the project team.

Figure 1 - Geographical location of the project

Maximising the social value of the project

It has been precisely the criticality created by the strong difference in height that has driven the project team to transform this challenge into an opportunity. The idea has been to use it as a means to connect the neighbourhood to the broader territorial context, that is the city level on the one side and the river with its path and cycle lanes on the other (Figure 2).

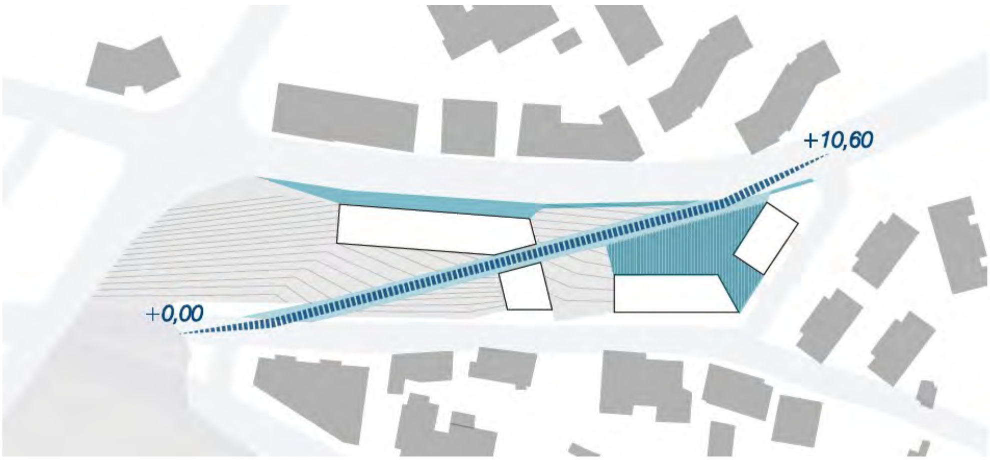

Figure 2 - The path that connects the social housing redevelopment to the wider urban context

Once the pedestrian axis cutting through the neighbourhood has been ideated, it was immediately clear that an opportunity existed to use the social housing redevelopment to impact beneficially also its neighbouring zones so as to become a resource that could avail the whole city. The new path effectively creates a door which connects the social housing neighbourhood to the east part of the city of Teramo developed after the second world war (Figure 3). The two areas, despite being in close proximity, were not easily accessible to one another and therefore social interactions were limited. Furthermore, the pedestrian axis also represents a convenient shortcut to head towards the city centre, thus allowing the wider population of the city to benefit from the redevelopment and its social and green spaces.

Figure 3 - The redevelopment as a new door to and from the city

The new connection with the wider context allowed the design team to reflect on how to maximise the usefulness of the spaces available at the boundary of the social housing neighbourhood. The most notable change to the wider city context has been the one envisaged on Via de Gasperi (Figure 3). This is primarily part of a ring road which pedestrians tend to avoid due to the lack of available spaces for them. However, with the new neighbourhood there is a piazza overlooking Via De Gasperi as well as the west body of the redevelopment placed 5m backward from the street. The clearing created has the shape of a little boulevard or a linear piazza, which allows people to stop by and use the space, either for chilling out or to shop in the businesses trades embedded to serve the city (red areas in Figure 3). The redevelopment has also foreseen trades and services specifically designed for the neighbourhood which are, therefore, embedded in its fabric and but still within easy reach from the main street (orange and yellow areas in Figure 3). This contributes to a strong sense of community whilst also allowing the city and the neighbourhood to mingle harmoniously. Overall, the pedestrian axis represents in fact the backbone of the whole redevelopment to which services, trades, circulation, and structures are all linked.

A further social element taken into account was that of maximising the landscape value of the site, which enables views of both the city centre and the surrounding mountainous areas up to the massif of Gran Sasso. This has been obtained by a creating a wide space between the two main bodies of the redevelopment which are separated by 25m. Additionally, the Piazza at the top level has a large terrace at one of its corners that opens up a view on the river and its surrounding woods.

The last aspect related to social cohesion, diversity and sustainability has been that of providing flexible living spaces that could suit a very diverse range of users, from studio to four-bedroom flats. This has been obtained through simple yet flexible living modules spread across floors and buildings not to cluster specific users' categories all in one place (Figure 4).

Figure 4 - Overview of the different modules to suit the various users of the neighbourhood

Passive and low-energy architectural strategies employed

The site of the redevelopment has been analysed in detail under the idea of a bio-climatic design. Such analysis allowed to understand the specific environmental conditions of the site to inform planning strategies and maximise passive gains and the use of low-energy solutions. Software modelling has been used to identify the areas mostly exposed to direct solar radiation throughout the year by means of shadows cast (Figure 5) and thermographic analysis (Figure 6 – left). This information allowed to understand how to benefit from solar energy as well as which areas would be the most critical during summers and therefore requiring shading to let users occupy and enjoy the outdoor areas.

If on the one hand solar gains are an excellent way to minimise heating demand, on the other wind speed and direction is the 'summer equivalent' to allow for passive cooling. Therefore, thorough wind and computational fluid dynamic analyses have been carried out to understand prevailing wind speeds and directions over the whole year (Figure 6 right and Figure 7).

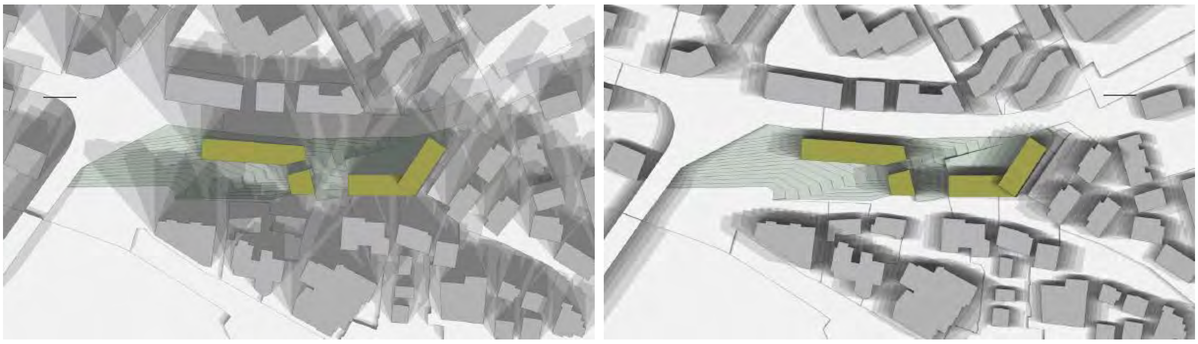

Figure 5 - Shadows cast at 21st Dec (left) and 21st June (right)

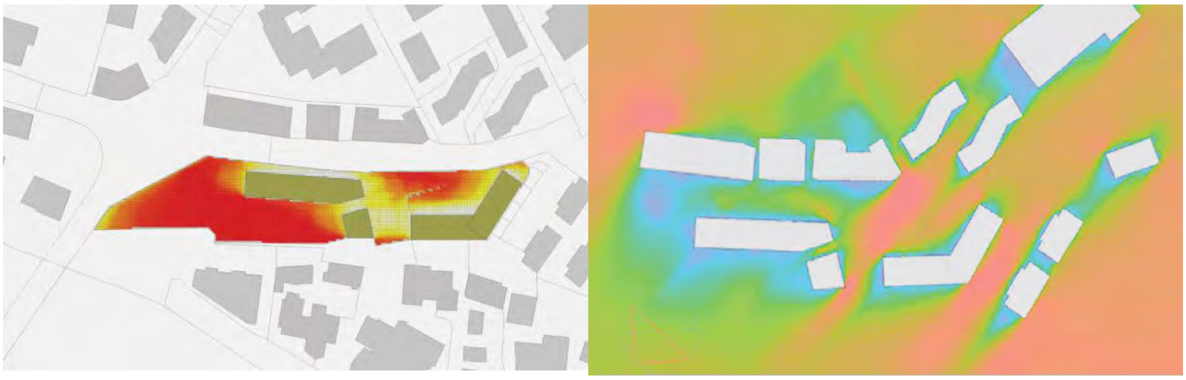

Figure 6 - Thermography (left) and wind direction (right) analyses for the site

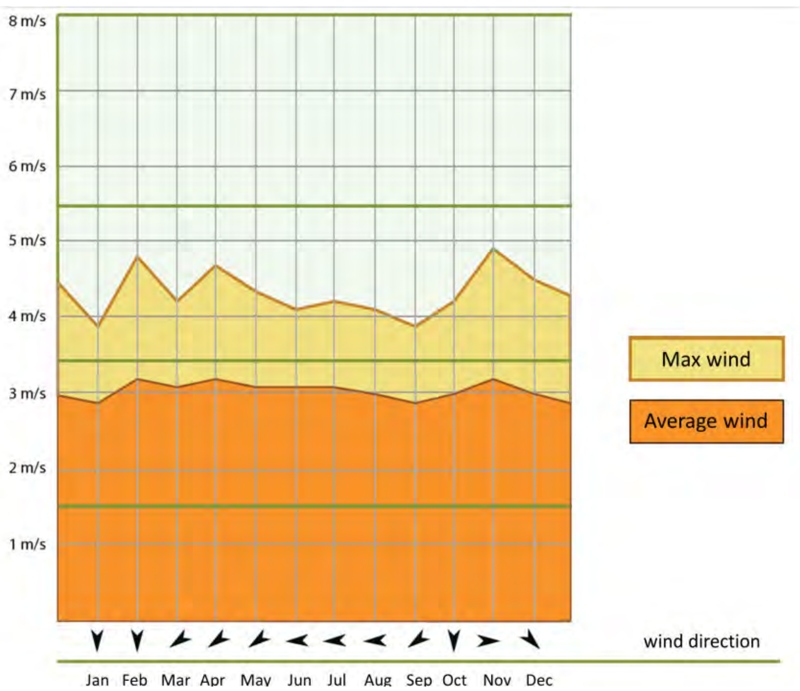

Figure 7 - Analysis of wind speed and direction throughout the year

Understanding the potential the wind had to offer greatly informed both the orientation of the buildings, their heights, and the landscape design to enable corridors for the air to flow and ensure good circulation across the whole redevelopment. In line with principles for good design through natural ventilation (Santamouris and Allard, 1998), cross ventilation between the windward and leeward side of a building has been employed as much as possible. This was followed by the use of cross ventilation on two adjacent walls, single sided ventilation with wing walls as to drive air indoor, and – eventually – single sided ventilation without wing wall as the least favourable option. These were clustered in a scale from Optimal to Scarce and as Figure 8 shows 80% of the living modules were characterised by an Optimal or Very Good score and 95% however had a Good or above score.

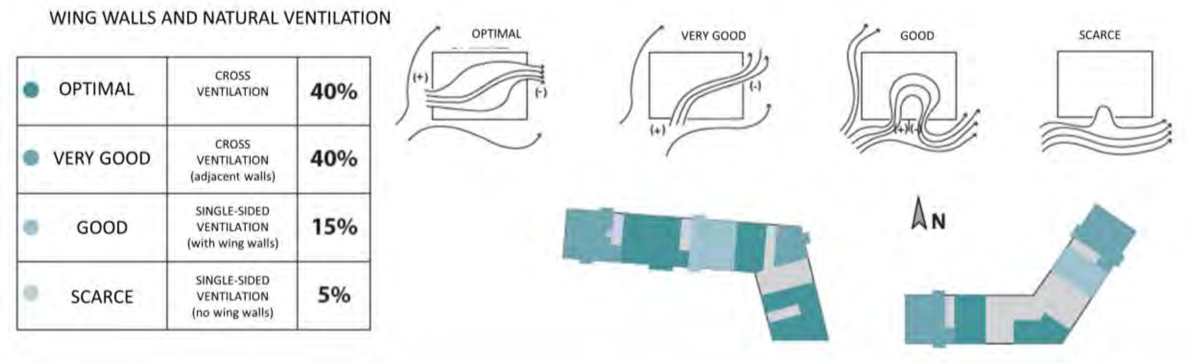

Figure 8 - Natural Ventilation Analysis

Conclusions

This paper has presented the project for the redevelopment of a social housing neighbourhood in the city of Teramo, Italy (Figure 9).

Figure 9 - Side view of the project

The aim of the council was to provide a redevelopment for the neighbourhood that was economically viable. However, the project team went beyond this and has looked at environmental and social sustainability aspects as well. Challenges have been transformed into opportunities through intelligent planning, rigorous analyses, and a collaborative holistic approach to the design of living and social spaces. Passive and low-energy architectural strategies have been used to minimise the energy consumption of the whole development whilst maximising the opportunities that the surrounding natural environment had to offer. Coincidentally, the social needs of the area undergoing redevelopment as well as those of the whole city have been included, enabling a much more vibrant interaction between the neighbourhood and its surrounding areas. Local commercial activities are also embedded throughout the social spaces to give back the built environment to its prime and ultimate users and to incorporate principles of economic sustainability as well.

The project has therefore successfully delivered a plan for a neighbourhood where utterly different building users are brought together under the same roof, and social interactions are not just possible but in fact encouraged. The case study presented in this paper can be adopted in and adapted to different contexts thus handing back to architectural design the honour and the moral responsibility to produce spaces in which humans as well as nature can thrive.

Design to Thrive

Learning from the chawl. A vernacular urban typology for contemporary communities

Shruti Shiva[1] and Jorge Rodriguez-Alvarez[2]

[1] Architectural Association, London, United Kingdom, Shiva-Ganesh@aaschool.ac.uk
[2]Architectural Association, London, United Kingdom, ETSA Universidade da Coruna, A Coruna, Spain, Alvarez_Jo@aaschool.ac.uk;

Abstract: Mumbai, India's teeming metropolis experiences staggering rates of urbanization, causing an undue exploitation of the built environment. However, this growth is asymptotic to the needs of the city, failing to accommodate large numbers of rural migrants and causing a massive shortage of affordable housing. Although the government has proposed a program of rehabilitative schemes to relocate slum dwellers into high density towers, these buildings lack adequate light and ventilation, and fail to retain the existing ties within migrant communities. The chawls were built by mill owners to house communities of migrant textile workers. It is a dense residential typology characterised by linear blocks, articulated around open corridors and communal courtyards. This paper studies the potential of this typology to inform contemporary passive design, while outlining the role and performance of its key features in providing comfort and creating an enriching social environment. Fieldwork and analytic work were carried out to gain a holistic understanding of both, the environmental performance and cultural value of the chawl. The paper concludes by culling the learning outcomes from this typology, to propose a new outlook for sustainable high density housing through the preservation of urban communities.

Keywords: Mumbai, Chawl, transitional spaces, social housing, density

Introduction

Contemporary India is a landscape of duality. While almost 68% of the population still lives in a rural setup (Urban Agglomerations, 2014) the country is experiencing one of the most intense processes of urbanisation. Indeed, some Indian cities are among the largest and most dynamic cities in the world. Mumbai is a paradigmatic case, the urban fabric of the so called 'maximum city' (Mehta, 2004) is in a perpetual state of flux.

During the British Empire, Mumbai became an important economic node due to its natural harbours. Textile production and maritime trade were the main activities that triggered massive immigration flows from all over the country. This demographic influx caused a housing shortage as the city could not cope with the pace of immigration (Arunachalam, 1978). Mill owners reacted by developing housing estates for their workers. They created a new typology of multi-tenanted shared utilities housing around a communal courtyard, which would later be known as 'chawl' (Shetty et al., 2007).

Despite the decline of the mills from the late 70s (D'Monte, 2002), immigration did not decrease. In order to keep tenant-based housing affordable, the Rent Control Act was introduced (Dighe, 2014), which levied a cap on the amount of rent that landlords could elicit from tenants (Department of housing, 2000). Eventually, this cap discouraged landlords from constructing new chawls while leaving existing structures in a derelict state. The lack of alternatives led to the proliferation of slums, which today, exist as a physical manifestation of systemic failure.

In order to tackle the growing number of illegal settlements, the government launched the Slum Rehabilitative Schemes in 1995 (Singh, 2012). Under this programme, following the consent of 70% of squatter dwellers, the slum is demolished and the inhabitants are relocated in multi-storeyed housing blocks. However, the new buildings not only fail to provide adequate daylight and ventilation conditions but they also fail to create any sense of community or social ties (see figure 1). This research aims to look into potential alternatives to slums and rehabilitated schemes by analysing the social and environmental characteristics of the chawl. The aim is to find inspiration for sustainable social housing in Mumbai.

Figure 1 A rehabilitated scheme and a slum. The environmental quality of the governments' alternative does not get any better than current conditions (Wikimedia Commons, 2016)

The chawl typology

As alluded to in the introduction, chawls (Fig. 2) can be defined as the social housing of colonial times that were built to house migrant mill workers (Adarakar, 2012). Largely concentrated in the south of Mumbai, these housing blocks gained their name from the *marathi* word 'chaal' which meant 'to walk' (Deshpande, 1958). The typical chawl is a U-shaped building, where each wing is composed of a wide open corridor that connects one-room tenements. The wings define a central courtyard that became a centre of activity and community life. Chawls can accommodate nearly 1,200 people per hectare, thus they can be considered a high density social housing typology (Edwards, 1909).

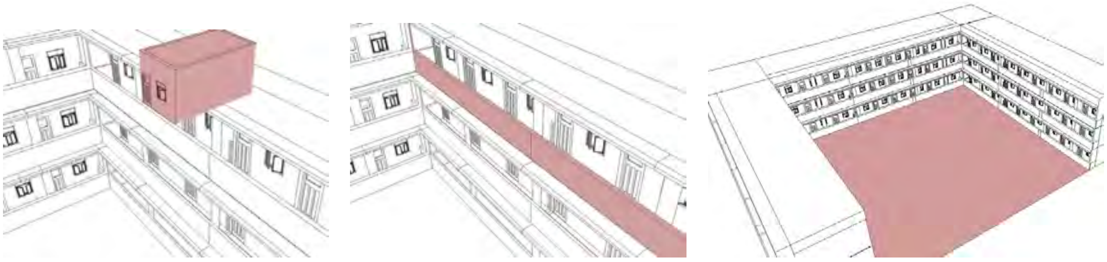

Figure 2 The main parts of the chawl From left to right: The room, the communal courtyard, and the corridor.

Chawls were initially constructed using brick masonry and load bearing wooden framework (Urban, 2013). Later when the construction of chawls moved from private to governmental sector, they were built with a concrete framework and brick masonry to reduce the cost of material and labour (Shetty et al, 2007). A chawl can be characterised by some of its distinct architectural features, namely:

The Room (kholi): A kholi or a unit, consisted of living quarters and a kitchen, measuring around 3 by 3.5m. It can accommodate up to 8 people (Fig.2).

The courtyard (maidan): Most chawls were known for their ample proportioned enclosed courtyards. These courtyards became extremely important social enablers, where festivals, religious functions as well as day-to-day activities like playing cricket, spontaneous discussions and ancillary kitchen activities occur (Fig.2).

Corridors: The characterising feature of a chawl could easily be its long, entwining corridors that serve as key access points for the room inhabitants. Marked at the end of these corridors is an opening, where the main stairwell occurs. This opening is also where common sanitary facilities are located. Due to the compact size of the housing units, corridors serve a unique function of becoming an extension to the living space (Fig.2).

Figure 3 The life in the chawl as depicted by Karandikar (2010): Courtyard, corridor and unit.

Previous studies about the chawl define them as 'vertical villages' in the city (Adarkar, 2012), where courtyards and a series of semi-open spaces, each blurring the lines between private and public, resulted in the creation of a heterogeneous community within a highly urban city (Fig. 3). Karandikar (2010) in her study on two chawls in Mumbai, refers to them as a model for affordable housing. She alludes to the prevalent social diversity, economic and environmental sustainability and the ability to house large densities as important learning outcomes. However, she also warns about the impracticalities of refurbishment, mainly due to their dilapidated state. She rather suggests imbibing the qualities of the chawls into new affordable housing schemes.

Fieldwork

In order to understand the performance and quality of the various space types, a typical chawl was selected to conduct fieldwork. Site visits were carried out in the summer period and during the rainy season. The fieldwork consisted of interviews with the occupants as well as measurements to monitor thermal conditions in courtyards, corridors and dwelling spaces.

The dwellers' perspective

Interviews revealed some key behavioural and social patterns with direct environmental implications:

- Families tend to stay together, thereby resulting in a high density in the small dwelling units, leading to high metabolic gains.

• Women would not give up their private kitchens, which they use intensely. Therefore, cooking is a major source of internal gains.

• The corridor is used as an extension of the dwelling: children use the corridor to study in the afternoon and it used as a communal space during the evenings. The corridor is also used for sleeping purposes in the night if the unit gets uncomfortably warm.

• The courtyard is used not just by children for playing, but also by the adults for communal functions and festivities throughout the year.

Thermal performance of the chawl

Spot measurements were made at the courtyard, the corridor and inside the unit at different times during a summer day and a day in the rainy season. It was observed that air temperature inside the unit was consistently higher than both the outdoor temperature measured at the courtyard and the air temperature in the corridor.

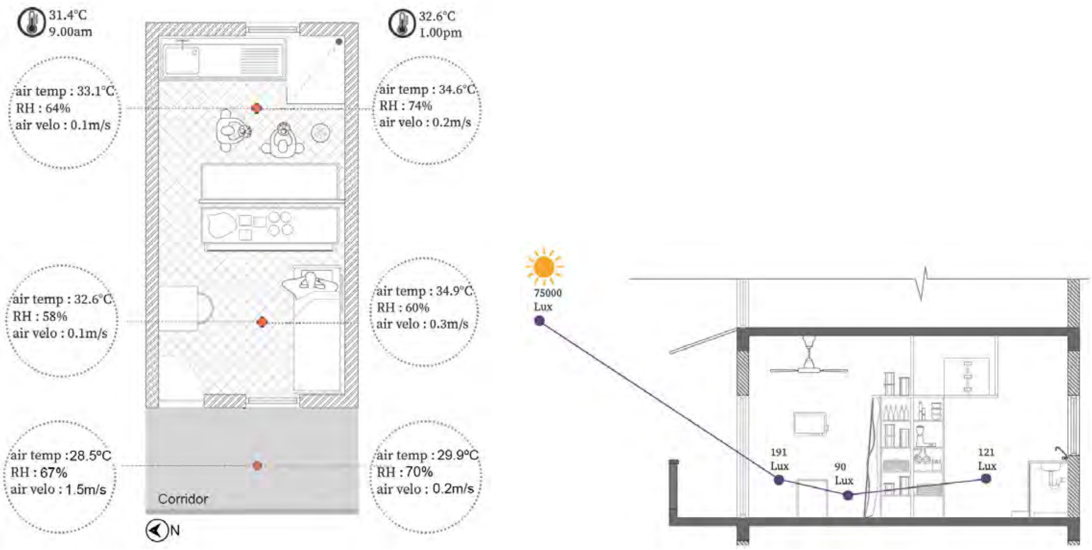

Figure 4 Left:Spot measurements showing temperature, humidity and air movement at 9.00am and 1.00pm. Right: Daylight levels at 1.00pm

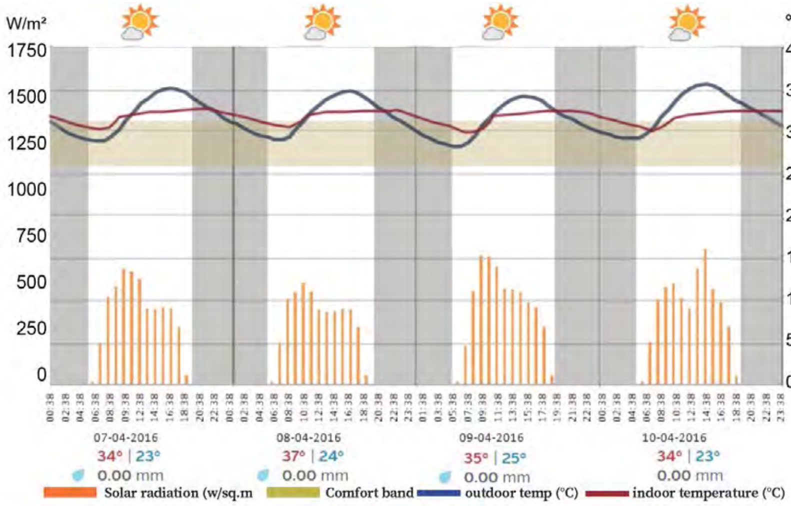

Figure 5 Thermal readings in April (hot season). The temperature in the unit is remains flat and below outdoor temperature during the day

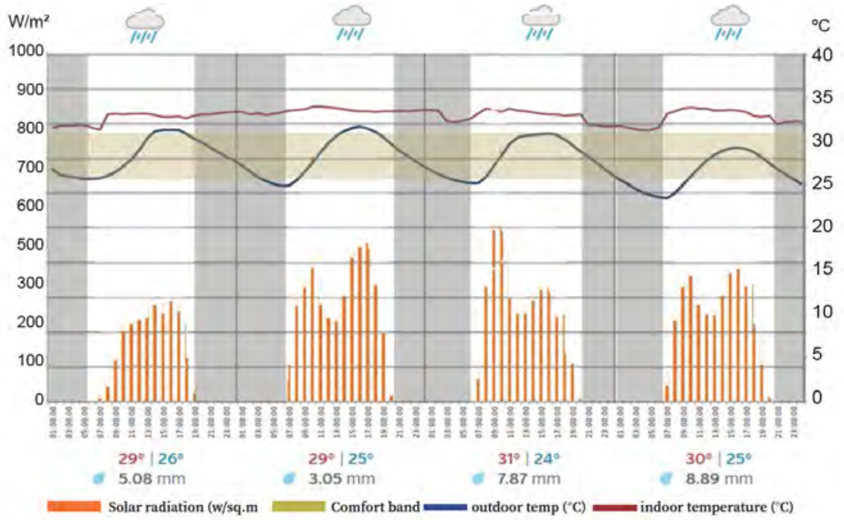

Figure 6 Thermal readings in July (rainy season). The internal temperature is constantly above outdoor and comfort

In addition, a data logger was placed to study the dynamic performance of the chawl over a week in April and a week during the rainy season, in July (Figs 5 and 6). The following observations can be pointed out from the data logger readings:

- The unit is strongly decoupled from the outdoor and while this helps preventing extra gains in the summer, it also prevents heat dissipation during the milder rainy period when the outdoor temperature is lower than the internal one. Moreover, the high thermal inertia and inadequate ventilation prevent efficient dissipation of the internal heat gains. The low window to wall ratio (0.19), has a negative impact in the thermal and visual quality of the unit. The increase of night ventilation, when there is full occupancy, could help reducing the internal temperature in both seasons.
- Occupants' adaptation takes place as they use transitional spaces (i.e. the corridor) for a number of tasks (sleeping, studying, playing...). In addition, occupants tend to keep windows shut during the afternoon when air movement through the space does not lower air temperature. Strong solar gains are observed in the corridor at certain times. The addition of screens or shading devices would provide further adaptive opportunities and allow extended usage of the corridor during the day.

Design research

Fieldwork analysis suggests that ventilation and the symbiotic relationship between the corridor, the courtyard and the dwelling units are critical features in the chawl's environmental performance. The detailed behaviour of these interconnected spaces is further explored through thermodynamic simulations and CFD analysis. A first stage focuses on the courtyard and the outdoor microclimates that are generated. A second stage addresses dwelling units, testing different strategies to improve their thermal performance. Finally, the corridor is thoroughly analysed as a transitional element between the unit and the courtyard.

Analytic work

Courtyard

The aspect ratio and shape of the court were analyzed by measuring the average incident radiation over one typical hot day in existing chawls. It was concluded that the U shaped typology effectively helped reducing radiation on the pavement. This shape was then further tested to define the relationship between aspect ratio, incident radiation and induced wind velocity. It was concluded that greater the aspect ratio, larger the average incident radiation; conversely to increase wind velocity. According to these observations, narrow courtyards offer better conditions. A conceptual courtyard was generated using an aspect ratio and shape derived from the previous study to analyse the impact of surface material (Fig. 8). Various ground cover materials were analysed using Envi-met software and the average surface temperature was calculated and translated into resultant PET values. The results are tabulated in table 1. The results show that grass is a preferred material in lowering ambient temperature thereby helping in reducing the PET.

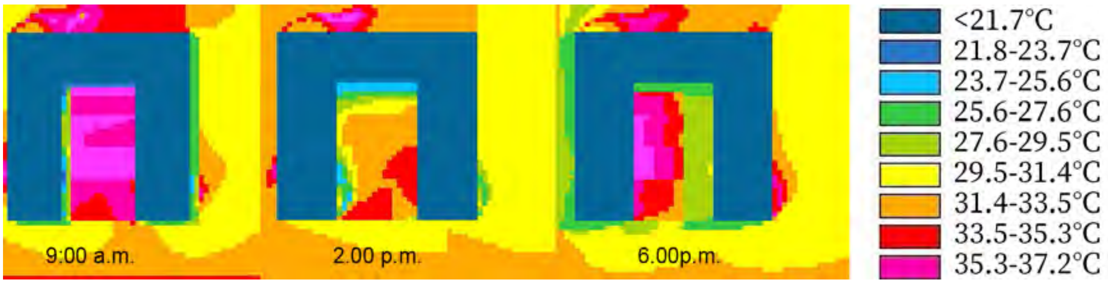

Figure 7 Surface temperature at various times of the day for a conceptual courtyard

Table 1 Surface temperature on the courtyard for different cover materials

	a)Concrete paving	b) Brickbats	c) Paver block	d) Grass
Surface temp (°C)	35.2	38.3	37.2	33.3
PET (°C)	29.1	30.9	30.7	28.6

Unit studies

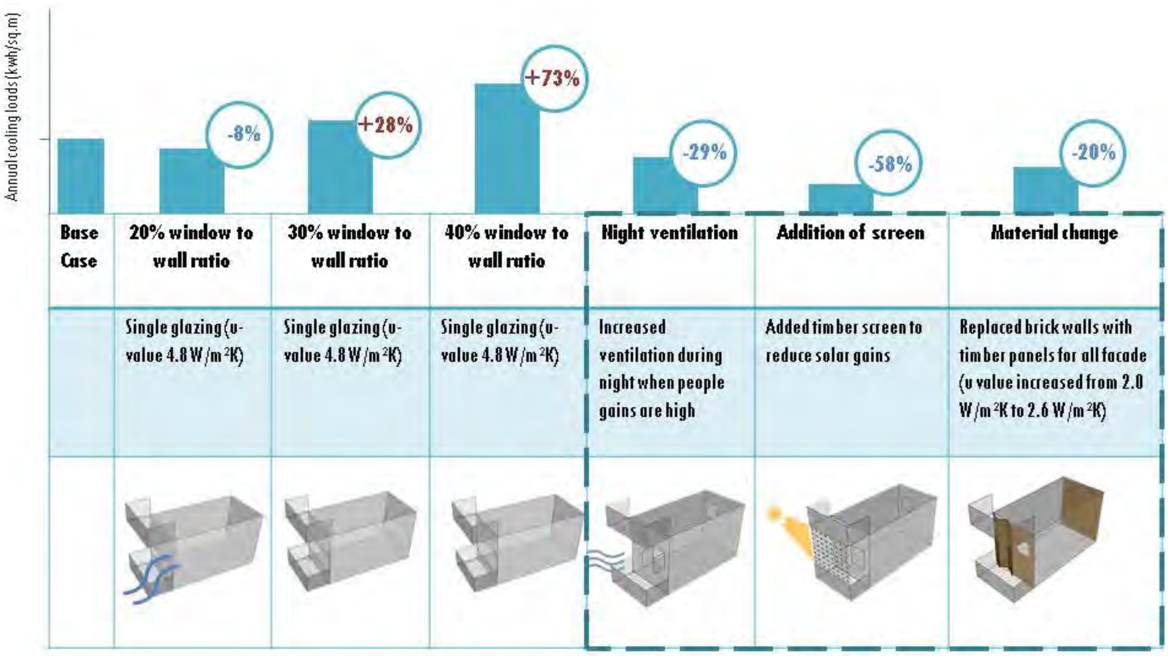

Figure 8 Thermal performance of potential measures in the units

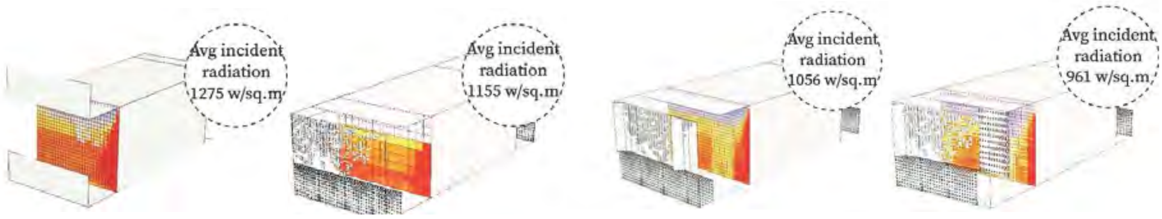
The fieldwork indicated a thermally poor environment in the unit caused by high internal gains, inadequate ventilation and insufficient solar shading. Thermodynamic simulations were performed to test potential improvements. The base case was defined using data from fieldwork (Fig. 4). The effect of various ventilation and radiation scenarios was assessed, using cooling loads as synthetic indicator (Fig. 8). The increase of ventilation by a moderate enlargement of the openings, together with screens to control solar radiation, were the most effective strategies.

Corridor

The corridor was tested for the same factors as the courtyard : reduction in radiation, induction of wind thereby creating comfortable spaces. With the renewed possibility of using the corridor as an extension to the living space, it became necessary to arrive upon a depth that would promote a social culture, would accommodate spill over functions while providing adequate shading. Average incident radiation was calculated using Ladybug over one summer day and the length was gradually increased from the existing a minimum of 1.5m to 3.0m, for all orientations. It was concluded that beyond 2.6m the returns are not significant enough for the extra load on structure and cost it would incur. Hence, a depth of 2.6m was chosen for the corridor. Further, various combinations of shading devices were introduced to increase adaptive opportunity. The lightest shading was applied to the north orientation, where vegetation and movable panels were used. For the south, a combination of movable shutters, movable screens and vegetation was applied. The west and east, receiving the most radiation, were treated with fixed screens and movable shutters. The shading systems were further validated by generating shading masks and tested for daylight to ensure natural light is not obstructed because of the shading, results of which are illustrated in figure 9.



Base case (2.6m overhang) base case+vegetation base case+movable shutters +vegetation Base case+screen+ shutters +vegetation

Figure 9 Radiation analysis of the impact of shading in reducing solar gains

Conclusion

This paper has demonstrated that chawls are a valuable built precedent that can inspire the design of new community schemes. However, current chawls are not optimised for comfort. The research explored the thermal performance in existing chawls and the interaction among their main elements: units, corridors and courtyards. Improvements were devised and tested for all three elements. The courtyards were optimized in materiality, shape, vegetation and form to encourage an array of uses within them. For the unit: the increase of window-to-wall ratio, the reduction of thermal mass and additional shading devices were proven the most effective. As for the corridor, the reduction of solar gains by providing movable vegetated screens has been proposed. PET values of the improved case were generated using ENVIMET and Rayman to validate the various optimizations strategies that were deployed. It can be noted that PET produced lie within the comfort zone (figure 10). Thereby reimagining the chawl as a solution for social sustainable high density housing.

Abstract: Thinking about the development of cities, demographic changes and changing lifestyles are the challenges of today. In order to create livable places for everybody, we need to think urban planning in a new way. By making sure, that all parts of a community have access to their surroundings and can participate in shaping the landscape they live in, we create an inclusive, welcoming neighborhood with a unique identity. To highlight the peculiarity of a place we have to focus on tradition and culture taking into account the people using the urban landscape. Currently, some groups have a hard time to understand and contribute the ways of nowadays planning processes. In some places, elderly people can´t be an active part of their environment, out of the loss of mobility. Being outside of a neighborhoods' community reduces their quality of life as well as the diversity of the urban landscape. Through the initiative 'Cycling Without Age' they get a chance to engage to the local society - the neighborhood can reconnect to its stories, its memories and the natural variety, which is necessary to create an exceptional place.

Keywords: urban landscape, quality of life, intergenerational, cycling

Introduction

Urban places reflect their communities and these communities are interacting with their environment. In their interacting, people living in these communities connect to cities, regions and urban landscapes. They shape places in an individual and unique way and are able to identify with their surroundings. Just with an active participation in forming their neighborhood, people will turn urban places into lively, inviting and human spaces, they enjoy to linger.

If a certain part of the community fails in the interaction and the process of city building it means, the form of the city and its public space changes through the loss of diversity and lacks an important component. It will not only exclude this non-participatory group from city life, but also rejects the profit from the potential knowledge, the richness and resource that this group has to offer. Especially people, who cannot deal with the current speed and permanent change of cities nowadays, stop involuntarily, but consequently to be a vital member of the urban society.

In the combination of cities growing rapidly and the phenomenon of aging Western societies one could predict an increasing aging population in many Western cities. Here is no denying it: like it or not, we are all getting older. 'According to the UN World Population Prospects report, the global population of older people is growing at an unprecedented rate. By 2050, for the first time in human history, there will be more over-65s than children under

15. The number of people over 100 will increase by 1,000%. And as by then 70% of the world's population will likely live in cites, this will present huge challenges, and cities will need to adapt.' (The Guardian, 2016).

Especially the generation, who has been living in a certain city the longest and has maybe grown up there, knows its culture, its habits and its traditions best. This calls for greater ideas of obtaining an inclusive society that facilitates all of its inhabitants to actively be engaged in its shaping.

Fortunately there are some promising concepts. One of them is 'Cycling Without Age' that in fact already overcame the stage of a concept. This paper will present that initiative, its importance for people as well as urban city planning and show the poten5al benefit for all involved.

Figure 1. Cycling Without Age

The right to wind in your hair

Facing the demographic change and hectic globalization, the city will go through the challenge of remaining a place for everybody and keeping a unique identity. However, cities grow fast. And cities get older - as do its inhabitants. Apart from the well-known meaning, getting old signifies here as well the gaining of life experience and a shaping of identity, whereby the belonging to a place leads into a growing collection of stories and a deepening of tradition.

But incomprehensibly, history and local tradition are nowadays often considered as nonvaluable looking at the fast taken decisions in the fields of urban planning and architecture: Buildings are being demolished easily; parks, squares and paths rather completely renewed than carefully supplemented. The story of a place looses the battle against the neo-liberal city development, where value is only calculated in terms of direct profit. Newly realized constructions often don´t get older than 50 years and older buildings are easily replaced motivated with greenwashing arguments. If you demolish a building you don't only physically remove it from the cityscape, but also rub out all the stories connected to the place. Personal memory will be forgotten and the ones, who can still remember, are often no longer an active part of the urban environment respectively the community platform of their surrounding neighborhood.

This reason among others connects to the general tendency that the urban city landscape loses its older generation. Under the contemporary circumstances they can't be a part of the city, its speed and its expressions any longer. As a consequence elderly people lose the city space they grew up in. Their lack of mobility coupled with the separation from the local community seriously reduces their quality of life. The initiative 'Cycling Without Age' deals with the question of how to enhance their mobility and how to get them back as daily users of the city landscape. It has emerged from the Danish cycling culture with its tradition for using bicycles as an everyday means of transportation and it rides on a strong wave of voluntarism that is stimulated by a longing for community and purpose. The layout of the city of Copenhagen allows independence to elderly, young and immobile people through a well-developed public transport system and advanced bike lane network. A perfect set-up and a thought through city planning emphasizes projects on a human scale. With that in mind, Ole Kassow started the movement 'Cycling Without Age' in 2012 with the aim to help the elderly get back on their bicycles defying their limited mobility. He started offering free bike rides in a trishaw to the local nursing home residents. Convincing Dorthe Pedersen, who was working as a civil society consultant at the City of Copenhagen by then, of the idea, they bought the first five trishaws and launched 'Cycling Without Age', which has now spread to all corners of Denmark and since 2015 to another 28 countries around the world (Cycling Without Age, 2017).

Intergenerational cycling is an opportunity to get to know urban surroundings from a different angle and to help give our busy city life strong historical roots. It is about cycling through the streets for the sake of it and results in a benefit for all participants: Elderly people profit greatly from having their mobility enhanced and from expanding their social network. The pilots not only get a lot of good exercise, they also get to engage in intergenerational exchanges that bring forth stories of life, which are otherwise easily lost. The passers-by are also an active part in this dialogue: Cycling through a city is way more communicative than driving with a car, because it is easy to get in touch with others nearby. There isn´t a cover, which absorbs the street life and insulates the inmates like in a car or the public transport. Speed and perception appropriate to the surroundings, invite to have a closer look, be aware of and participate in the context.

This urban context is part of a new method of rethinking the city. The public space is transformed into an urban framework for spontaneous and flexible use. With an unobtrusive mindset, public space should adapt and react to different needs, and over that not forget the memories of places and people. 'Cycling Without Age' is an interactive and life-affirming way of slowing down and taking the time to listen. The city space is being enjoyed and a diverse urban landscape is created by people using it. With this in mind, it is a clear benefit for a city to connect to its traditions and to people, who know the city in order to be able to create an identity.

Identity can certainly be formed through the building structure and vegetation - but even more through stories and people. So these human parameters should be relevant for the planning process as existing building structure, topography and climate (among others) already are today.

Figure 2. A Collage of the Lost

An exigency for urban planning hair

The city is a changing place, diverse and unsteady, and working with it, isn´t just a task for city planners and architects, but as well for social workers and all the other parties dealing with and moving through the urban space. Tomáš Valena pleads in his book ’Beziehungen - Über den Ortsbezug in der Architektur’ [Relations - About the locations in architecture] for a sensitive way of integrating the natural, existing surroundings of a place in the process of creating beaer, safer neighborhoods. For him, genius loci - the relation to the context and its characteristic atmosphere - is a major point in working with city landscapes and the quality of life.

Transferring the parameter ’genius loci’ to the population of cities, everybody involved in the planning process learns in a first step about the speciality of a certain place, its culture and ultimately its identity, build up through history and tradition by looking at the locals and studying their way of using the city. In a second step urban planning needs to work within flexible frames, which allow a renewal of forgotten memories and the spreading of lost stories.

Learning from the past and the existing conditions, one need to respect these memories as a valuable gift to create the future. Especially from the people, who have been living in a place for a long time, one can get precious knowledge, which leads into a sustainable, human development.

Strangely enough, this symbiotic effect is hardly recognized in connection of planning a neighborhood. But a social coexistence can just take place in a city, where people know each other, talk to each other and are to a certain degree caring for each other. Creating a sustainable landscape on human behalf, urban planning containing social inclusion is a key factor for the development of a city in eyesight with its inhabitants. Sustainability has to be associated with the social factor of knowing each other. It simply means that we need to improve the amount of time, we spent in direct contact with people shaping the neighborhood: We need to listen carefully.

The city space is a living landscape, always developing and adjusting to its vivid setup. Characterized of its diversity, its changes and its stories, our urban surroundings have to be developed in a way, people can be actively playing a role in the process. This is doubtlessly of importance as the WHO ascertains as following: ’Quality of life is generally admitted to be the result of a fruitful interaction with the environment in its different forms, rather than a mere question of health conditions.’ (WHO, 2001). Quality of life refers for instance to mobility and people’s needs as feeling home and safe at a place, enjoying and belonging to a community. The fulfillment of people’s needs is important for the well-being of everybody and a major precondition for the sustainable development of their urban context.

’Since sustainability implies a balance between environmental, social and economic qualities, policies that seriously decrease an individual’s quality of life can hardly be called sustainable.’ (Marshall, Banister, 2007). A deep knowledge of the provided urban setup of a place combined with an understanding of the people, one is planning for, is therefore, a significant requirement in the development of urban spaces. Enhancing the quality of life is not a simple task, because of the complexity and the difficulty in capturing all the relationships, the dynamics and the features, that exist and are relevant.

But a smart and intelligent urban planning can help improving the quality of life - it is not just a matter of beautiful buildings, safety or clean air, but should as well contain aspects of human satisfaction - whereby accessibility and participation are two of them.

Conclusion

People are making the city to a vivid and lively place - inviting, matchless and welcoming. Not to speak of people of a certain kind, neither a certain age or a certain ethnical background - a diverse collage of people is, what makes an inclusive city to a unique place.

Rethinking urban planning as a discipline, focusing on people of all generations, asking them for help to shape their own places, we will look at the city as a diverse neighborhood – as diverse as the people living there. These places offer opportunities to meet, foster intergenerational relationships and more than that, be inviting around the clock. For the Danish architect and urban planner Jan Gehl, a quality of life in a city can be rated by the appearance of older people and kids. They are representing the ones, who choose actively and out of enthusiasm to stay in the urban landscape - or to leave it. They can decide to go every moment, but if they remain longer, the city remains hospitable to them. Gehl puts it very clear by saying: ’A good city is like a good party. You know it’s working when people stay for much longer than really necessary, because they are enjoying themselves.’ (Gehl, 2010).

Accordingly, the city can strengthen social network by creating vibrant neighborhoods, encouraging relationships and improving the quality of life through creating urban places for everybody and having the patience to listen.

A case study on Budapest: Lessons on urban resilience

Nikolett Watson-Puskás[1]

[1] Independent Researcher, London, United Kingdom, niki.puskas@gmail.com

Abstract: The city of Budapest was chosen to demonstrate how bottom-up initiatives are able to facilitate participatory design, provide a sense of ownership, giving back the sense of place and the 'right to the city' (Lefebvre, 1996). The post-socialist city has been subject to rapid urban transformations in the past years, most of which are via a top-down approach, presenting challenges which are considered typical due to its socialist history. Its recent policymaking is studied with the impact on the urban fabric and society and how it seems to be unique in some aspects in spite of its historical context, offering lessons to other cities on societal and urban resilience. A number of bottom-up civic initiatives are enumerated in order to analyze how they respond to policymaking fallacies thus leading the way towards resilience. Furthermore, how might they contribute to empowering communities and in the long-term, create an impact what may prospectively support the transition towards a low carbon future.

Keywords: post-socialist city, participatory urbanism, societal resilience, bottom-up initiatives

Introduction

United Nation's New Urban Agenda (NUA) was adopted in Quito, October 2016 (consequently by the UN General Assembly in New York, January 2017) aiming at 'the achievement of the Sustainable Development Goals (SDGs) and targets, including SDG11 of making cities and human settlements inclusive, safe, resilient, and sustainable.' (UN, 2016) Hence providing raison d'etre in a global context for the topic of well-being and placemaking on the agenda of PLEA2017. However, a number of professionals argue the manifesto is not yet followed-up by a clear roadmap providing framework and guidance for implementation. Furthermore, it was discussed how the Multi-Stakeholder Panel including scientists for consultation has been discarded, hence the NUA possibly missing valuable insight. Thus researchers, scientists and professionals have to take leadership in the development of a holistic and interdisciplinary urban science, which must consider the social, ecological and technical infrastructural nexus of urban existence in the quest for urban sustainability, liveable cities, social equity and resilience. (McPhearson et al., 2016)

Global goals can only be reached via local initiatives therefore in practical terms researchers over various locations shall engage in groundwork, bringing together diverse stakeholders via participatory methodologies, for which the local and national governments' collaboration is also needed. To pave the roadmap, the assessment of relevant case studies on a local level is necessary to draw lessons and disseminate for our common benefit. In this paper, the city of Budapest was chosen for such study. Since the fall of the Iron Curtain in 1989, it carries a post-socialist heritage defining the socio-economic and consequently the spatial and urban shaping of this city. Recent years political climate is creating an even more interesting atmosphere, thus offering valuable thoughts on societal resilience and reclaiming the right to the city, as it presents a case on 'what happens when the government does not collaborate or facilitate'.

Setting the Scene

The scope of works, definition of relevant terminology, considerable theories are summarized and Budapest's brief background is given as cornerstones of present paper.

Methodology

The methodology adopted here for data collection and analysis consists of qualitative research elements such as informal interviews with citizens of Budapest and various observations over the past two years, combined with the in-depth review of literature on the city as well as on key topics the research questions entail.

Research questions of this paper fall in the context of SDG11 and encompass the degree of citizens right to the city in placemaking, which is addressed via participatory urbanism and sequentially if they can claim the right for environmental justice. In Budapest particularly, how civic and bottom-up initiatives facilitate these in the evident lack of governmental responsibility and leadership.

Urban Theory

The core discipline to address the above set challenges is urban theory, thus a brief enumeration of relevant contemporary theories is necessary.

Although driven by good intentions, the lack of addressing some of the crucial elements resulted in failed concepts such as new urbanism, which neglected ecological complexities (Rios, 2013) and landscape urbanism, which although addressed the gap between design and ecology, humanity and ecology, recognised the importance of systems thinking and certain elements of resilience: indeterminacy and flexibility, yet lacked practical consideration for cultural systems. These contributed to the emergence of tactical urbanism (and other '-isms'), focusing on micro-environments to achieve more participatory, emancipatory places preserving and celebrating local knowledge, culture and collaboration thus achieving resilient places in a non ego-driven manner but via social ecosystems. (de la Peña, 2015) Similarly, phenomenological placemaking advocates participatory design and community spirit, highlighting sense of place does not come from physical architectural design of a space, rather from social processes. (Aravot, 2002) Consecutively, meaningful urban design accentuates interdisciplinarity and improving quality of life via its three key terminologies: being teleological, catalytic and relevant. (Inam, 2002)

The evolution of theories indicate how urban complexities are increasingly being treated in a more holistic and interdisciplinary manner, recognising attributes such as fluidity, transformative, organic systems where nature forms an integral part. This provides ground for developing resilience, well-being and genuine placemaking.

Resilient Cities

Originally defined by Holling in 1973, resilience is a system's ability 'to absorb change and disturbance without changing its basic structure and function or shifting into a qualitatively different state.' In the sustainability context, the focus is on the ability of this system to 'self-organize and adapt to change'. (Levin 1998; Holling 2001; Walker and Salt 2006). It can also be defined as an essential attribute of social-ecological sustainability. (Walker and Salt 2006). Via a holistic approach, cities are treated as living organisms, every element impacting another, in a fluid and constantly changing complex system. Therefore, resilience is an essential system component.

Citizens are naturally a central component in a city, thus the human-environmental interactions shall be studied with especial emphasis, since humans have a serious impact on the natural environment and the focus of our study: this complex entity called city. They should also be fundamental stakeholders in the shaping of the urban fabric and in the pursuit of well-being and placemaking there shall be discussion on citizen resilience, that is addressing challenges faced along the road of developing these concepts. Ultimately these notions should enhance human life in a sustainable way with respect to the natural world we live in. What happens when these principles are not being recognized, honoured and leading the agenda? Well, the concept of citizen resilience is needed severely.

Budapest Today

The urban landscape of Budapest is mainly characterized by its post-socialist heritage, policymaking of its current illiberal democratic regime and since 1990 a unique, two-tier administrative system shifting some power to the district level.

A post-socialist city carries attributes such as lack of trust, lack of individual initiatives, culture of complaint, a radical separation of 'us' and 'them' as in civil society versus 'the state'. (Polanska, 2008, Grazuleviciute-Vilenskie and Urbonas, 2014) This applies to Budapest too, although an increasing number of successful civic initiatives can be witnessed, implying a growing trust in 'us' yet deepening abyss with 'them'.

Policymaking works in a rigid, hierarchic and bureaucratic, top-down fashion in today's Budapest. There is no open data policy in place, or real citizen-empowering collaborative initiatives, which are recognised valuable instruments for placemaking. (Good examples for these can be found in the UK.) Albeit recent years have seen significant re-shaping of the urban fabric via policymaking, with rather grandiose planning, resulting in rapid urban transformations. The general trend is business as usual with the advent of shiny soulless office and residential buildings claiming to be 'green', going hand in hand with displacement and gentrification and patterns of the post-communist cities: the downtown, popular tourist areas and the neighbourhoods of the elite converging to Western cityscapes, posing harsh contrast to decaying city-parts. (Dingsdale, 1999, Kok and Kovács, 1999, Ladányi, 1997) A classic example is the Corvin project, which aimed to address ghettoization, but just shifted social exclusion geographically. (Keresztély and Scott, 2012)

A number of public spaces were subject to debatable recent remake, in fact one too many to provide an exhaustive enumeration here. Perhaps the first milestone in this 'movement' can be agreed as the 2011 street re-naming campaign of the Fidesz political party upon its return to power. Not physical alteration per se, yet inarguably shaping public space and conception, it affected streets, squares and the city's sole airport as well. The overarching concept of governmental initiatives root back in Soviet occupation: 'artificially emphasizing historical events that were relevant to the Soviet ideology.' (Vaitkuviene, 2010) The same witnessed today packaged into 'national identity', along with using urban design as an instrument to consolidate neo-authoritarianism mostly via falsified or no public procurement like with the reconstruction of Kossuth square, proclaimed as 'democracy square', technically an intimidating ample sterile space. (Akcali and Korkut, 2013) There is a National Football Stadium Development Programme in place, under its umbrella the Groupama Arena was realized and opened in 2014 and the New Puskás Stadium in the pipeline for 2019, argued as one of the World's most expensive stadiums at an estimated total of 618 million euros. Another highlight is the renewal of the Castle District in Buda since the prime minister wishes to relocate there from the Hungarian Parliament. However, the most debated, some call it 'mega project' is the Liget Project aimed at the City Park, sparking fierce dispute over the right for environmental justice. Yet, there is still a scale up: it needs no explanation what it means for any city to enter bidding to host Olympics. Budapest was - up until recently – candidate for the summer games of 2024.

Some of the above examples will be reviewed as they triggered exemplary civic action, thus demonstrating social resilience. Sadly, contemporary Budapest's self-proclaimed technical elite (e.g. mayors, architects) who are so eagerly transform the landscape (Akcali and Korkut, 2013) seem to completely neglect the holistic approach and sustainability manifesto including citizen well-being and the right to the city. Corruption and PR are the driving force instead, when resources are being allocated. (Egedy et al., 2016) This provides somewhat extreme example as more fundamental ideology is at stake since 'public space is constantly eroded by private interests, thus, the democratic character of society is jeopardized.' (Sennett, 2002)

Sustainable city?

Upon the in-depth study of the above cases it becomes crystal clear there is significant growing frustration amongst the citizens of Budapest for multiple reasons – in such case, should we even begin to contemplate if it is a sustainable city? The answer is most likely no.

As part of the European Union, the city has an Integrated Design Strategy, not very ambitious national renewables goals (refer to REN21 2015 report data), situated in a country where there is practically no recognition or incentive to convert to renewables, getting ready to build a new nuclear power plant (Paks 2), whilst many EU neighbours have already dashed miles away in the 'renewables race'.

Yet, we must consider sustainability for it is fundamental in achieving the concepts under discussion in present paper, it must be a driving force in resilience and the question must be answered: What are the inspiring examples in a seemingly bleak landscape then?

The resourceful people of Budapest - Resilient citizens

Buck (2015) reminds us of the significance of framing an issue, thus this paper weaves a positive storyline. Likewise, Castan Broto (2015) discussed how contradictions inspire change, exactly what we witness here. Moreover, a hypothesis that citizen resilience increases exponentially with the governmental strain is considered.

Consecutively, Tarrow (1994) suggests, in a phase of elevated conflict arising from elites setting certain political agendas, collective action could be triggered, which may even result in a systemic change – revolution. Akcali and Korkut (2013) forecasted Budapest as Europe's rebel city in the crusade for cultural and social capital, whilst policymaking creates potential for ongoing protest, which was happening on the streets in April 2017. They also foresaw citizens coming up with innovative ways to claim the right to decide. 'And civil society movements — originating in cities — make clear these win-win opportunities: 'creative place-making', 'localism', 'shared streets', 'universal design' are each about mobilizing local assets to generate liveability and resilience benefits.' (Rowe, 2013)

Ergo we pursue and witness how bottom-up civic initiatives take leadership in the urban realm – a prime testification of what societal resilience is.

Examples of citizen-centred urban design

A highly concise enumeration follows of some notable initiatives in Budapest with the manifesto of the more the people amalgamate and interact, the more they bolster empathy, well-being on a community level (Foster, 2016) contributing to cultivating resilience and promoting SDGs.

A unique phenomenon rooted in Budapest are the 'ruin pubs', the first was Szimplakert in 2002, sprouted all over town since and beyond – in Berlin for example. A classic example of bottom-up temporary urbanism, it became a unique selling point for city branding and tourism. Szimplakert started as a social experiment, a simple venture to finance the promotion of art and culture. They organized cultural events and nowadays also have the Sunday Farmers Market where traditional produce is sold, promoting the slow food movement and teaching about artisan food crafts. In 2013 it won the Viennese Sozial Marie prize for social innovation.

kultúrAktív is an NGO established in 2010, has a number of initiatives under the umbrella of familiarizing and educating citizens on their built environment – the first of its kind - with innovative instruments via gamification. They believe some vulnerable social groups are under-represented, like children, thus having little to no influence on decision-making. One of their projects is Pop-up Pest, aimed at youth, first tested in Budapest during the European Mobility Week in 2012. It is centred at cooperative learning embedded in the target audience's living environment replicated as a giant board game - which we enter and all become equal. Their ultimate goal is empowering citizen engagement in urban development, teaching contemporary urban concepts such as community gardening and public art for example. (Tóth and Poplin, 2013)

Instances of community gardening are founded by KÉK (Contemporary Architecture Centre), not only promoting urban cultivation (i.e. sustainable food production) and improving green infrastructure, but allowing city children to reconnect with nature and teach them skills bridging the gap of having no access to a garden. The initiative is not only about co-working and gardening, but includes meals together, community music jams, group yoga sessions and there was also a midnight painting activity for a new site. The concept of 'planetary gardening' is relevant here, emphasizing the important element of human liability to care through the allegory of nurturing the garden – a notion here scaled up to a planetary level, thus becoming a symbol of more complexity. (Buck, 2015)

Furthermore, smart landscapes must emphasize that technology alone is not a sufficient tool for sustainable agendas. (Buck, 2015) At the heart of the above initiatives shaping the urban environment is the promotion of old-fashioned physical human connections, which are essential for citizen well-being as well as for the facilitation of genuine placemaking. It is crucial in the digital age, which significantly shifted the realm for socializing. Future generations should be raised to understand what physical connections mean, being part of a community and living in symbiosis with nature – which implies knowing nature via first-hand experience.

Continuing with the challenge of sharp contrast between civic and governmental activity, an example is the start of the migrant crisis in 2015. Budapest was not prepared and Keleti Railway Station spontaneously became 'camping site' for the Syrian refugees. The government ignored the issue, but a civic initiative quickly emerged through a Facebook group: Migration Aid had thousands of people joining the cause of giving humanitarian help over just a few days. They spread to a network of five additional cities in Hungary, organized chaos into a system, collected and distributed food and essentials, even arranged a spontaneous screening of Tom and Jerry for refugee children: a temporary community theatre, offering a valuable lesson on equality, diversity and what it means to be human.

The controversial governmental Liget Project also triggered civic action via forming the 'Ligetvédők' group who advocate for participatory democracy and against the playing of policymaking loopholes to redesign space technically reducing green surfaces. They erected tents and maintain ongoing protest since March 2016, yet another example of temporary urbanism, with their two constant camping sites marked on GoogleMaps. Along with further development projects such as the Dagály lido, József Nádor Square, Római-part it prompted NGO-s and some professionals to unite and publish a manifesto, backed up by Greenpeace Hungary to advocate the protection and preservation of urban green surfaces. A demonstration of reclaiming the right to the city, citizens and authentic professionals demand environmental justice – so far falling on deaf ears, yet persisting.

Recently the tension also peaked with the Olympics 2024 candidacy. Momentum Movement started the 'Nolympics' initiative (January 2017) seemingly from nowhere and easily over-achieving the signature target to call for a referendum. In the end, people of Budapest did not get their right to decide, though the city stepped down from candidacy. Then the case of Central European University gave momentum and changed the dynamics in April 2017, with ongoing protest on the streets, some people used orange watercolour to mark the Fidesz rule on public buildings over liberal democracy, a symbolic temporary alteration of the city fabric.

The urban fabric is very adaptive, flexible, a multifaceted symbol, thus can be played with. An ordinary street can be temporarily transformed into something entirely different with added value, like the 'words alley' (Art Moments Festival, 2015), where every pedestrian could write their favourite quote on the pavement with coloured chalks – a simple concept challenging everyday perceptions, providing platform to share something meaningful with others. Similarly, there are 'book-stops' in Budapest, open libraries based on community trust: give and take, promoting equal rights for access to knowledge and culture.

Ascertainment and recommendations

It is every government's and professional's fundamental duty to (re)present socially and ecologically responsible leadership. It is clear from scientific literature that the city is a living entity, constantly evolving and flexible fabric woven of many intertwined layers, thus a merely technical, rigid monodisciplinary architectural approach will not suffice. An equally elastic professional approach must be adopted, designers cannot claim total authority, instead should facilitate open-ended design, urging community participation in the shaping of spaces as they belong to these spaces and vice versa, the space belongs to them. (Dhar and Khirfan, 2016, Tardiveau and Mallo, 2014, de la Peña, 2015)

The main barrier against the demanded change in Budapest is bureaucracy backed-up with rigid ancient infrastructure (including both hard and soft elements). There is an increasing global demand and pressure for change. Some city mayors realize this and choose to lead change, for example Enrique Peñalosa former mayor of Bogotá. In the lack of such public leadership, the activism of Ligetvédők and Momentum Movement are good examples of challenging the status quo and initiating grassroots movements amongst the citizens of Budapest and Hungary, bringing together the community for important causes.

Leaders should realize the most effective instruments for resilience and liveability scale in multiple dimensions, thus granting numerous benefits, some demonstrated above like local food production, community workout, open access to knowledge. Furthermore, heat island effect mitigation, water- and even crisis management. (Rowe, 2013) Growing research proves and quantifies the benefits of nature on human well-being and the resilience of places (see journals e.g. International Journal of Environmental Research and Public Health, BMC Public Health, Landscape Ecology), yet there is no equal evidence of nature-based solutions becoming a fundamental aspect in planning and redesign projects – consequently these cannot be referred to as development or revitalization projects and definitely not as sustainable or resilient. A paradigm shift is needed, authentic attitude in wanting to create meaningful urban design. Until we reach that, present case study demonstrated how in the seemingly complete lack of socio-ecological safeguarding from the top-down, local communities and civic initiatives step up and demand the collective right to a healthy city! They respond to policymaking fallacies, thus empowering communities, creating impact, which may contribute to the transition to a low carbon future, converging to environmental justice – prospect for a beautiful chain reaction.

Citizen resilience is fundamental for authentic sustainable urban development, yet not enough – dialogue is needed, it is time for 'the top' to listen to the people, to change the narrative. This is not a story about power, it is about empowering, harnessing scientific wisdom, bettering ourselves and our environments for everyone's benefit. Otherwise the risk of scepticism and disenchantment of 'experts' and policymakers persist. After all, 'the city itself is a commons – a shared resource' generating goods for human flourishing. Citizens should be central actors influencing its management and governance. (Foster, 2016) Lastly, this paper cannot emphasize enough the fundamental truth of Mancebo's words (2015): 'Inherent to urban resilience is an integrated, holistic understanding of the connectivity and interdependence of the physical, social, environmental and cultural assets and systems of a city...Thus, a sustainable city should result from the confrontation—or the synergy—of choices made by multiple actors, each acting for its own concern.'

Closing remarks

The above recommendations are for all professionals in order to implement authentic placemaking in line with SDG11. This paper argues for citizen-centred design and the utmost importance of granting environmental justice to achieve well-being and meaningful places. Existing good examples must be considered, including traditional societies as they 'represent thousands of natural experiments in how to construct a human society. They have come up with thousands of solutions to human problems, solutions different from those adopted by our own WEIRD [Western, Educated, Industrialized, Rich and Democratic] modern societies.' (Diamond, 2012)

Following the narrative and values respected in this paper, this research will be taken further in a regional comparative action research. Participatory methodologies will be implemented in various case studies to further contribute to the scientific community in paving the way to sustainable liveable urban environments.

Parametric Optimization of Solar Hot Water Systems for Different Building Types under Hot Climate

Kheira Tabet Aoul[1], Ahmed Hasan[2] and Hassan Riaz[3]

Architectural Engineering Department, College of Engineering, United Arab Emirates University, Al Ain, UAE, [1]kheira.anissa@uaeu.ac.ae, [2]Ahmed.Hassan@uaeu.ac.ae, [3]hassanuaeu59@uaeu.ac.ae

Abstract: Building integrated solar thermal systems are considered an attractive alternative to traditional heating systems for water heating applications. They yield a high potential to efficiently and cost effectively meet a large portion of hot water demand in different building types. However, their performance to great extent depends on the climatic conditions, building water heating requirements and the optimal design and sizing of collectors. The present research attempts to identify a unified parameter for solar thermal sizing for various building types based on their hot water demand under a hot climate. The building types include residential, hospitals, schools, offices and industry. The analysis is conducted numerically through a conjugate heat transfer model executed through TRNSYS platform. The parameters investigated include the collector tilt angle (0° ≤ φ ≤ 90°), azimuth angle (-90° ≤ β ≤ 90°), collector inlet temperature and collector inlet water flow rate. Eventually a unified design parameter of collector aperture area required per unit footprint area for each building type is determined. The unique parameter will help architects in optimal sizing of the collector for specific building types under a hot climate, taken as the climate of Abu Dhabi, United Arab Emirates.

Keywords: Solar water heating systems, building types, parametric optimization, TRNSYS software

Introduction

Bridging the gap between energy supply and demand is and will remain the major challenge of the 21st century. The total world energy consumption has increased two folds reaching up to 13699 Mtoe (million tons of oil equivalent) from 1971 to 2014 (International Energy Agency, 2016). Along this trend, the average installed energy capacity in the Gulf Cooperation Council (GCC) countries was 1149 Watt per person in 2005, which is much higher than the world average (297 W per person) or the European Union (700 W/person), but less than USA (1460 W/person). The GCC countries needed to increase their electrical capacity by 60,000 MW, which represents 80% of the 2011 installed capacity, to meet demand in 2015, making them one of the highest energy consumers per capita in the world (Alnaser and Alnaser, 2011). The United Arab Emirates (UAE) consumed 40740 GWh per capita in 2015 in all sectors collectively (DEWA, 2015), resulting in per capita carbon emissions two times higher than the developed countries (Kazim, 2007).

The energy used in the building sector varies among countries and ranges for example from 30% in the US to over 70% in the Gulf Countries (IEA, 2016; EPCE, 2010; DEWA, 2015; Kazim, 2007). Out of the total energy consumed in buildings, space and water heating needs can be as high as 81% in cold climates (U.S. Energy information administration, 2015) and 30 % in hot climates (Kempener et al, 2015).

In the UAE cooling and domestic hot water needs account for 55% of the energy used in the building sector (Radhi, 2009; Global solar thermal energy council, 2010). The abundant solar radiation in the UAE renders the provision of solar hot water, in particular, an attractive, efficient and economical option to supply housing, commercial and industrial building occupants' needs (Islam et al, 2009; Ghaith and Abusitta, 2014).

The optimum performance of Solar Hot Water Systems (SWHS) depends on its design parameters and the climatic conditions. There are very few studies conducted under the extremely hot climate of the UAE. The existing literature reports on optimum performance considering the right selection of the orientation and tilt angle (Yakup and Malik, 2001, Qiu and Riffat, 2003). Optimal tilt angles for few places has been reported as $\Phi = \varphi + 3.5$ for Egypt (El-Kassaby, 1988), $\Phi = \varphi + (4 \text{ to } -10)$ for China (Tang and Wu, 2004), $\Phi = \varphi + (19 \text{ to } -34)$ for Izmir, Turkey (Ulgen, 2006) and $\Phi = 24°$ for Abu Dhabi at south facing direction (Jafarkazemi and Saadabadi, 2013, Khalil and Alnajjar, 1995).

However, an optimisation of all the influential SWHS design parameters in relation to different building types and their corresponding hot water demand has not been assessed. Hence, the current study attempts to comprehensively cover the unique relationship between collector parameters to hot water demand in different building types to optimize collector performance under a hot climate, in this case, Abu Dhabi, United Arab Emirates (UAE)

Methodology

Simulations were carried out to assess the contribution and effectiveness of SWHS in meeting specific hot water demands in housing, hospitals, schools, offices and industry under the UAE hot climate. The objective was to determine the optimal parameters of flat plate solar collector (of surface area $2m^2$), inclination angle, azimuth angle, and collector inlet water flow rate. A transient thermal model was developed using TRNSYS software (TRNSYS, 2004), integrating the solar thermal collector and auxiliary heating source to provide hot water demand, meeting building occupants' needs in the different building types considered. Eventually, a ratio design parameter of collector aperture area to building area was determined for each of the studied building types.

Results and Discussion

Simulations were conducted employing a typical means year (TMY-2) weather data for Abu Dhabi. Parametric influence of collector inclination angle, azimuth angle, collector inlet water flow rate and collector inlet temperature were determined.

Collector Tilt angle

The performance of solar collector depends to great extent on their inclination angle (Shariah et al, 2002; Moghadam et al, 2011). Designers generally locate collectors on the building roof (pitched or flat) or on the façade (vertical wall). The same is simulated by varying monthly collector tilt angle (Φ) from 0° (representing flat roof) to 90° (representing south facing façade) with an increment of 5°. The average thermal gain (Q_c) is plotted against tilt angle (Φ) in Figure 1 to determine the optimal (Φ) for each month. The thermal gain (Q_c) of January (winter) is 1.95kWh/m^{2}at the tilt angle of 0° which kept increasing to reach at 3.25 kWh/m^{2}at the tilt angle of 50° (pitched roof). Beyond 50°, it gradually dropped to reach 2.2kWh/m^{2}at the tilt angle of 90° corresponding to its potential location on a vertical wall such as facades (Figure 1).

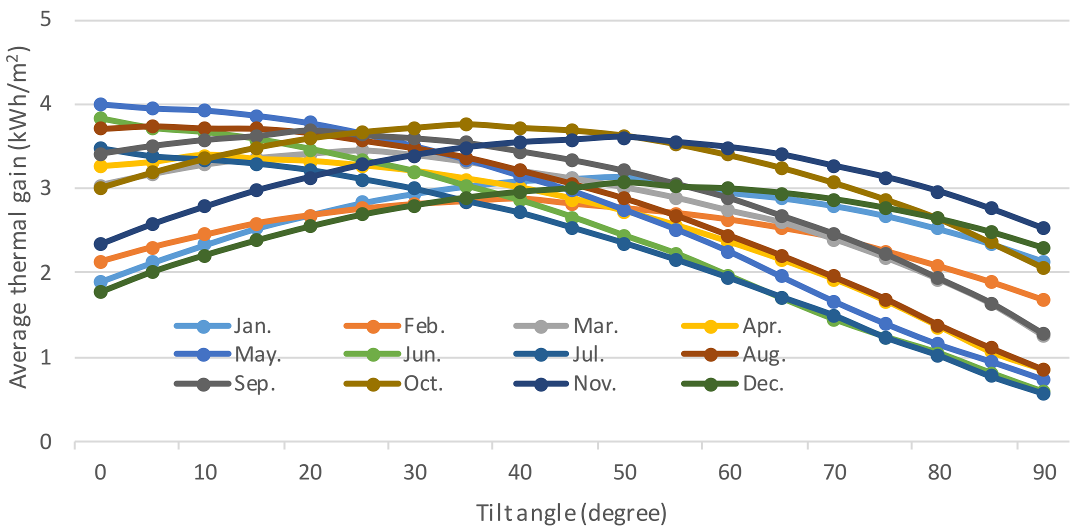

Figure 1: Monthly average thermal energy production of solar collector at various tilt angles

Hence, the 50° is the optimal pitch angle for south facing collector in January for Abu Dhabi. Similarly, for summer months i.e. May, the average Q_c was 4.11 kWh/m^{2}at the tilt angle of 0° which kept decreasing with an increasing angle to reach 0.75 kWh/m^2 at 90°, suggesting that 0° is the optimal collector tilt angle in May. Similarly, the optimal tilt angles for each month were determined based on maximal Q_c (Table 1).

Table 1. Optimum monthly collector tilt angles for enhanced thermal energy gain

Month	**Φ_{opt}**	**Thermal gain (Q_c)**
Jan	50	3.23
Feb	40	2.97
Mar	25	3.58
Apr	10	3.59
May	0	4.11
Jun	0	3.93
Jul	0	3.57
Aug	5	3.87
Sep	20	3.81
Oct	35	3.86
Nov	50	3.72
Dec	50	3.18
Average	23.75	3.62

To determine the yearly optimal fixed pitch angle, the collector slope was varied 12° above and below the average latitude of the place (24°) thus ranging from 12° to 36°. The maximum Q_c of 1207.47 kWh/m^2 was obtained at 24° (Figure 2) represented by latitude of the place thus being in agreement with previous findings (Islam et al, 2009). Further, knowing that rooftops are not always available for optimum solar water heaters layout, the performance of collectors installed at the optimum angle (24°) is compared to a 0° and 90° incline, corresponding respectively to a flat roof and vertical wall and the collector area required per building area is compared for the different building types (Figure 3).

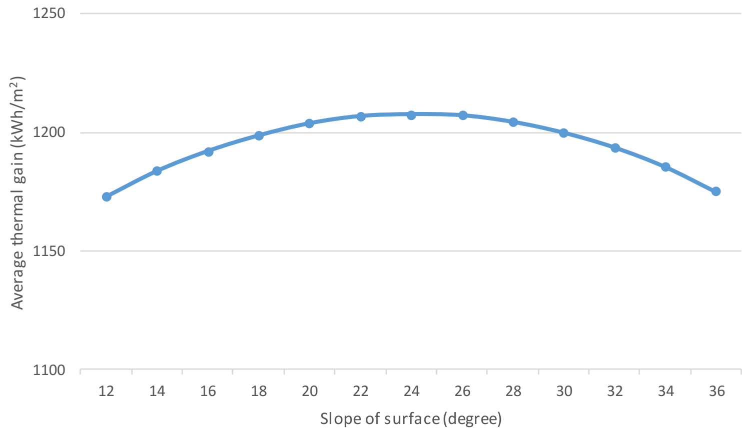

Figure 2: Impact of the off-latitude tilt angle on the thermal energy production of solar collector

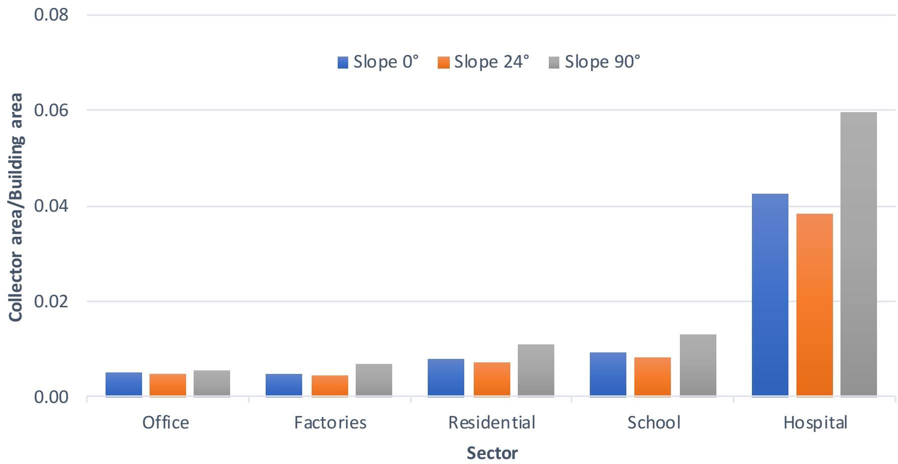

Figure 3: Ratio of collector area required for unit building area at collector tilt angles of 0°, 24° and 90°

The results show that the wall-mounted systems always required higher collector area per building area thus representing the least energy performance. The sloped roof and flat roof integrated thermal collector's performance is comparable due to very low latitude at the site. Comparing building types, the Hospital buildings required highest collector area per building area mainly due to higher occupants' load. The building type characteristics for fundamental parameters of the building and solar collector are presented in Table 2 to determine the collector area required per building area for the different building types considered.

The observed trend depicts that for south facing roof the value of Q_c is peaked at the azimuth angle (β) of 0° due to collector being installed in the northern hemisphere and decreases with an increase in β . For east and west facing maximum gain was achieved at 90° and -90° respectively and it also decreases with the change in orientation. Thus optimal β is 0°, -90, and 90° for the south, west, and east facing roof respectively (Levent Bas, 2010). In comparison, Q_c of the collector installed at south facing pitched roof is 30 % and 22 % higher than west and east facing pitched roof correspondingly. Variation in thermal gain by changing the azimuth angle is attributed to the sun's position as shown in Figure 4.

Table 2: Solar collector area required to meet hot water demand for various building types

Parameters	Residential	Hospital	School	Office	Factories
Building Size (square meter)	1000	1000	1000	1000	1000
Floor area allowance per occupant (square meter per person) (International Building Code, 2009)	19	Patient room: 11 Other spaces:22	Classroom: 2 Vocational spaces: 5	9	9
Occupant load (Number of people)	53	68	350	111	111
Hot water demand (gallon per person per day) (ASHRAE Handbook, 2011,The engineering toolbox 2016)	35	35	3	5	10
Total hot water demand per building use (gallon per day)	1855	2380	1050	555	1110
water temperature Tr (°C) (The engineering toolbox 2016)	45	65	45	45	45
Solar heated water per m^2 of the collector (gallon per square meter)	261	248	505	113	257
No of collector required	7	20	4	5	4
Collector to building area ratio	0.0071	0.0383	0.0083	0.0049	0.0043

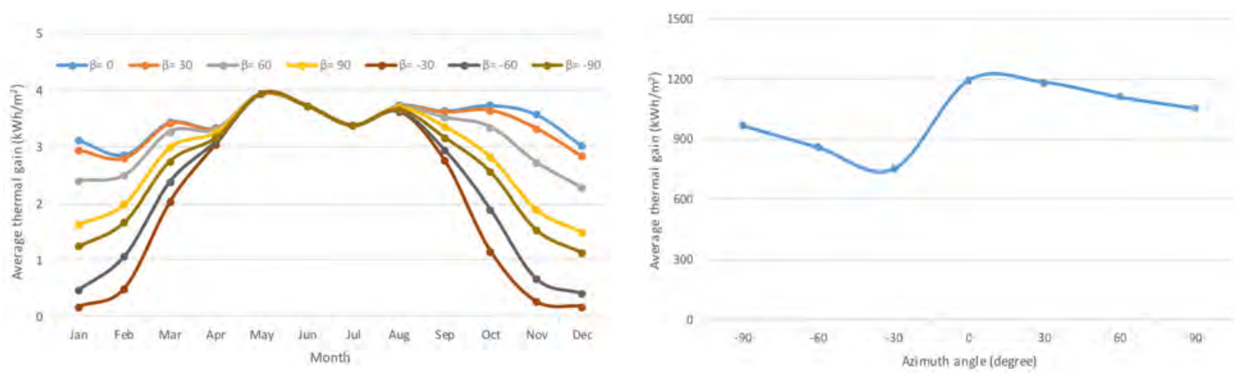

Figure 4: Monthly (left) and Yearly (right) average energy contribution from solar collector with varying azimuth angle

Inlet flow rate

Daily water consumption for each building is calculated from code requirements to size the collector storage tank and is kept fixed for the whole year. Since the thermal collector only recovers energy during the daytime, the varying daylight intensity and hours affect the thermal energy received by the collector. The variable energy available at the absorber needs demands variable water flow rate for optimal energy recovery. The optimal water flow rate inlet to the collector thus needs to be determined for different months. The total daily water demand is circulated through the collector during daytime (represented by daylight hours) at various flow rates to determine optimal flow rate for each month and building sectors. The summer season (May and June) had the highest number of daylight hours with an average of 13 hours, while the winter season, (January and December) had the lowest daylight hours with an average of 10 hours in Abu Dhabi (El Chaar and Lamont, 2010). Inlet water flow rate was higher in winter months and lower in summer months for all building types shown in Figure 5. Moreover, the hospitals required the highest while offices required the lowest water flow rate (gallon/hour).

Inlet temperature

The influenced of ambient temperature on the collector inlet water temperate is incorporated in the model by assuming the inlet water at slightly higher temperature than the ambient due to heat retention in water. The collector inlet temperature is assumed to be 3 – 4 above the average daytime ambient temperature ($T_{avg\text{-}amb\text{-}day}$). The highest value of $T_{avg\text{-}amb\text{-}day}$ was observed in May being 41.98 °C and the lowest was in January being 25.57 °C (Hasan et al, 2016 (b). Values of monthly average water temperature ($T_{avg\text{-}water\text{-}day}$) (blue line) and corresponding thermal gain (Q_c) for each building type are presented in Figure 6 at secondary and primary vertical axis respectively. For the lowest inlet water temperature, thermal gain (Q_c) is the maximum and vice versa, which complies with the heat transfer mechanism as the heat transfer rate increases with the increase in the difference of temperatures between the two media. Thus, thermal performance of the system will stay higher in winter which is coincidentally the maximum hot water demand regime eventually leading to the best collector performance.

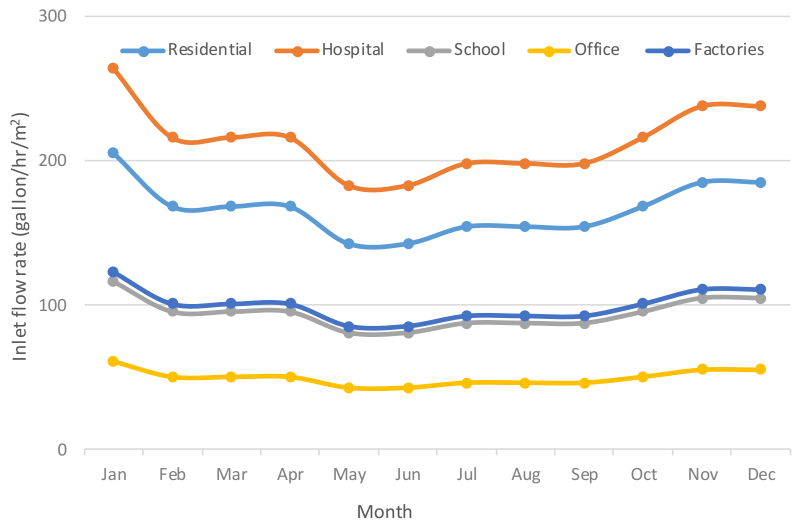

Figure 5: Monthly average inlet water flow rate for residential, hospital, school, office, and Industrial sectors.

Overall system performance

To evaluate the energy performance of the solar collector, the required water (ASHRAE Handbook, 2011) and temperature ranges (The engineering toolbox, 2016) were finally simulated with the optimized collector parameters and the yearly Q_c was determined for all building types summarised in Table 3. The hospital was the highest while the office was the least hot water consumers with the water temperature demand of 65°C and 45°C respectively. Hospital saved 23% while office saved 57% energy required for hot water production by incorporating solar thermal collector as presented in Table 3.

Conclusion

This current research has examined the energy performance of SWHS in various building types in the hot climate of Abu Dhabi, through TRNSYS simulation model. The simulation campaign has yielded in optimal collector tilt angle, azimuth angle and collector inlet water flow rate with respect to different seasons and building types represented by water demands. An optimal tilt angle of each month is identified to exploit the maximum potential of the system for the studied location, Abu Dhabi, UAE which ranged from 50° at maximum for

January to 0° for May. The optimum azimuth angle was found to be β= 0°for south facing while a 22% and 30 % drop in thermal yield was observed when the collector faced exact East and West respectively. It is observed that the wall mounted collectors are least effective compared to the flat roof and pitched-roof integrated systems. Additionally, the collector area required per building area shows that the hospital exhibits the highest collector area compared to building area. It is observed that an auxiliary heating source is required to compensate the temperature fluctuation as well as to provide a continuous supply of hot water throughout the year. The current study only limits itself with energy gains and is limited in scope. In order to practically apply the observed findings, further study is underway to compare the cost and benefit analysis of the proposed interventions.

Legislation, Strategies and Incentives to Solar Energy Adoption by Apartment Buildings in Rio de Janeiro, Brazil

Marcelo de Mattos Bezerra[1] and Alfredo Jefferson de Oliveira[2]

[1] Department of Architecture and Urbanism, PUC-Rio – Pontifícia Universidade Católica do Rio de Janeiro, Rio de Janeiro, Brazil
[2] Department of Arts and Design, PUC-Rio – Pontifícia Universidade Católica do Rio de Janeiro, Rio de Janeiro, Brazil

Abstract: Brazil has one of the highest rates of sunlight in the world and Rio de Janeiro could be a leader in solar energy adoption in the country. This Paper presents the current situation of solar power in buildings in Rio de Janeiro, Brazil. Besides photovoltaic power systems - energy generation - energy consumption for providing hot water in the residential sector makes up 26% in the southeast of Brazil. In addition to solar panels, solar power is suitable for water heating. This is a bibliographical and exploratory research paper. Some interviews with Brazilian solar energy specialists are put forward. The main topic will be the legislation, strategies and incentives towards large-scale adoption in the city of Rio de Janeiro with smart grid concepts. The paper introduces a discussion and some comparisons on the main topics in Rio de Janeiro with a few cities and countries to propose some new approaches and items to increase adoption. To conclude this paper will propose improvements for the government and municipality to reach a new level in solar energy and thermal systems.

Keywords: Solar Power, Sustainable Construction, Apartment Buildings, Rio de Janeiro

Introduction

“Solar energy is the most abundant energy resource on the planet and is available for direct (solar radiation) and indirect (wind, biomass, hydraulic, etc.) use. The Brazilian approach is directed towards the use of solar energy in both ways, for both heating and lighting, using two routes: the thermal route mainly for heating and for the generation of electricity, in particular via photovoltaic panels for various uses such as lighting, pumping and communication.” (PEREIRA et al., 2012)

The first five countries as to installed solar electrical power capacity - Germany, China, Italy, Japan and the United States - produce 70% of the world total. In 2018, it is expected that Brazil will be among the top 20 countries for solar power generation (BRAZIL, 2015).

Solar irradiance in Brazil varies between 4,200 and 6,700 kWh/m2 per year, higher than that existing in countries known for the use of solar power, such as Germany between 900 and 1,250 kWh/m2 per year, France between 900 and 1,650 kWh/m2 per year and Spain between 1,200 and 1,850 kWh/m2 per year (PEREIRA et al., 2006).

According to the International Energy Agency (IEA, 2010, apud in EPE, 2014), systems in residential and commercial buildings should correspond, in 2020, to approximately 60% of photovoltaic power generation and photovoltaic power stations to 30% of the total. This projection demonstrates the attractiveness of small-sized systems this decade with a cost reduction trend for setup (EPE, 2014).

Buildings consume energy both during the construction period and throughout their useful lifespan. In Brazil, the percentage of electric power consumed by (commercial, residential and public) buildings is 47.6% (EPE, 2013). Out of the total energy produced in Brazil, 23.3% is used by the residential sector with the following distribution nationally and in the Southeast Region (see Figure 1) where the state and city of Rio de Janeiro are located (LAMBERTS; DUTRA; PEREIRA, 2014):

Table 1. Distribution of Power Consumption in Brazil and Southeast Region in the Residential Sector

	Brazil	Southeast
Refrigeration (refrigerator and freezer)	27%	27%
Water Heating	24%	26%
Lighting	14%	14%
Air Conditioning	20%	11%
Other (washing machine, iron, hi-fi, microwave, TV, etc.)	15.5%	17.2%

In Brazil, a large part of power generation comes from hydroelectric power stations, however there are challenges with this model, since only large-scale facilities are constructed and they are situated far from various points of consumption, thereby requiring high-cost infrastructure as to construction and maintenance. Besides this fact, there are also various consequences from the flooding of productive and previously occupied areas. It is worth reiterating that all the forms of power generation, even renewables, have pros and cons, but their combining and the proper case-by-case selection will be important to determine the best model with a combination of them.

Figure 1. Brazilian Southeast Region indicated in black

In Brazil, besides photovoltaic systems, a solar-derived solution is solar water heating, since even though Brazil is a tropical country, hot water is always used in homes and apartment buildings. Electric power and (oil-based) natural gas are used. One of the attributes of adopting solar water heating is the estimated payback time.

In apartment buildings in the city of Rio de Janeiro, penthouses and roofs are used privately and collectively, mainly as follows: when private, as penthouses or premises of ordinary apartments and, when collective, as common areas for residents, service areas (water tank, lift machine room, among others) or just roof tiling. Among new demands and potential uses, green roofs and vegetable gardens, rainwater catchment systems (for possible reuse), solar panels and solar water heating systems stand out.

The growth in the use of air conditioning due to the failure to adapt buildings to the climate and trend towards increasing average temperatures due to global warning command attention (LAMBERTS, DUTRA, PEREIRA, 2014). In addition, it is relevant that the highest levels of sunlight occur in the hottest regions and seasons, making them suited to photovoltaic systems that could be used for cooling systems.

The estimated photovoltaic generation capacity on roofs of residential buildings in Brazil is approximately 287 TWh per year, 2.3 times more than residential electricity consumption in 2013, demonstrating that distributed photovoltaic power generation in these same buildings could supply their portion of demand (GREENPEACE, 2016).

The National Electric Power Agency (ANEEL) foresees that by 2024 the number of consumers / electricity generators will be around 1.2 million, with solar power leading, thereby indicating exponential growth even during the current time of crisis in Brazil.

Various countries have been following policies incentivising the use of alternative sources, such as solar power, instead of fossil fuels, with 395% expansion by solar power in the form of photovoltaic panels between 2003 and 2013 (FONTES, 2017). EPE (2014, apud in FONTES, 2017) also highlights the role of source incentive programmes promoted by countries such as Germany, Australia, China, Spain and the United States. Technological development has occurred mainly in Germany, the United States and Japan and secondarily in Italy, Spain and Norway. Despite this, Esposito & Fuchs (2013, apud in FONTES, 2017) stress that studies for technological development in the photovoltaic industry are concentrated in China, the current leader in the production of solar panels.

Solar Power Scenario in Brazil and Rio de Janeiro

In Brazil, there is between 4.5 kWh/m2 and 6.3 kWh/ m2 of sunlight a day (COLLE et al., 1998 apud HASHIMURA, 2012). Based on a comparative analysis, the sunniest place in Germany, the country investing most in solar power, receives 40% less radiation that the least sunny area in Brazil. In Brazil, for a long time photovoltaic solar power has been associated with rural development programmes and access to electricity in isolated locations (HASHIMURA, 2012).

To generate the power consumed in Brazil in 2010 (455.7 TWh) 3,844 km² of solar panels would be necessary, corresponding to 0.045% of Brazilian territory (RÜTHER, 2012 apud in TORRES, 2012), which demonstrates the potential of this alternative.

As expected, on a city basis, the greatest potential is observed in the urban areas of large cities, where there is greater availability of housing, the installation of panels in buildings representing a very interesting function. As an example, the largest state capital in the country, São Paulo, has a potential equivalent to a tenth of the installed capacity worldwide in 2010 (MIRANDA, 2013).

According to the Empresa de Pesquisa Energética [Energy Research Company], producing power in Brazil from solar panels installed on building roofs costs less than the power sold by 10 of the 63 electric utilities companies in Brazil. According to data from 2012, electricity from a 5 kW solar system cost approximately BRL 602.00 (US$ 299) per MWh, while providers charge between BRL 240.00 (US$ 199) and BRL 709.00 (US$ 352) for residential power. The solar option on roofs is increasingly more competitive when compared with electricity from public utility companies. The cost of electricity in the residential sector in Rio de Janeiro is BRL 521.00 (US$ 258) per MWh, the average price with respect to what utility providers charge in Brazil. The cost of electricity in the business sector is BRL 470.00 (US$ 233), both substantially less than electricity generated by photovoltaic solar power (RIO, 2012).

Rio de Janeiro receives annually 1.7 MW/m2 in solar radiation (Meteonorm data), with daily average irradiation of 5.18 kWh/m2 (BLUESOL, 2017), while the city of Rio de Janeiro receives on average 4.63 kWh/m2 of solar energy per day (RIO, 2012). Currently, the

State of Rio de Janeiro holds fourth place in installed photovoltaic systems, with more than 600 systems (BLUESOL, 2017).

The city's design and the model of occupying the roofs of apartment buildings combined with sun exposure challenges in roof areas may give rise to a solar power inclusion strategy and policy in urban areas. The city of Rio de Janeiro has a large number of buildings existing in consolidated neighbourhoods. Buildings have diverse heights and are close to mountains in various locations causing shading that reduces the catchment yield potential. On the other hand, combination with other demands (commented upon in the Introduction) such as green and rainwater catchment areas will be decisive for the success of a solar power inclusion drive.

It is worth highlighting that for new buildings there is the need for designs to envisage already the system from the beginning and a necessary overhaul of legislation for buildings, in line with the combination vision suggested above among the solutions. For existing buildings, some flexibility must be added to the legislation.

An important vision for existing buildings will be to take action, in consolidated neighbourhoods, in city blocks with projects integrating various buildings, in many neighbourhoods with the same heights and project solutions (BEZERRA; OLIVEIRA, mar. 2016).

In the city, there is a sustainability-related qualification named Qualiverde, launched in 2012 by the City Council, with points for the inclusion, among others, of renewable power systems and solar water heating. Nevertheless, this qualification has not been adopted on a large scale, since it established incentives for buildings with increases in areas and other aspects and mainly reductions in taxes for construction and future housing units, all not yet approved (BEZERRA; OLIVEIRA, Sept. 2016).

Incentives, Legislation and Laws

Due to the need for diversification in energy sources, Germany, Spain, Italy, USA and Japan stand out due to the incentives from government subsidies for expanding the use of renewable power sources with government programmes incentivising the use of photovoltaic solar power, making them the biggest powers in the quality of installed solar panels worldwide (TORRES, 2012).

The 100,000 Roofs Programme implemented in Germany between 1999 and 2003, considered the biggest programme in the world for the introduction of photovoltaic solar power, made loans available to the population for the installation of systems connected to the power grid. The support framework involving subsidised loans was renamed subsequently to Solarstrom Erzeugen - Solar Power Generation (JANNUZZI, 2009 apud TORRES, 2012).

In 1995, by way of Law no. 9074, the status of Independent Energy Producer (PIE) was established, starting Brazil's path towards home power generation. By compensating for the energy cost involved, in this way it ensured for producers unrestricted access to SIN (National Interconnected System), which coordinates and controls the system, made up of national companies for the production and distribution of electricity in Brazil. In 1996 (Law no. 9427), ANEEL (National Electric Power Agency) was founded, a fundamental agent in the solar scenario (ALVES, 2014).

In 1997, CONFAZ (National Council for Treasury Policy) - by way of Accord no. 101 - granted an exemption on the Sales Tax (ICMS) for transactions involving equipment used for solar and wind power generation (SILVA, 2017).

The National Climate Change Plan (PNMC), created in 2008 by the Federal Government, had the main aim of promoting domestic actions contributing to the minimisation of climate changes, such as the expansion of the photovoltaic solar power industry and rural electrification development.

Resolution no. 482 dated 2012, created by ANEEL, establishes general conditions for micro and mini generation of electrical power and draws up so-called "Net Metering". The System makes it possible for consumers to install systems connected to the public power grid, being compensated for all generated power placed on the grid. Enterprises must have a maximum output of 1,000 kW (1 MW). If one installs solar panels, one may save up to 95% in electricity bills (ALVES, 2014).

In 2015, the Ministry of Mines and Energy (MME) launched the Development Programme for Distributed Generation of Electric Power (ProGD), with the objective of incentivising the use of solar power generation. The Programme expects an investment in the sector of approximately BRL 100 billion by 2030. Currently, Brazilian consumers benefit from various tax exemptions as to generated power. By way of Law no. 13.169, PIS [Social Integration Programme] and COFINS [Contribution for Financing Social Security] are exempted nationwide by the government. By way of the accord created by CONFAZ, ICMS is also exempt. In addition, there is also a reduction in IPI [Tax on Industrialised Products] and a discount on TUST [Tariff on Transmission System Use]/TUSD [Tariff on Distribution System Use].

ANEEL Regulatory Resolution 687 of 2015 creates shared generation characterised by the bringing together of consumers, within the same franchise area, by way of a consortium or cooperative, with a consumer unit with micro or mini generation distributed to a different place from the consumer units where surplus energy is compensated (included by ANEEL Regulatory Resolution 687 dated 24/11/2015). Another procedure made possible by this same resolution was remote self-consumption which allows consumer units owned by the same Legal Entity or Individual owning a consumer unit with micro or mini generation in different places, within the same franchise or permit (utility provider) area, to compensate for the generated surplus (ANEEL, 2012).

In 2016, by way of Regulatory Resolution No. 687, the rules were improved and new generation forms were added, allowing greater benefits for consumers as to their own power generation systems, as building and condominium residents (BLUESOL, 2017).

There is the expectation of new incentives, undergoing study, with the use of FGTS (severance pay indemnity fund) for acquiring photovoltaic systems (BLUESOL, 2017).

Some cities and Brazilian states also have their own incentives, such as the city of São Paulo - capital of São Paulo, the state with the strongest economy in the country neighbouring Rio de Janeiro - with Law 14.459 of 2007, known as the "São Paulo Solar Law", which requires new buildings constructed in the capital to be prepared for the installation of solar water heating systems. Buildings with units featuring up to three bathrooms must possess infrastructure allowing for the installation of a thermal tank and solar panels for generating solar power. The law also requires the installation of the system in new residential - single or multifamily - buildings with four or more bathrooms per housing unit (TÉCHNE, 2009).

Perspectives of Specialists

This part of the text presents the results of questions put to specialists in solar power with different roles in the Brazilian market on the following topics:

Moment

Loys (2017) considers that "with the solar potential offered by Brazil and the rates or price structures that are being used, responsible for increasing energy, mainly residential and commercial energy," Brazil has the potential for much greater photovoltaic generation and should be positioned among the largest generating countries in the world. For Halfeld (2017), solar power continues to be a solution adopted by a minority, with financial reserves combined with investment analysis, not adverse to risk.

Calili (2017) evaluates that "despite achieving progress with Aneel Resolution 687/2015" (it altered points of Resolution 482/2012) and market growth in 2016 (...) "few projects are signed by installation companies, above all (...) small-sized." According to Rauschmayer (2017) in general, Brazil is still at a beginning stage in the centralised generation sector, but he is optimistic, in terms of distributed generation, commenting that last year there was approximate growth of 300% with respect to the previous year. Campos (2017) understands that the market for solar power in Brazil still faces some barriers, with a large part being the lack of tax incentives, since the end price for customers is still high.

Legislation for Apartment Buildings

Rauschmayer (2017) considers the legislation to be positive, due to allowing necessary actions in apartments such as the installation of systems on building roofs. Loys (2017) interprets that Brazil should already have established a "law requiring the use of this technology in residence and businesses, even on a small scale."

In the perspective of Calili (2017), the legislation is not effective, since "the net metering system established by Resolution 482 limits greater investment by residential and business consumers" and considers that, as exemplified by countries such as Germany and the UK, "liberalising the market is important, meaning making it possible to sell surplus energy, and not just using it for compensation" without limiting the installed capacity of equipment in this new context to average consumption. According to Halfeld (2017), despite allowing the use of photovoltaic energy, the legislation is very weak, since the actions rely on resolutions (482 and 687 mentioned), but which "can be cancelled or altered at any moment without notice."

Campos (2017) considers the legislation for housing to be effective, but with challenges in the circumstance of (condominium) residents generating their own energy because of the need for authorisation to place solar panels in a collective area.

Barriers

"Article five of Resolution 687 establishes that private enterprise is to be responsible for reinforcing the public grid in most cases", which combined with the lack of transparency of providers (utilities) results in "private enterprise having no interest in building photovoltaic power stations" (HALFELD, 2017). Loys (2017) indicates as the main barriers: "The lack of knowledge among consumers and mainly among professionals linked directly to projects, specifically architects and engineers", since he notes that it is rare for an architect or engineer to know how to use this technology in projects and absence of knowledge of the "multiple functions a panel can fill in a building."

Rauschmayer (2017) indicates as barriers a lack of financing and a difficulty in obtaining profits, with the way in which one pays in the insignificant reduction of the electricity bill, thereby not providing much incentive. Calili (2017) enumerates three large barriers: regulatory, as mentioned above; financial, needing specific lines of credit with attractive rates for entrepreneurs; and technical - currently the electrical grid, due to not being intelligent, limits greater reach by photovoltaic technology, due to the need for net metering installation. Campos (2017) adds the lack of tax incentives, the absence of "bank loans and complexity of unnecessary documents sent to utility providers."

Incentives, suggestions and references

Calili (2017) interprets that there are few incentives and that the Brazilian market is over-contracted, due to the economic crisis, seeing the need for "state and federal tax incentives for a more robust photovoltaic market to come about." Calili (2017) suggests "a improvement in the regulatory framework which clogs up the acceptance process for this source of generation by power distributors."

For Halfeld (2017), there are no differences in incentives with respect to housing types - individual or collective. It is not effective for all cases. Halfeld understands that "the best incentive is always tax-related. A reduction in IPTU [municipal property tax] for environmentally friendly buildings would be a great help." Halfeld continues by commenting that another solution, based on outside experiences, would be the freeing up of energy credit selling, under which, in countries such as the Netherlands, consumers can choose from which company to buy energy paying a transmission fee to the local distributor. In this way, the owner of a small solar park can generate power for numerous interested parties, improving competitiveness and reducing the cost of this item for the population.

Rauschmayer (2017) observes that "the incentive nowadays is an exemption to the tax on the equipment, which does not cover all the equipment," and suggests the use of subsidised credits or direct subsidies. Campos (2017) stresses that "the legislation does not differentiate between apartments or residences, what differentiates is the size of the equipment." Campos interprets that the main incentive for acceleration is to adopt a so-called "feed-in-tariff" policy, in which government pays the consumer for excess power with a special rate, however there is "a lot of apprehension about the (...) energy structure, without smart grid systems (...)" with the possibility of a collapse. Campos concludes that there is the need for an immediate investment by utilities to set up smart grid systems.

Germany is a benchmark for Loys (2017) and Campos (2017). Loys (2017) understands that "the government has introduced renewables or energy efficiency concepts in legislation or in certifications, but culturally Brazil is still a country with a lot of waste including in energy." Loys (2017) affirms that renewable energy providers should be able sell their surplus for a price above that of the energy purchased from electric utilities and consumers should have the possibility to choose the type of energy.

Conclusion

As evidenced, Brazil has huge potential to become a country where solar power makes up its main energy source.

Adoption in apartment buildings brings various advantages such as consumption at the same location of generation and reduction of dependence on infrastructure, but in cities, such as Rio de Janeiro, there are construction challenges, due to the use of roof areas for differing uses and to shading hindrances as a result of the buildings themselves and nature (mountains within the city perimeter).

There are laws, but they are still far from bringing about the scenario necessary for large-scale adoption. Based on the result of the survey on specialists, it was made clear that there is a total lack of effective incentives and an absence of dialogue among the various parties involved in the process: government, utilities, developers and designers.

There is also a dearth of research applied to the subject making it possible to quantify, simulate and test solutions integrated with existing and new buildings.

An integrated public policy will be the next fundamental step for the inclusion of solar power.

One of the next steps of this research group will be to analyse the potential of including and adopting solar power in consolidated neighbourhoods in the City such as Copacabana, an object already studied in previous research.

Abstract: The reuse and adaptation of existing urban infrastructure and the appropriate management of economic and social resources contribute to the sustainable development of a community, encouraging energy consumption habits, usage of resources for a systemic, sustainable and consolidated habitability at a neighbourhood of the city of Pereira, Colombia. The implementation of an appropriate policies and reactivation of a deteriorated areas of the city is an opportunity to establish an appropriate set of strategies and policies, as a planning instrument of the territory. The fundamental concepts of urban regeneration transcend the need for a modernization, becoming catalysts of sustainable policy management, urban sustainable development, conducive to change the linear cycle of construction for a renewable system of sustainable construction. The process of urban regeneration as a policy of integral improvement and planning explores the economic, cultural, social and physical reactivation of a sector in the city, starts with the implementation of glocalized policies of urban resources, arranged by concerted acts that represent the state, public agencies, communities, and economic investors.

Keywords: Latin American Urban Regeneration, Local Urban Sustainable Development, Glocalization, Community Sustainable Policies

Introduction

Latin American cities establish their own dynamics of urban planning such as: changes in land use, habitability, mobility, expansion, reactivation and influence on environmental, economic, social and cultural aspects at populated city center. The Villavicencio commune is located adjacent to the downtown of Pereira, on the east side of the city. It comprises four neighbourhoods, Villavicencio, Berlin, Corocito and Los Andes. It is a dynamic sector that faces urban, social and environment deterioration as a result of insecurity, micro-traffic, insalubrity and lack of urban integration.

The Renewal Plan of Ciudad Victoria, favored migration and commerce to the Villavicencio commune, by evicting a social group that found a place on one of the oldest sectors of the city. The commune was the right place to settle down because of the urban fabric and land use configuration into low height buildings at not an expensive value.

The urban landscape is modified architecturally, with interventions in constructions that occupy new social groups. This architecture is often rewritten on the buildings occupied in order to provide a cultural "identity" to that inhabited landscape. (Gutierrez, 2012)

The revitalization and modernization of The Villavicencio commune, with polices of urban regeneration, proposes to identify a strategy applied to cultural, social and economic variables to allow an improvement on its urban structure and configuration. The upgrading of the neighbourhood, starts from its own demands to be carry out as a collective effort, to contribute with measures and guidelines applied to the specific demands.

Urban regeneration consists of an integral development and schemes of creation of sources of work to increase housing to overcome local social problems where multiple disadvantages are concentrated (European Commission, 1997).

The identification of the strengths and opportunities of participatory action originates an individual actions that involves technical and social strategies of analysis such as the integration between human factors and the environment, implementation of territorial planning models.

The sustainability associated with supporting aims to empower the inhabitant in urban decisions, establishing actions and procedures oriented by these individuals to devise the economic, social and environmental viability of their territory. "The regional and local powers have a fundamental role in working, in urban regeneration tasks, from territorial planning to urban development and its implementation, focusing on such tasks, the permanence of regeneration, new urban development And the benefit of the existing city in relation to urban expansion. " (Committee of the Regions, 2010).

Local community initiatives are created anonymously by bottom-up residents, sometimes locally implemented by public agencies or by national voluntary organizations from top to bottom. All are linked voluntarily (without remuneration) in an effort made by local communities. (European Commission, 1997).

The result of energy exchange between the atmosphere and the soil is palpable in the microclimate of the Villavicencio commune, in response to its own geographic, topographic and climate characteristics. The local sustainability is connected to the microclimatic conditions and its influence on inhabitants, buildings and public space.

Adapting to the environment means low-impact urban interventions, in some circumstances like green facades, these specific measures of the place contribute to the configuration of the microclimate, the urban environment or a neighbourhood. The small scale presents tools of analysis, of the different local characteristics like, the microclimate, and it is necessary to understand aspects like, the solar exposition and the wind patterns around the buildings. If not mapped, the microclimate before beginning its work, could choose the wrong procedures (Lenzholzer, 2015)

Urban regeneration procedures need to evaluate and to implement management techniques of microclimatic particularities such as radiation, air temperature, relative humidity, wind patterns, thermal conductivity of materials and human factors to strengthen a local strategy that adapts its policies in the improvement of processes of sustainable management.

Urban sustainability depends on the understanding of human factors and the capacity to mediate between the climatic effects necessary in the urban planning to design and manage efficiently with the climate. An example of integration of policies and urban development is the Public Policy of Sustainable Construction for the Metropolitan Area of the Valley of Aburrá in Colombia, which establishes management plan and technical guidelines that allow to qualify the sustainability processes from the urban scale to the local for the conditions. (AMDVA-UPB, 2015)

Urban regeneration is a strategic activity, connecting short periods of time with measures for immediate difficulties and long-term estimates to avoid future problems. Focusing on getting a clear vision of what to do. It is concerned with setting priorities and making them possible. It proposes an interventionist approach, which is achieved by working societies, trying to benefit a wide range of organizations, agencies and communities. It can be measured, evaluated and reviewed. It is related to specific and potential needs in a particular region, city, district or neighbourhood. It is connected to other zonal policies and programs. (Roberts P, Skyes, H. 2016).

Sustainability and urban regeneration guidelines contribute into finding common objectives and solutions applied to social, economic and environmental development. For example, the reuse strategy at the Villavicencio commune as a sustainable policy contributes to eliminate new constructions, reducing the effect on the carbon footprint and prolonging the life cycle of materials over time, preserving the social cohesion of communities and reactivating the economic growth of activities in the sector by promoting new land uses and maintaining ownership of land while avoiding gentrification.

New policies of sustainable development at the Villavicencio commune establishes a frame of reference where the processes of Management in Urban Regeneration could be implemented and their models integrate social, economic and environmental variables for the development of sustainable development with an efficient improvement and modernization of the urban structure. A new Urban Regeneration plan should be implemented and their models to integrate social, economic and environmental variables for the development of sustainable conditions with an efficient improvement and modernization of the urban structure.

Low-carbon regeneration schemes are poised to become more common as cities are increasing their leadership role in addressing climate change, omitting national governments and taking action even in the absence of legality and international blindness of Agreements. (Jones, P. 2013)

Sustainable Urban Regeneration provides management tools for intermediate cities to be attractive for urban development, and to recuperate quality of life to benefit its population, enhancing economic and social development to connect with other urban center.

Integral Improvement of Neiborghoods, MIB as an Urban Regeneration policies.

Figure 1. Before and After Bello Horizonte Neighbourhood, Pereira. (Ministerio de Vivienda de Colombia)

Intervention on existing urban structures with high levels of physical and social degradation have been carried out as a policy of urban development in Colombia since 1950.

Deteriorated sectors of the cities have had little improvement on processes of transformation and modernization, generating static physical structures with limitations in the generation of territorial development opportunities. Integral Improvement of Neiborghoods, MIB is a city plan of ordinances oriented to improve the physical urban structure of a city sector in decay. As a set of policies is not a regeneration procedures because in most cases do not involve communities participation as a City Planning establishes the borders of intervention.

In 1951, the municipal administration of Bogota, carried out an agreement with the center for formation and training of technicians, CNVA. To generate a reference of intervention to improve of the housing conditions, creating "programs of emergency". This policy were developed in two moments, the first intervention focused on rehabilitation, improvement and eradication of parts of the city which have poor physical conditions and the second, prevention seeking to limit the emergence of new settlements in precarious conditions. The interventions carried out by the emergency programs were focused on improving the physical conditions of the identified settlements. The improvement of neighbourhoods with basic services of infrastructures at consolidated neighbourhoods, and the rehabilitation of neighbourhoods focused on legalization, the generation of urban norm, the endowment of infrastructure and the construction of housing. The eradication of slums implied the transfer of families due to their location in non-urbanized soils due to risk conditions or the impossibility of providing public services.

Table 1. Guidelines Policy Consolidation of Integral improvement of districts for Colombia. (CONPES 3604)

Risk Intervention	***PUBLIC SCOPE***	Focuses on the intervention of the urban structuring systems that make up the physical environment of the intervention area.	Actions that eliminate the risk conditions of the population, from works of mitigation or relocation of housing.
Ordinances			Actions of planning from projects that allow the legalization and regularization of settlements.
Public Residential Services			Scope of work that allow the consolidation of basic services of water, energy and sanitation to guarantee the habitability and health of the settlements.
Recovery and Environmental Protection			Actions on the management of areas not susceptible to urbanization before they are invaded to preserve their value within the urban fabric of the city.
Accessibility and Mobility			Actions that allow an adequate mobility within the intervention area and connect in an integral way to the rest of the city.
Public Open Space and Equipment			Actions to consolidate the systems that provide services to the population to guarantee the consolidation of the settlement.
Titling	***PRIVATE SCOPE***	Focuses on the intervention of the complementary structured systems, mainly residential buildings present in the area of intervention.	Direct actions that allow the security on the property, generating tranquility and rooting among the inhabitants of the area of intervention.
Improvement of Housing			Actions for the improvement of housing in health, protection and operation.
Re-densification with New Housing Developments			Recomposing the urban structure requires a differential and more effective use of the land, so re-densification actions allow the resettlement and the opening of the area of intervention to new inhabitants.
Community Participation	***SOCIAL & ECONOMIC SCOPE***	Focuses on the transversal actions of social, cultural and/or economic character that allow to involve the community in the process.	Actions that are in a transversal way to the physical transformation, activate the interest of the community to improve, conserve and develop the characteristics of the settlement.
Institutional Strengthening			Actions that allow the presence of the public administration from services and activities that generate meetings between the parties in search of the permanent development of the community.
Security and Coexistence			Actions that seek to improve the quality of life of people, seeking the consolidation of a community in peace.
Generation of Income			Actions that allow the economic development of the population, which allows more purchasing power to improve their habitat and the eradication of illegal activities within the community.

Nevertheless, the practical development of programs determines the importance of social work to prevent and eliminate negative social conditions, such as generation of vicious circles. Granting stimulus by programs that are population appreciated as an opportunity to generating improvements to precarious conditions, as Eric Carlson says, "any urban renewal program must take into account human aspects and the importance of the group's work as an essential part of physical planning" ICT, 1966: IX (Torres , 2009)

CONPES 3604, defines a set of guidelines for the consolidation of the policy of integral improvement of districts, establishes the program's performance in three broad areas, including the areas of intervention public and private, the social responding to the human dynamics existing in the intervened sectors.

CONPES establishes elements required for the development of programs for integral improvement of neighbourhoods, MIB. Beginning with the studies to establish the tangible and intangible conditions of the settlement, going through the articulation with the territorial planning, with the capacity to provide structuring systems in public space, public services, and environmental management of the municipality to determine the environmental risk conditions to the settlement. The figure 2, Cycle Program Integral Improvement of Neighbourhoods shows the procedure established for this type of interventions in two possible actions on the territory depending on the requirements and needs of the same, the first an improvement properly said, and the second the resettlement of the population when it is required.

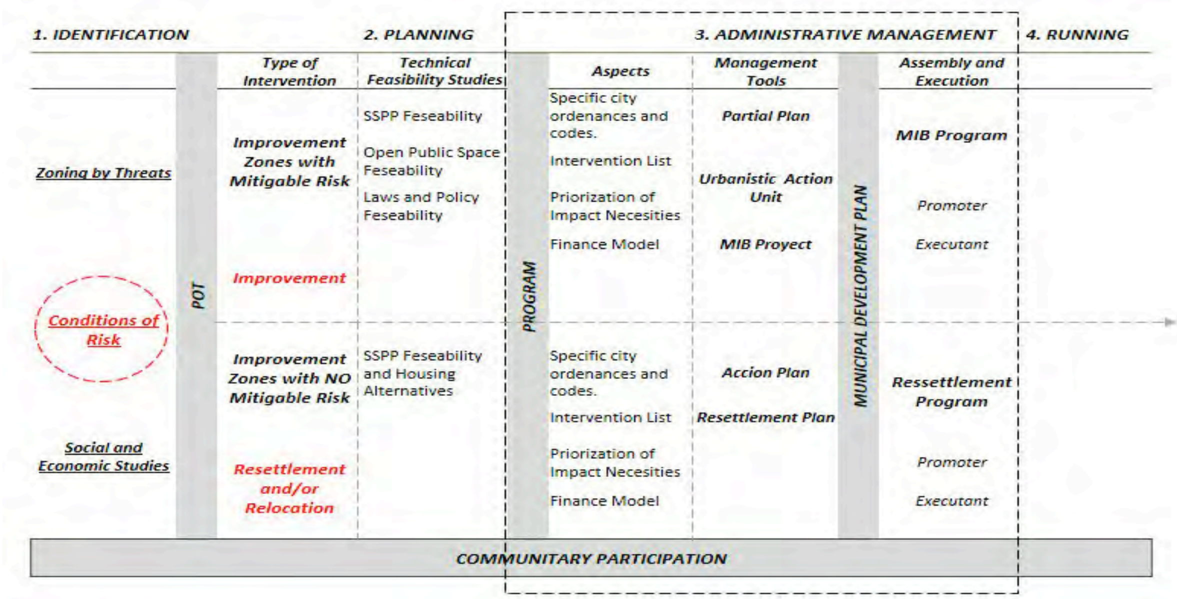

Figure 2. Cycle Program for Integral Improvement of Neighbourhoods – MIB (NDP, 2009)

The city of Pereira have developed two urban interventions with different results. First was a MIB at Bello Horizonte at the Cuba Commune on the west side of the city. The second was Ciudad Victoria, an urban renovation plan next to the Villavicencio commune. See table 2 for a parallel figure between urban interventions in the relevance of actions.

Table 2. Parallel of Urban Interventions at the City of Pereira, Colombia

		BELLO HORIZONTE	***CIUDAD VICTORIA***	***VILLAVICENCIO COMMUNE***
Risk Intervention	*PUBLIC SCOPE*	Areas of risk are established and work is done with the community for protection.	The areas of the Egoya collector are determined and established as public space.	There is a condition of slope that causes the re-localization of housing. Measures not in place.
Ordinances		A surgical order is made to improve the existing conditions, respecting the maximum the settlement.	An order is made that does not take into account what exists	Local city ordinances should be applied such as POT and Partial Plans.
Public Residential Services		The infrastructure is provided to the neighborhood to consolidate the provision of the service with quality.	The location of the area guarantees the availability of the service. The intervention focuses on the modernization of the networks.	The area has a respectable network of services. It requires to legalize service at informal housing.
Recovery and Environmental		The perimeter green areas and a public recreational area are consolidated.	It consolidates the public space around the protection floor.	The area around the Egoya fault must be consolidated.
Accessibility and Mobility		The road network is conditioned to guarantee pedestrian mobility and public and private vehicular transport.	The road mesh is conditioned to guarantee pedestrian mobility and public and private vehicular transport.	To connect the existing system to the city grid. Pedestrian paths are fragmented with opportunities of consolidation at city block centers
Public Open Space and Equipment		It creates a recreational public space, a synthetic football pitch, and a small covered meeting space that are physically connected by a Pompeian.	The Victoria Civic Square and the Lucy Tejada Cultural Center are created.	There are no consolidated connections between public spaces. To improve existing recreational spaces.
Community Participation	*SOCIAL & ECONOMIC SCOPE*	The community is actively involved in the whole process.	Did not take into account the existing population of the area; a displacement was generated with homeless population and drug addicts.	There are several organized groups that represent the interests of the population and seek community welfare.
Institutional Strengthening		Consolidated board of local action. Currently has a representative of the community in the Municipal Council.	There is no action. It is well balanced by the central location of the intervention area.	There is no quantification for this characteristic.
Security and Coexistence		The permanent work with a community allowed integration and social controls.	This is not addressed in the process.	There is no security due to the lack of coverage of the service.
Generation of Income		Working with the community, the urban structure is transformed to generate new trades around the centrality.	New developments such as mall and anchor retail store were developed. This is not addressed in the process.	Informal resources.
Titling	*PRIVATE SCOPE*	A titling process is generated for families who demonstrate the required legal conditions.	It is not required. Property integration is sought, but has not been developed.	It is required a titling because there are some areas with not legal housing at risk conditions.
Improvement of Housing		The improvement actions are carried out to the dwellings that present the worst conditions of habitability.	No action is foreseen inside the existing buildings, the total renovation is sought.	Improvement measures are required at existing housing.
Re-densification New Housing Developments		There are no new housing projects.	New housing projects are truncated by the economic speculation of the land and management of the municipal administration.	Low-rise buildings are predominant. The real estate market wants to densification in height.

The Social and economic environment strength of the MIB planning is to integrate the public and the private sectors to solve with creativity, ingenuity, an adequate budget physical conditions in an integral way of sustainable planning. Another way of taking actions of sustainable development, can be acquire with the implementation of policies based on indicators that characterized of the quality of life and services for a smart city.

International standards for the sustainable development were develop by the International Organization for Standardization, ISO on its standard number 37120:2014. The applicability of these standards provides valuable information of analysis looking forward sustainable development strategies. A smart neighbourhood recognizes its efficiency to improve quality of life, and services where a sustainable indicators provides an understanding of direct actions for a feasible strategies, to investigate variables that reflect the appropriation of sustainable development by their population.

The ISO 37120:2014 contemplates indicators that can be transferred from the international standards to local policies. To diagnose the urban sustainable development of improvement of the Villavicencio commune. It’s important to assess a standard analysis that allow to classified local data and to produce a methodology guide to categorize variables.

Table 3. Comparison of Indicators of Sustainable Development

	ISO 37120 : 2014	***VILLAVICENCIO COMMUNE***
1. Economy	Unemployment data, levels of poverty, a percentage of young unemployment and full time employees, number of business and number of new patents.	Unemployment makes measurement difficult because informal work is one of the main sources of resources for the population.
2. Education	Female students percentages, number of students who complete the Elementary, Secondary & University. Includes a ratio of student / professor at elementary school.	The neighborhood has three educational institutions for primary and secondary to cover the population. The majority of the population do not have university education.
3. Energy	It determines the access to service, energy consumption and the interruption of service during a year.	It has stratification in the cost in relation to the city. There is no alternative of energy production, nor incentive policies to reduce consumption.
4. Environment	It measures the amount of harmful particles and greenhouse gas emissions in tons per capita, nitrogen dioxide concentration, sulphur dioxide, ozone concentration and noise levels impact.	Requires studies to determine the air quality and the effects of gases generated by the small and medium industries of the sector.
5. Finance	Debt coverage indicator of debt, cash capacity to cover interests, bill rates and securities indicators.	The capacity of indebtedness is minimal because the majority of the population does not have access to bank credits due to the informality of their work.
6. Emergency	Amount of fires per each 100 miles/hectares, death by natural disasters per each 100 miles/hectares, prompt response by emergency calls, and response to first call from fire department.	There is a deficit in the provision of emergency services, since there are no first-level hospital or care centers. The deficiency of fire stations is generalized in a city.
7. Government	Measures the level of participation in the last municipal elections, rate of convictions for corruption per 100,000/ha and voters registered in relation to people of voting age.	Citizen participation is limited in women and young adults. The Corruption and crime is high. There is little representation of the population in government institutions.
8. Health	Life expectancy, number of hospital beds, number of doctors, percentage of under-five death rate, number of nurses, number of mental health professionals and suicide rates.	The basic health service is provided by health centers and not by hospitals since there are no first-level hospital in the area.
9. Recreation	It takes into account the amount of .2 m / person available for recreational spaces both indoors and indoors.	There are three parks in the sector but the public space deficit is high for the existing population.
10. Security	Number of police officers, number of suicides, crime rates against property. It takes into account the response time to calls to police before an event.	There is a deficit in security. There is a plan to build a new policy station in a selected neighborhood.
11. Shelters	It assesses the percentage of inhabitants living in poor neighborhoods, the number of "homeless", and the number of unregulated households.	New housing centers are needed because of proximity to Liberty Park which is well known area for homeless.
12. Waste Management	It measures the percentage of population with sanitation facilities, total solid waste collected by the municipality, waste sent to an incinerator or landfill. The capacity to generate hazardous waste in tons per capita is also calculated.	The commune is connected to the sewage system and rainwater collection of the city. There are no own policies for the management of waste or garbage.
13. TIC Innovation	Number of internet connections, the number of mobile telephone devices and the number of fixed telephone lines.	There is no quantification for this indicator. The internet service is contracted with particular providers of the service.
14. Transportation	Number of kilometers of high-capacity public transport network, number of journeys carried out by public transport, percentage of workers using a different mode of transport.	There is a limited service in public transportation. There are not bicycle lines.
15. Urban Planning	It measures the hectares of green areas, a number of trees planted annually, and the number of jobs per household.	No new areas has been created, existing infrastructure is maintained, community participation.
16. Water Management	Percentage of the population that has facilities for wastewater collection and the level of treatment of water purification.	There is no quantification for this indicator.
17. Potable Water & Sanitation	Percentage of population with drinking water facilities, consumption of drinking water per capita, number of hours of water service without interruption and percentage of water loss.	Drinking water is supplied by the city, there are sectors of the population located in areas of risk that do not have the service.

The implementation of indicators of sustainable development in cities, offers the possibility of developing methodologies and models that establish criteria of urban regeneration at the neighborhood level, that contribute into dimension and implementation of sustainable development policies of smart cities. These processes require the participation of professionals and community leaders incorporating trans-disciplinary strategies that guide decisions to obtain sustainable development indicators that respond to technical, economic, social, urban and environmental issues.

The findings in this study display significance of development regeneration strategies as a need to address an integral respond into the urban planning of neighbourhoods. The existing policies do not respond to criteria's about sustainability as challenge of designing existing sectors on cities includes to integrate social and economic, private, public participation of different groups of its community. To recognize renovation and regeneration planning as a mayor force of transformation of the existing urban fabric of neighbourhoods which contributes to the sustainable design of cities in Latin America as develop a responsible attitude about the preservation of the environment.

Solar Thermal Venetian Blinds – Transparency, User Comfort and Solar Energy in one!

Simon Frederik Häringer[1], Ikbel Abderrahman[1], Puttakhun Vongsingha[2], Tilmann E. Kuhn[1], Paul-Rouven Denz[2], Christoph Maurer[1]

[2] Facade-Lab GmbH, Am Wall 17, D-14979 Grossbeeren/Berlin, Germany

Abstract: Solar thermal venetian blinds (STVB) combine the switchable transparency and glare protection of venetian blinds with decreased temperatures of the interior glass pane and a supply of solar thermal heat. Venetian blinds placed between two glazing units as e.g. in closed-cavity façades can reach high temperatures. Removing the solar thermal heat from the slats reduces the temperature of the glass unit facing the interior which increases the thermal comfort for people inside the building. This also reduces the cooling load because less heat flows from the façade to the building interior. The solar thermal heat can be used e.g. for domestic hot water and dehumidification to reduce the carbon footprint of the building. Different varieties of STVB can be designed and two examples are presented to show the potential of STVB.
Heat pipes are used to transfer the absorbed solar energy from the slats to the vertical header tube. Heat pipes and header tube are connected by a dry switchable thermal coupling allowing full movement of the slats. As the STVB uses only few additional parts compared to conventional venetian blinds and focuses on mass-produced parts, it has the potential to offer a very competitive price for solar thermal heat.

Keywords: building-integrated solar thermal (BIST), solar thermal building envelope, thermal comfort, venetian blind, double-skin façade

Introduction

The development of solar thermal venetian blinds (STVB) pursues the idea to use the energetic potential of solar irradiation on transparent façades. STVB can enhance the functionality of venetian blinds by adding solar thermal collector functionality into it. Large transparent façade areas can thus actively contribute to a reduction of primary energy demand while having the same structure and benefits of the façade system. Furthermore STVB have the potential to improve the thermal comfort by lowering temperatures for venetian blinds mounted in between glass units as e.g. in double-skin façades.

Building-integrated solar thermal collectors (BIST) have saved 40% in the past compared to building-attached collectors installed after the initial construction (Cappel et al., 2015; Maurer et al., submitted). But space for opaque BIST is limited with modern architecture thriving for highly transparent façades. Especially in high-rise buildings, venetian blinds are often used in between an outer and inner glazing and can reach high temperatures due to solar irradiance (Gratia and Herde, 2007a). STVB could resolve this problem and reduce the heat flux to the building interior which decreases the cooling load.

State of the art

BIST & Transparency

The idea of removing solar thermal heat from the building envelope dates back to (Morse, 1881). Semi-transparent solar collector window systems were proposed by (Fuschillo, 1975). An overview of related research on Trombe walls, BIST air collectors, is presented by (Saadatian et al., 2012). BIST collectors for opaque building envelope areas are market-available in various forms (IEA SHC Task 51, 2016; Maurer et al., submitted). For transparent BIST, fewer technologies are available. A semi-transparent BIST with seasonal sun shading was invented by (Robin, 2002; Robin Sun) and installed in many buildings. Permasteelisa developed a semi-transparent BIST with small slats and seasonal shading (Maurer et al., 2013; Maurer et al., 2014). A semi-transparent BIST with vacuum tubes and perforated concentrator sheets is available from (Ritter XL Solar GmbH, 2017; Wolf and Molter, 2012). All previously listed collectors work with liquid as heat-transfer medium, whereas Kollektorfabrik developed a semi-transparent BIST which is used to heat air directly (Maurer et al., 2012). Two transparent BIST technologies using water in between glass units are under development (InDeWag, 2017; Stopper et al., 2013). This approach offers full visual contact to the exterior but lacks glare control and the solar thermal efficiency is small.

Several patents have been filed which claim or could be interpreted as solar thermal blinds, some of which appear to be tiltable like (Bittmann, 2006; Pierce, 1977). However none of the technologies known to the authors offer STVB that are both tiltable and retractable as proposed in this contribution. To the best of our knowledge only theoretical studies of fully tiltable and retractable STVB with liquid heat transfer medium have been published. Different theoretical approaches for solar thermal venetian blinds were discussed by (Cruz Lopez, 2011). Another theoretical study claims possible reduction of solar heat gain by 33% in Mediterranean climates for STVB in double-skin façades (Guardo et al., 2015). The STVB presented in this contribution aims to close this gap between theory and practice by employing a switchable thermal coupling.

Overheating of conventional venetian blinds in cavities

Venetian blinds placed in the cavity between an outer and inner glazing can experience a serious overheating problem. (Gratia and Herde, 2007a, 2007b) studied the effect of venetian blinds, their color and position and other parameters on cavity and blind temperatures and energy consumption in double-skin façades (DSF). Thermal comfort can be affected negatively if the temperatures of the glazing facing the room differ significantly from the air temperature and surface temperature of the room's walls as defined in the ISO standard 7730 (International Organization for Standardization, 2005).

Another drawback of high cavity temperatures is the additional stress it puts on components. In closed-cavity façades (CCF) this is particularly important as they by design lack the option for ventilation as possible for DSF and can reach temperatures up to 85°C (Lutz, 2012). New technical solutions were developed e.g. for the venetian blind mechanism to withstand the high temperatures (Schrag, 2015). Last but not least high cavity temperatures can also increase solar heat gains to the building interior (Gratia and Herde, 2007a). Depending on the U-value of the interior glazing a significant portion of the heat absorbed in the cavity can enter the building rather than being released to the environment.

Working principle of solar thermal venetian blinds

A typical façade element with a solar thermal venetian blind consists of an outer glazing and an inner double or triple glazing. The STVB is mounted in between the glass units as shown in Figure 1. The slats of the STVB absorb the incident sunlight. Different types of slat coatings can be used such as conventional or spectrally selective coatings with strong absorption. Solar heat pipes are used to extract the absorbed solar energy from the slats. Different heat pipe geometries can be used and either be attached to the bottom of the slat (e.g. cylindrical heat pipes) or used as slat itself (e.g. flat heat pipes). The heat pipes are connected to a vertical header tube placed in the façade element frame. The heat is transferred from the heat pipes to the fluid in the header tube via a dry connection. For this purpose a switchable thermal coupling is being developed and has been filed for a patent. This switchable thermal coupling transfers the heat when it is closed. If it is open the slats are free to move and can thus be tilted, raised and lowered as known from regular venetian blinds. To improve the thermal contact between each heat pipe and the header tube adapters can be used. The combination of using heat pipes and the switchable thermal coupling leads to having only two simple hydraulic connections per façade element and no flexible tubes. The STVB is designed to need as little maintenance as conventional solar thermal systems. A control strategy can be implemented to optimize thermal comfort, energy harvesting and user comfort considering daylight demand and glare protection. Ideally an automatic but user-adaptive control is used with purpose of maximizing user comfort and energy performance.

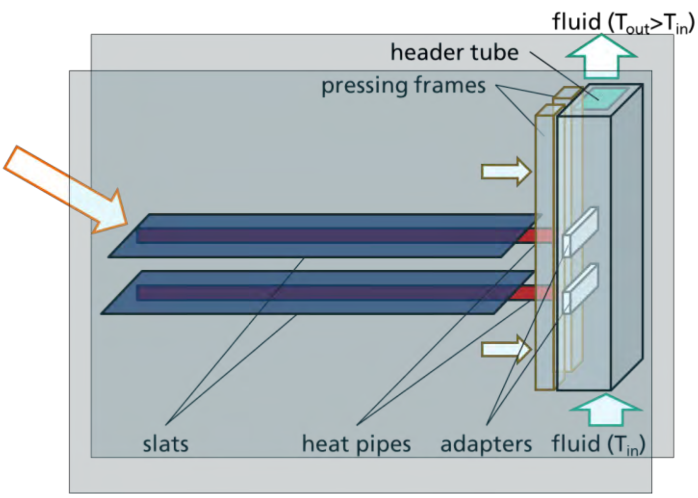

Figure 1: Working principle of solar thermal venetian blind

Solar heat pipes are well-known from their application for example in vacuum tube collectors. However operating these heat pipes in horizontal orientation is yet challenging and is currently being optimized for application in STVB. Another technical challenge is designing the switchable thermal coupling in a way that it provides good heat transfer, allows all slat movements and has the same service life as the façade at competitive costs. A test sample with two different mechanisms is being manufactured to gain more knowledge about feasibility and durability of the mechanisms (cf. section “First test sample”).

Potential benefits of solar thermal venetian blinds

STVB have the potential to integrate solar thermal functionality into transparent façade areas and to improve thermal comfort in the building interior. STVB are particularly interesting to be used in double-skin façades (DSF) and façades with box-type windows. Closed-cavity façades (CCF) as a subcategory of DSF are promising, as they provide a clean environment to the STVB and no soiling of the slats will occur. The overheating problem present in CCF could be reduced by using STVB. An ideal application of STVB would be a building with large transparent building envelope areas, significant demand for domestic hot water in which external blinds are not desired or feasible. The design of STVB has large freedom since it combines the design possibilities of venetian blinds (e.g. shape, geometry, top and bottom surface coating, cf. (Kuhn, 2017)) and adds a dimension for the solar thermal functionality which includes the choice of heat pipe, mechanism etc. To illustrate the large design variety of STVB a variant focusing on a *low g value* and a variant focusing on a *high solar thermal performance* are being discussed in the next two subsections.

Focus low g-value

The aim of the STVB variety *low g-value* is to minimize the solar gain to the building interior and maximize thermal comfort in the building. The primary purpose of the solar thermal functionality is thus to lower the slat and cavity temperatures. By lowering the cavity temperature less heat flows to the inside and the temperature of the interior glass unit is closer to room temperature. If the STVBs are lowered and closed very small g-values could be reached. This is possible because the STVB in this case acts as solar control device and as solar thermal collector, i.e. direct radiation is absorbed or reflected by the blinds and excess heat is removed. However the excess heat is not simply removed but turned into useful energy which could be used to heat domestic hot water or for solar dehumidification thus providing a renewable energy source.

Figure 2: Visualization of three different façades with STVB, variety *low g-value*

STVB aiming at minimal g-values should employ slats with a reflective coating to minimize the absorption of solar radiation in the cavity in the first hand (cf. Figure 2). To remove the absorbed energy efficiently the heat transfer from the slat through heat pipe and switchable thermal coupling into the fluid in the header tube needs to be good. The temperature of the fluid when entering the header tube at the bottom of the façade element should be low to extract as much heat as possible, i.e. to cool the slat effectively. Also the thermal insulation between cavity and interior needs to be large to ensure heat is removed via the header tube and not into the building. This means double or even triple glazing should be used for the interior glazing and also the frame should be well insulated. With outdoor temperatures comparable or higher than the cavity temperatures a good insulation to the exterior is preferable. For outdoor temperatures lower than cavity temperature a small insulation could be helpful in additionally removing heat from the cavity. This heat however is lost as it is not turned into useful energy. A control should aim at maximizing daylight while minimizing glare and overheating of the room.

A promising application case of this STVB is an office high-rise building with solar dehumidification. To prove the potential of the STVB future studies will compare a building with STVB with reference cases. Examples for reference cases include the same building with conventional blinds in the glazing cavity with or without improved solar control glazing or with less transparent areas in building envelope.

Focus solar thermal performance

The STVB variety *high solar thermal performance* aims at maximizing the collected solar energy in form of heat. The solar thermal functionality aims at significantly heating up the collector fluid, e.g. to use it to heat domestic hot water. The STVB thus has to be designed such that it absorbs a maximum amount of incident solar radiation and to minimize losses of this absorbed energy to the environment.

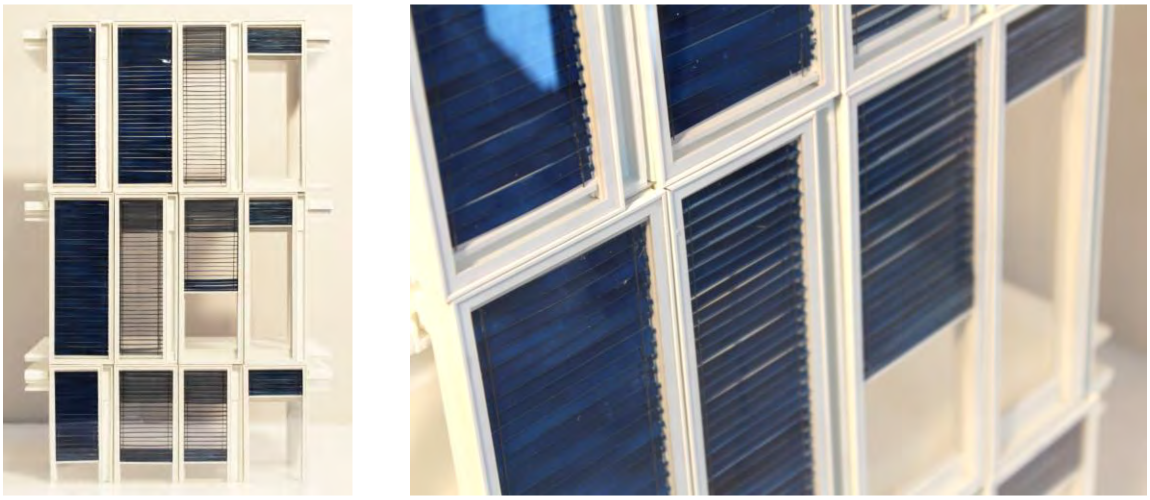

Figure 3: Architectural model of façade with *high solar thermal performance* STVB as presented at the trade fair BAU 2017 in Munich

High solar thermal performance STVB could use spectrally selective coating as known from conventional solar thermal collectors and photovoltaic cells. The appearance of this coating is dark blue as illustrated in Figure 3. The heat transfer between absorbing slat and fluid in the header tube should be maximized as in the *low g-value* variety. The fluid temperature at the inlet could be set to reach desirable outlet temperatures useful for its designated purpose such as heating domestic hot water. Here an optimization could take place with regard to maximizing the solar thermal performance and still maintaining a low g-value by operating the STVB at low fluid inlet temperatures. Insulation should be good to interior and exterior to minimize all losses. For the exterior glazing a trade-off has to be found between maximizing solar transmission and maximizing insulation properties with the overall goal of maximizing the solar thermal yield. If maximizing the solar thermal yield is the only criteria blinds should always be lowered and slats tilted to face the sun as proposed by (Cruz Lopez, 2011). However this is an impractical assumption. Daylight demand and user comfort should be taken into account and included in an automatic control that can be overruled by the user.

The application of the *high solar thermal performance* STVB would be promising for example in a high-rise building which is partly used as hotel. Reference cases for further studies aiming to prove the potential of this STVB could include the same building with conventional blind in the glazing cavity, or with conventional solar thermal collectors on opaque building envelope areas, or with stationary semi-transparent solar thermal collectors on opaque building envelope areas.

First test sample

Currently a laboratory test sample is being manufactured with the aim of testing the mechanisms of the switchable thermal coupling and the tilting and retracting of the slats. One particular configuration of the STVB was chosen for this test sample. A cylindrical heat pipe dummy of 10 mm diameter is attached diagonally to the bottom of the slat (cf. Figure 4). The diagonal configuration leads to a small operating angle of the heat pipe which improves its performance compared to horizontal orientation. Currently, flat heat pipes which work efficiently in horizontal orientation within the façade systems are under development. For the switchable thermal coupling an adapter between heat pipe and header tube was designed as visible in Figure 4. Two different mechanisms will be investigated for the switchable thermal coupling. Both aim at using a minimum amount of energy. For this purpose self-locking mechanisms were chosen that only require energy for the movement but none for the end positions *open* or *closed*. The first mechanism employs springs and self-locking solenoids, while the second mechanism uses a cam-shaft driven by a stepper motor.

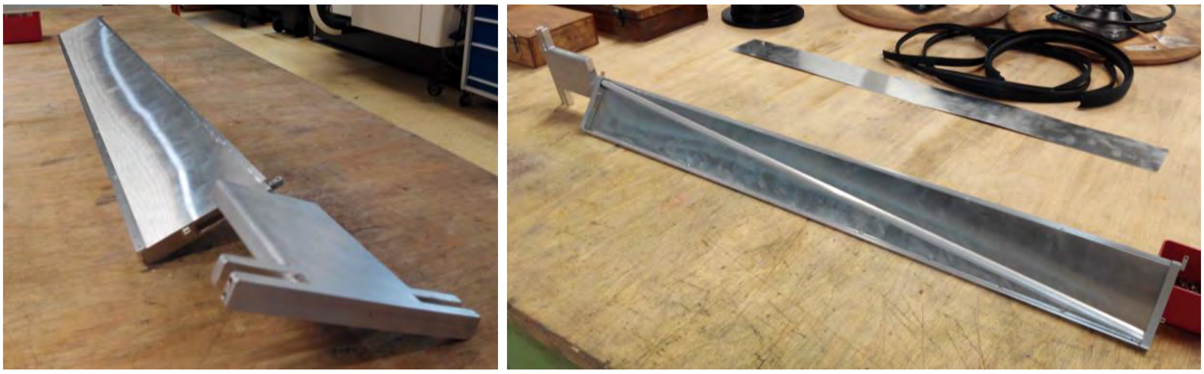

Figure 4: First produced slat of proof-of-concept test sample with adapter visible in the foreground (left) and bottom view with diagonal heat pipe mounting (right)

During the design of the test sample it was found that the slat design with the non-centered adapter poses a challenge to the tilting mechanism. This was resolved by moving the rotation axis of the slat into the actual center-of-mass of the slat assembly and adding mounting pieces to attach the tilting mechanism to the slat. Main focus during the testing period will be the reliability of the pressing mechanisms over many cycles of opening and closing the switchable thermal coupling combined with a large variety of blind movements.

Conclusion and outlook

The solar thermal venetian blinds offer the same flexibility as conventional venetian blinds and can improve the user comfort and the carbon footprint of the building additionally. With a few more components compared to conventional venetian blinds between glass units, STVBs can reduce the temperatures of the interior glass unit, the cooling demand and supply solar thermal heat to the building services. Many variants can be realized. Two promising cases are variants focusing on a *low g-value* and *high solar thermal performance*. Using heat pipes for the heat transfer and a switchable thermal coupling offers a safe and effective way to implement this functionality into a venetian blind. Two mechanisms for the switchable thermal coupling were developed and a test sample is currently being manufactured. It will be tested for reliability of the mechanism, especially with regard to the combination of blind mechanism and switchable thermal coupling mechanism.

Optimization of the slat in combination with improved horizontal heat pipe performance is an important next step in improving STVB. Thermal, energetic and optical measurements on a first STVB façade element are planned. The measurement results will then be used to calibrate a simulation model of STVB facades which can easily be used by planners to quantify the benefits of solar thermal venetian blinds for a specific building project. To enable the implementation of the system the constructional and architectural integration of STVB into the façade is developed in parallel to the technical aspects of the STVB itself. Finally, an integrated façade and building service solution for the STVB system should be designed to realize a holistic STVB façade solution in first reference projects.

Increasing the Utilization of Local Energy Potentials through Low Temperature District Heating Networks

Karl Martin Heissler[1], Jakob Metz[1], Thomas Auer[1] and Isabell Nemeth[1,2]

Abstract: The development of district heating networks over the last two centuries, changing from steam to pressurized water as medium for heat transport, has been an evolutionary process with various aims: preventing boiler explosions, raising comfort and saving fuels. With the substitution of steam, the supply temperature levels also decreased to 100°C or less, which led to fewer heat and process losses (Lund et al., 2014). However, the advantages of further lowering the supply temperatures to a level of 5°C to 40°C, especially in combination with solar thermal collectors, are unknown. In this paper, we present a modelling approach and a comparison of the thermal losses of a low temperature district heating network and a state-of-the-art district heating network. The thermal losses of the low temperature district heating network amount to 1.89 % of the district's total annual heat demand versus 12.97 % of thermal losses in a traditional district heating network. The results demonstrate how a further reduction of supply temperatures in district heating networks can reduce the thermal losses significantly and help district heating systems to become more energy efficient.

Keywords: Low temperature district heating networks, solar thermal, renewable energy, co-simulation, energy efficiency potential

Introduction

The 2015 United Nations Climate Change Conference set ambitious targets for the minimization of greenhouse gas emissions (United Nations, 2016). Every sector, especially the buildings sector with its 36 % of CO2 emissions share (European Commission, 2017), has to improve and become more energy efficient. Lowering the energy demand of buildings for space heating and domestic hot water production can therefore only be one piece in a puzzle that amongst other measures has to include the improvement of supply structure of buildings and districts. These were designed and built over the last two centuries, serving vastly different demands and requirements than those of today's energy efficient buildings. Currently, second generation district heating networks (DHNs), which are still in use, operate with supply temperatures of 100°C or higher (Lund et al., 2014). This leads to heat losses during transport due to the temperature difference with the surroundings. The DHN principle is to supply low mass flows at a high temperature level and to reduce these high temperatures on-site with mixing valves to a lower target temperature. For use in domestic hot water systems the supply temperature has to be reduced to a maximum of about 60°C. Low temperature district heating networks (LTDHNs) reverse this approach: cool supply temperatures in the network are lifted to the temperature levels needed precisely where and when they are needed (Sulzer & Hangartner, 2014). Previous studies examined LTDHNs supplied by groundwater heat and found a significant potential for the reduction of thermal losses by 25 % (Bestenlehner et al., 2014).

The approach of using a co-simulation environment of TRNSYS (Trnsys 17, 2014), BCVTB (Wetter et al., 2016) and Dymola (Dymola, 2016) allows the assessment of thermal losses of both DHNs and LTDHNs (Heissler et al., 2016). This simulation approach is expanded to enable an easier exchange of models within the frameworks and thus facilitate a comparison of the losses of DHNs and LTDHNs.

Methodology

Tools for modelling LTDHNs have to cope with highly dynamic and reversible flow conditions compared to traditional DHNs. The approach presented by Heissler et al. (2016) suggests a three-part simulation framework to cope with the various modelling requirements (Figure 1): Collector and Building Simulation, Interlink Zone, and Hydraulic Network and Storage Simulation.

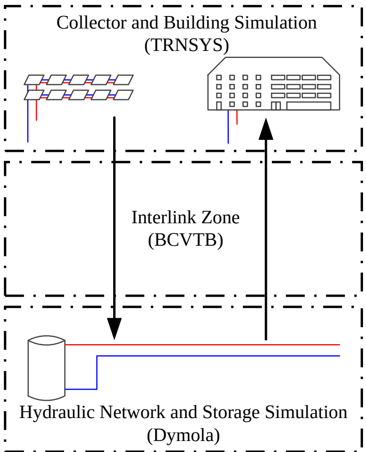

Figure 1. Simulation framework as proposed in Heissler et al. (2016)

In this work, we propose a separation of the Collector and Building Simulation into two parts: a Heat Demand Model and a Building Services Model. This allows for a more flexible approach and an easier exchange of models within the frameworks (Figure 2). Here, the Heat Demand Model is realized as an Excel Makro. The communication between the Building Services Model and the Hydraulic Network and Storage Simulation, which are implemented in two separate simulation environments TRNSYS and Dymola, is established by the tool BCVTB which enables data exchange during an ongoing simulation. With these simulation frameworks, two different types of networks, DHNs and LTDHNs can be compared. Both frameworks depicted in Figure 2 are supplied with identical weather data and heat demands. Each Building Services Model meets the heat demand by primarily using the local solar potential. If the heat demand cannot be covered locally, it is forwarded to the hydraulic network. The hydraulic network in turn meets this heat demand by circulating fluid through the loops supplying the buildings with heat. Depending on the temperature gradient between fluid and surroundings this fluid loses heat during transport. The aim of this paper is to compare the thermal losses of the two different types of networks, to pinpoint the magnitude and temporal occurrence of these losses and with that explore the energy efficiency potential of LTDHNs.

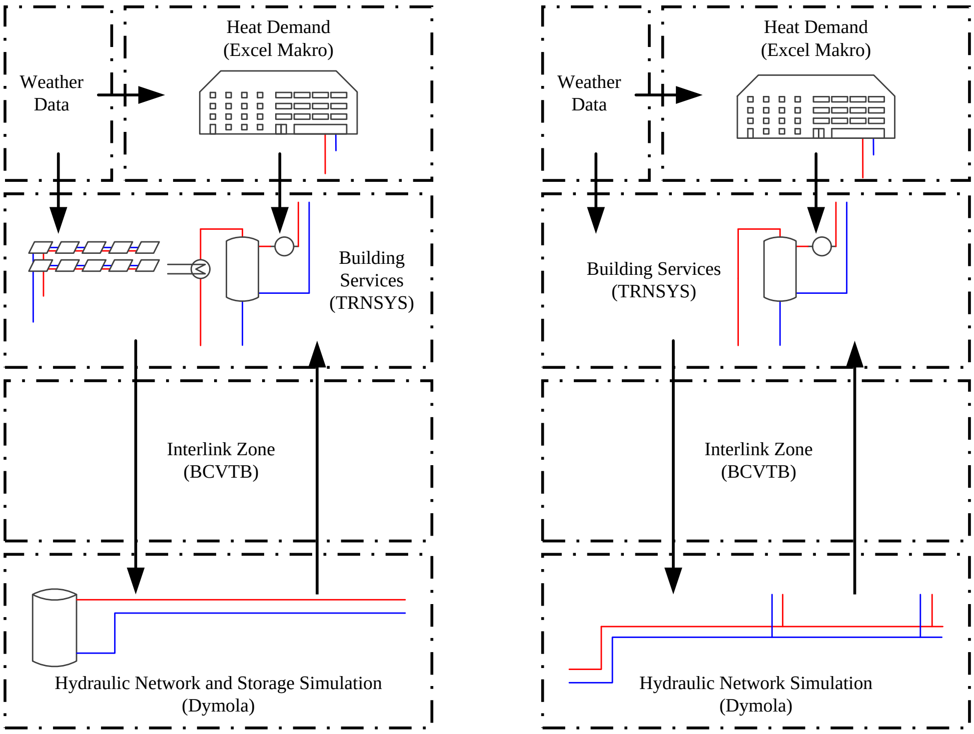

Figure 2. Model Frameworks (LTDHN left, DHN right)

The DHN and LTDHN frameworks shown in Figure 2 partially differ in the models they contain:

DHN framework

The **DHN Building Services Model** contains a small stand-by storage which feeds the heating water (HW) and the domestic hot water (DHW) loop (Figure 3):

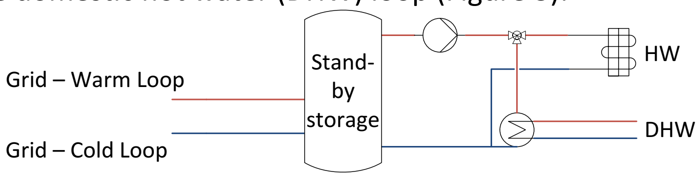

Figure 3. DHN Building Services Schematic

This storage is supplied by the **DHN Hydraulic Network Model**, a one-directional grid with fixed supply temperatures. To prevent cooling-down during times of low heat demand, supply and return line are periodically short-circuited (thermal flushing) to maintain a minimum supply temperature of 60°C in the outermost legs of the grid.

LTDHN framework

The main components of the **LTDHN Building Services Model** are the solar collectors, stand-by storage, buffer storage, heat pump and electric heater (Figure 4). The solar loop connects the collectors with the stand-by storage and the buffer storage. The stand-by storage is supplied by the solar loop or the secondary loop of the heat pump, and supplies the energy needed by the HW loop and the DHW loop, which is additionally heated by an electric heater. The heat pump is fed by the primary loop which connects buffer storage, heat pump and LTDHN. The aim of the LTDHN building services model is to maximize the local use of heat and use the LTDHN as overflow/source only when needed.

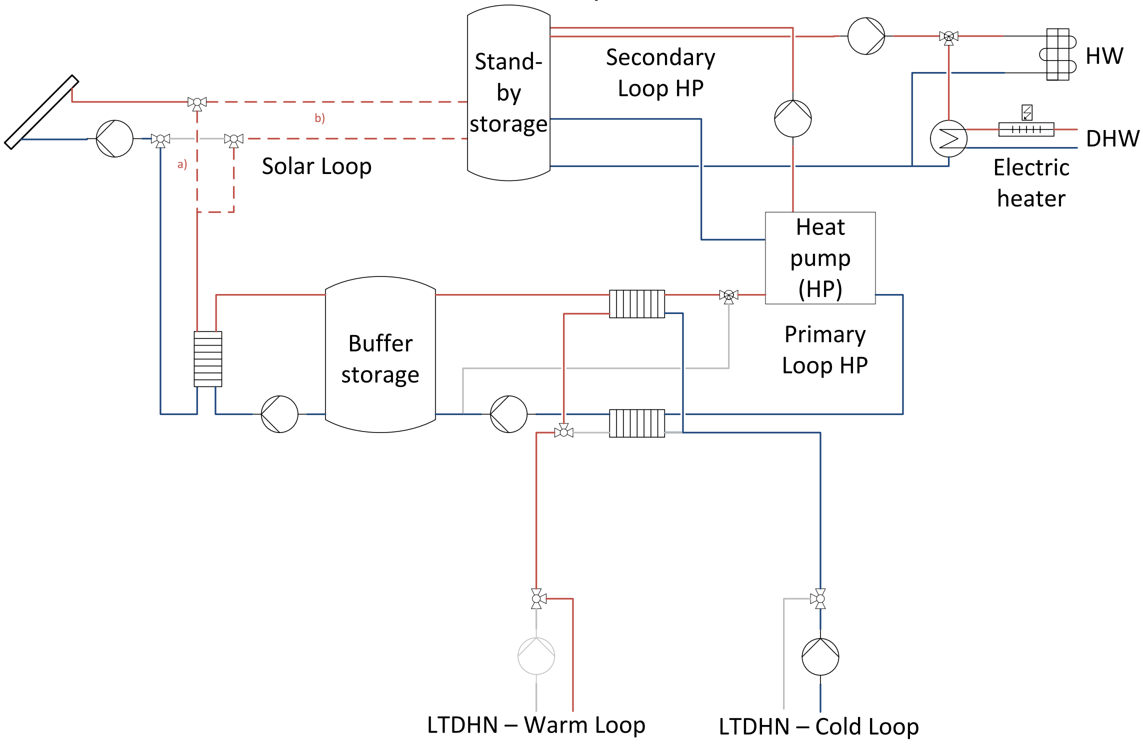

Figure 4. LTDHN Building Services Schematic

The main component of the LTDHN Hydraulic Network and Storage Model is a bidirectional grid which allows a reversal of flow within the grid depending on the applied loads and temperatures. A borehole heat exchanger acts as seasonal storage and ensures hydraulic balancing (Heissler et al., 2016).

Simulation

Both simulations are fed with identical load profiles which are based on a case study of an ecological model settlement quarter. The ecological model settlement quarter is part of a 30 hectare area, the site of the former Prince-Eugen-Barracks in the east of Munich, which is to contain up to 1800 flats and is currently under development (Opitzsch, 2014).

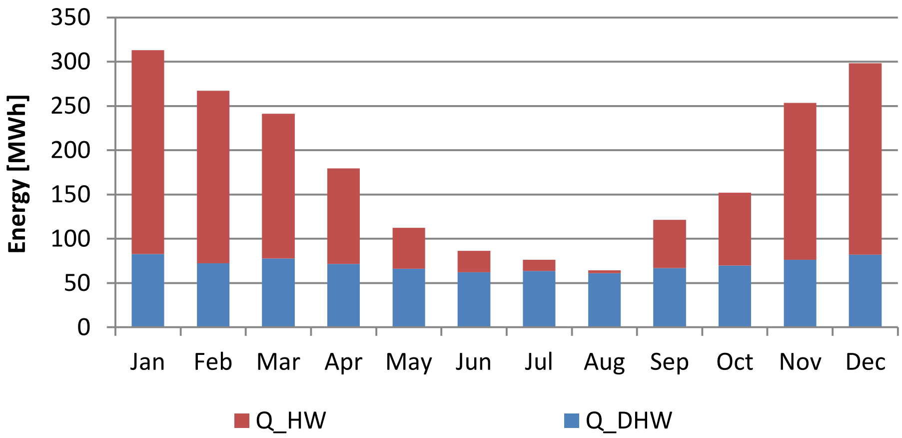

Figure 5. Monthly heat demand for HW and DHW production

The demand levels are calculated on the basis of DIN 4108-6 and are transformed into load profiles using VDI 4655. Figure 5 shows the cumulated monthly heat demand for HW (Q_HW) and DHW (Q_DHW) of the model settlement quarter.

The monthly heat demands add up to a total annual heat demand of 2175 MWh. Taking into account the transient process after initialisation, the results looked at are the results of the second year of a two-year simulation period. Table 1 shows the general simulation parameters:

Table 1. General simulation parameters

Parameter	*Value*
Total grid length	1830 m
Pipe insulation thickness	60 mm
Pipe insulation material	Polyurethane (0.03 W/mK)
Ground temperature level	2.2-13.8°C
Total annual heat demand	2175 MWh
Total heated floor space	53700 m²

The topology, length and architecture of the network models, the temperature level of the ground the pipes are installed in, the insulation thickness, the feed and tapping points of the connected buildings as well as the heated floor space are identical for both frameworks.

Results

Before comparing the thermal losses of the two networks, it is necessary to have a closer look at the boundary conditions which lead to these losses. Based on the supply temperatures of second generation DHNs of 100°C (Lund et al., 2014) and the topology at hand, as discussed earlier, average return temperatures of about 66°C are reached.

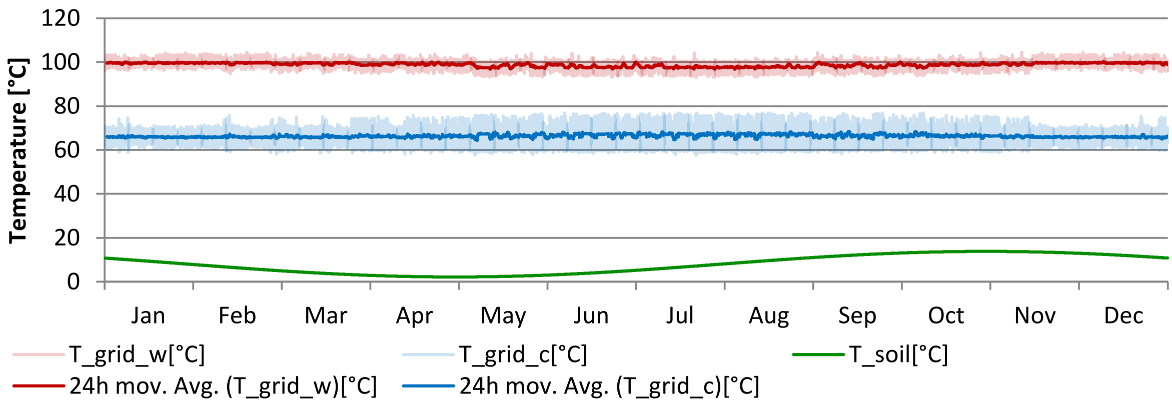

Figure 6. DHN temperatures of supply and return flow at the heat source.

Figure 6 depicts the temperature range in the supply (red) and return pipes (blue) of the DHN simulation obtained at the heat source. The bold red and blue lines show the 24 h moving average temperatures. In the background the highly dynamic hourly temperature values in light blue and light red are displayed. The supply temperature in the DHN does not change significantly over time. This reflects the ability of traditional heat sources in DHNs such as heating and combined heat and power (CHP) plants to adapt quickly to changing demand conditions.

The return temperature is not as evenly distributed, especially during the summer months. These are the months with the lowest heat demand (see Figure 5) which leads to stagnation and cooling-down of the fluid. The aforementioned periodic flushing to maintain a minimum supply temperature results in the temperature fluctuation depicted. The bold green line displays the undisturbed ground temperature over the course of one year.

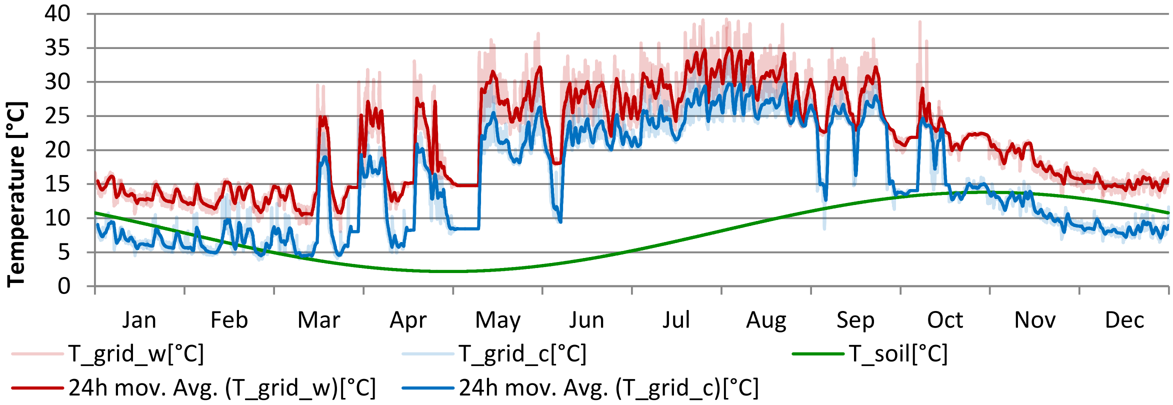

Figure 7. LTDHN temperatures of warm and cold leg connected to the seasonal storage.

Figure 7 depicts the temperatures of both warm and cold legs connecting the seasonal storage with the LTDHN. As before, the bold green line displays the undisturbed ground temperature. Compared with Figure 6 the absolute temperature levels and the temperature characteristics differ significantly. Here, they show a clear correlation between time of year and temperature level, as well as highly dynamic and fluctuating temperatures during the transitional seasons. Looking at the temperature differences between the fluid temperatures and the undisturbed ground temperature, the traditional DHN is operated with an average temperature difference of 74.6 K while the LTDHN operates with an average temperature difference of 10.2 K.

In the case of the DHN these temperature differences lead to a permanent flow of heat from the network to the surroundings. Figure 8 depicts the monthly thermal losses of the DHN. In total, these losses amount to 282 MWh per year, which is about 12.97 % of the total annual heat demand of the buildings.

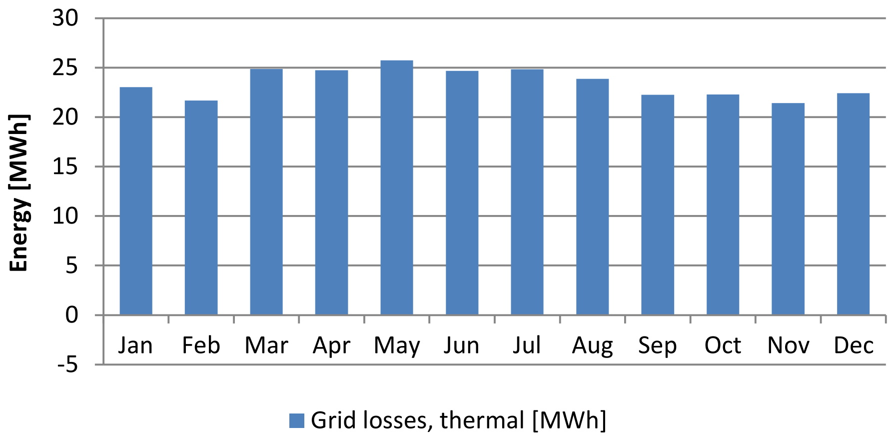

Figure 8. Thermal losses of the state-of-the-art DHN.

The losses of the LTDHN show a different annual distribution, correlating directly with the increasing temperature difference to the surroundings during the summer months

(Figure 9) due to high solar thermal collector gains. These losses amount to a total of 41 MWh per year, which is about 1.89 % of the total annual heat demand of the buildings. During the months December and January the average temperature level of the LTDHN drops below ground temperature resulting in negative losses, which are in fact heat gains.

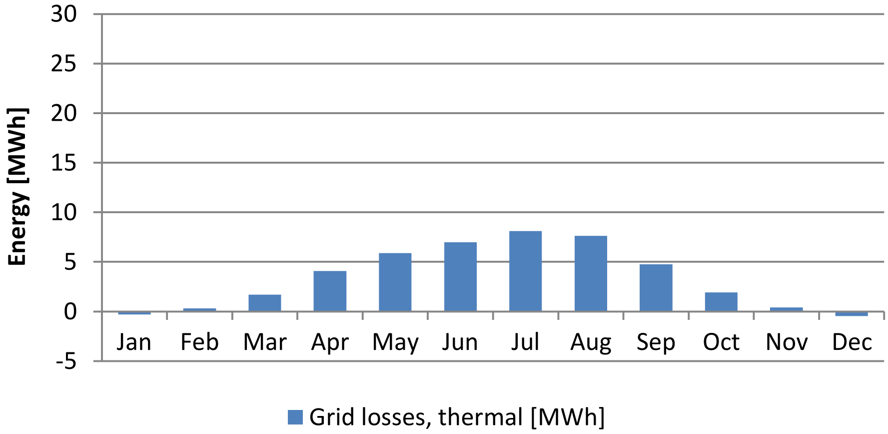

Figure 9. Thermal losses of the LTDHN.

The difference between the thermal losses of DHN and LTDHN amounts to 241 MWh per year, which is about as much energy as the model settlement quarter needs in the month of March for HW and DHW production.

Discussion and Conclusion

Comparing the calculated thermal losses of the DHN with the average losses of state-of-the-art DHNs in Germany of 13 % (Pfnür et al., 2016), a result of 12.97 % seems plausible. The simulation result of the LTDHN framework also quantifies the thermal losses of the LTDHN to about 1.89 % of the model settlement quarters total annual heat demand. This could potentially save 241 MWh of thermal energy every year, compared to the losses of the DHN.

With the above depicted temperature differences between supply and return lines of the DHN (32.5 K) and the LTDHN (5.9 K), we see that there has to be about 5.5 times the mass flow in the LTDHN compared to the traditional DHN to transport the same amount of heat. Therefore it is expected that additional electric energy has to be provided for the additional pumping capacities and heat pumps needed to operate a LTDHN. However, this does not account for heat pump gains, local solar gains or the prevention of thermal flushing, which could shift the ratio in favour of the LTDHN.

For the purpose of this study the ratio of renewable to non-renewable energy used by the system was neglected. Traditional DHNs are mostly powered by non-renewable fuels (BMUB, 2016) which makes the thermal losses of DHNs mostly non-renewable. LTDHNs on the other hand are largely powered by renewable energies, which lessens the impact of the few losses of a LTDHN further.

Further Research

Based on this result one of the directions of our future research will be the investigation into pumping power, heat pump power and pressure losses. Another focus will be a closer look at the potential of additional photovoltaic collectors as well as a comparison of different types of solar collectors in the LTDHN building services model. Future investigation could also include the effects of different types of seasonal storage and varying network layouts on the LTDHN.

PLEA 2017 EDINBURGH
Design to Thrive

A Social Survey (2016-2017) on How the Economic Crisis Affects Peoples' Attitudes Towards the Environmental Subjects

Panos Kosmopoulos[1*], Athina Kantzioura, Ioannis Kosmopoulos, Konstantinos Kleskas, Andreas-Michael Kosmopoulos

[1] K-eco Projects co, f. Director of the Laboratory of Environmental and Energy Design of Buildings and Settlements, DUTH
[*] Corresponding author: E-mail: pkosmos@env.duth.gr

Abstract: This article presents a panhellenic social survey regarding Environmental subjects. It is a well known fact that Greece is suffering from an Economic Crisis among other E.U. countries. This crisis coincides with the time that Greece is supposed to take measures for Environmental Protection in general, that should aim both at Energy Saving, and at gaining energy from Renewable and Alternative Sources. During the last twelve years, we have conducted social surveys regarding people's attitudes towards the Environmental issues and the application of RES (Renewable Energy Sources) every two years. This research aims at the investigation of how peoples' attitudes and views towards the Environmental subjects and the use of RES. are affected by the Economic Crisis, and a rather dystopian general future. How serious and important are the environmental issues considered to be when people feel that their everyday life is threatened? This subject is approached through a panhellenic survey analyzing the data gathered by questionnaires. Within a framework of an international economic crisis, Hellas has been the first of the European countries that has been badly affected. But at the same time, according to the E.U. Directives, Hellas has to conform with the regulations regarding the application and the use of Renewable Energy Sources. It is very interesting to see how environmental matters are faced in general, regarding energy sources, fuels and related costs during this transitory period. But parallel to the above, Hellenic people have to face their household economics, their traditional attitudes towards their environment (both built and natural) and their dependence from imported fuels (oil and gas). It is at least an intriguing subject to see how people cope with the above mentioned circumstances.

Keywords: Energy, RES, Environment, social survey, Economic crisis

Introduction

After an extremely heavy winter for Greece (below 0^oC for twenty days, very rare for Greece) (Table 1) and within a framework of an international economic crisis, Hellas has been the first of the European countries that has been badly affected. But at the same time, according to the E.U. Directives, Hellas has to conform with the regulations regarding the application and the use of renewable Energy Sources.

The first level, according to the recent legislation, regards the application of R.E.S. (Renewable Energy Sources) and especially photovoltaics in buildings whether private or state, in order to achieve electricity production from the shelter of the buildings.

The second level, regards the installation of larger units of P.V. systems in land properties.

The third level, refers to the large scale installations, which aim at a national level of R.E.S. exploitation.

It is also interesting to see how environmental matters are faced in general, regarding energy sources, fuels and related costs during this transitory period.

The sensitivity of Hellenic people towards environmental matters is a well known fact: the traditional architecture, the antiquities, the natural environment and the related protective legislation, have established a concrete culture, which more or less, nowadays has to be denied. It is obvious that a new environmental aesthetics culture has to be shaped.

But parallel to the above, Hellenic people have to face their household economics, their traditional attitudes towards their environment (both built and natural) and their dependence from imported fuels (oil and gas).

It is at least an intriguing subject to see how people cope with the above mentioned circumstances.

Among other research projects, every two years, we conduct a social research regarding the attitudes of Hellenic people towards R.E.S. (see Kosmopoulos 2002/2004/2006/2008/2011/2013/2015).

The increasing interest regarding the R.E.S. applications and their benefit, has been well shown during the past years, and also the increasing level of familiarity with the related subjects has also been shown.

But at this instance, with the official legislation on one hand pressing for the use of R.E.S., and the economic crisis on the other hand, the present social survey seemed to be at least intriguing.

The research project

The survey has been planned and carried out by members of the K-ecoprojects co. and a large number of students, postgraduates, and PhDs that have attend our lectures.

A large number of areas and cities have been covered, offering a satisfactory image of the subject.

As for the subjects among the citizens, there has been a random selection covering the whole area of each city and its suburbs, all age groups, and several occupation and educational level groups.

The questionnaires gathered, have been processed by the staff and the collaborators of K-ecoprojects. The task has been to extract easily understandable data, in order to help the authorities that might be interested to use the results of our survey.

The questionnaire is based upon the Guttman scale (Canter, 1988) but it has been adapted to the well approved and generally accepted 5 point Likert scale, in order to be comparable to all previous relative study (see Kosmopoulos 2002 / 2004 / 2006 / 2008 / 2011 / 2013 / 2015).

The survey

The research project, regarding the social attitudes towards the environmental subjects during this critical period, has lasted from 10/2016 to 3/2017, all over Hellas (and Cyprus) through the collection of questionnaires, and has covered the respective number of valid questionnaires:

City	Quest.	City	Quest.	City	Quest.

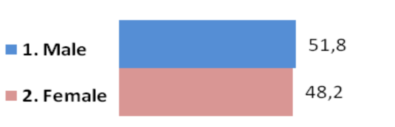
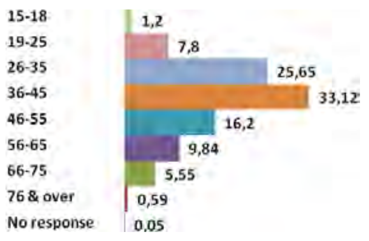
The social survey results

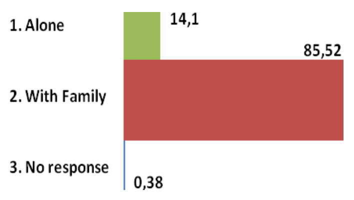
2. Sex



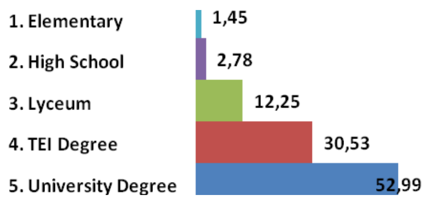
3. Age Groups



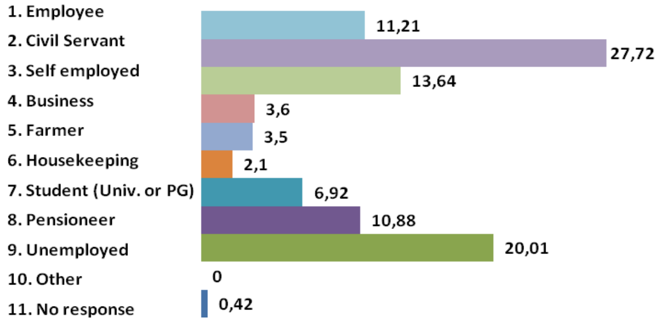
4. I live...



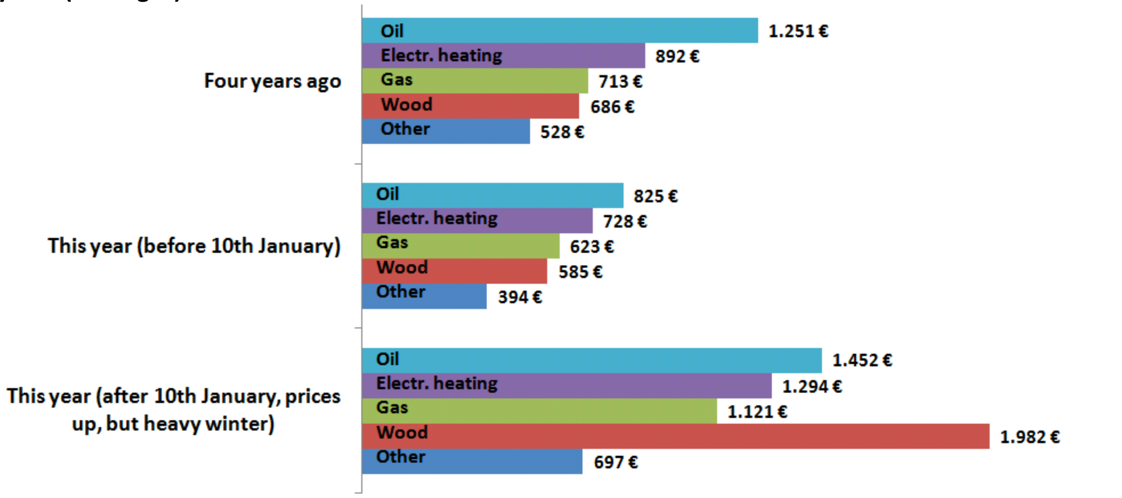
5. Educational level



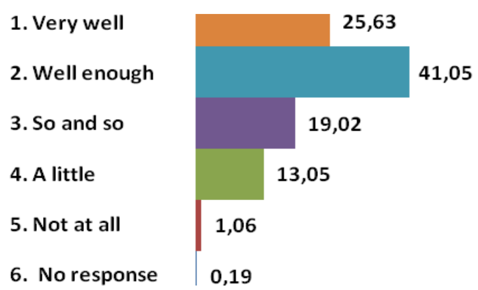
6. Occupation



7. How much money did you spent annually on various forms of energy, e.g four years ago and how much this year? (Averages)

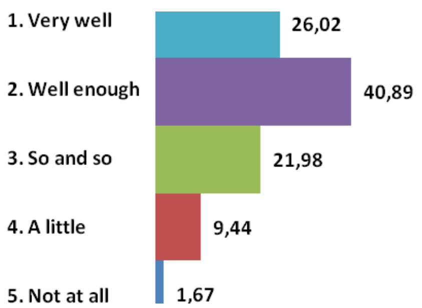


8. Do You know what Renewable Energy Sources are?

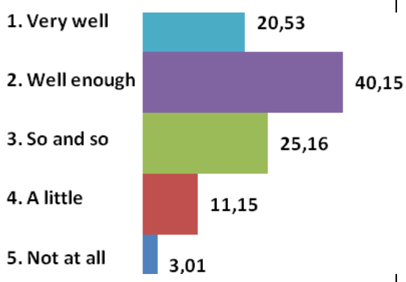


9. How well do you know about the following:

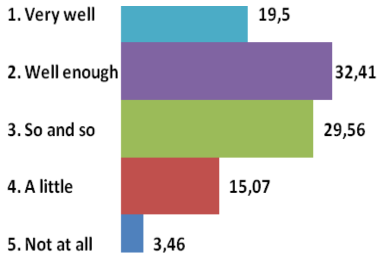
9.1 Photovoltaics in buildings:



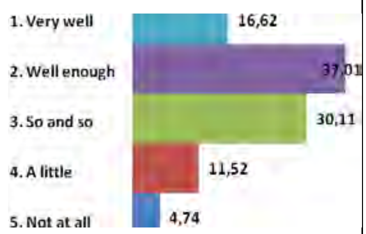
9.2 Photovoltaics in land properties:



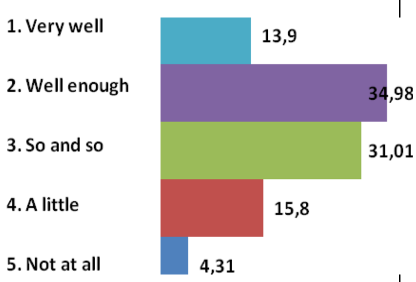
9.3 Photovoltaic Parks:



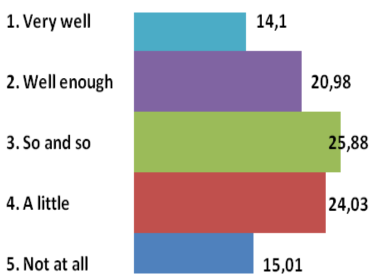
9.4 Wind Generators:



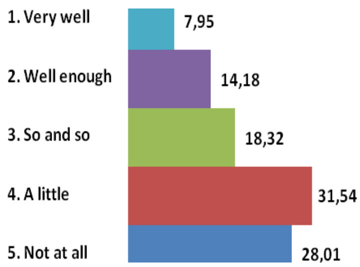
9.5 Wind Generators Parks:



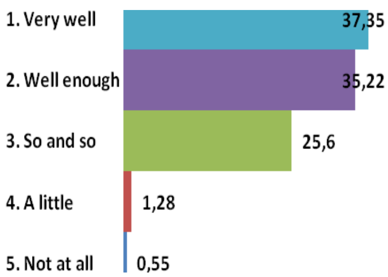
9.6 Geothermy for buildings:



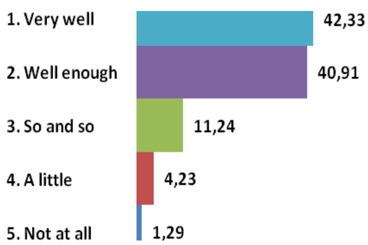
9.7 Geothermy for settlements:



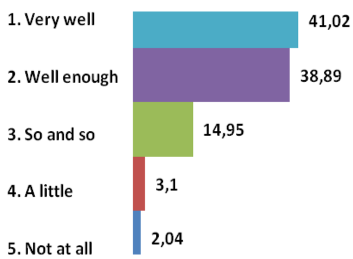
9.8 Biomass (wood blocks and pellets):



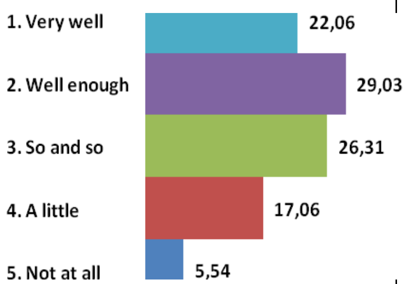
9.9 Double Glazing



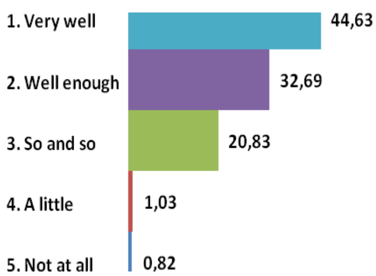
9.10 Insulation in walls



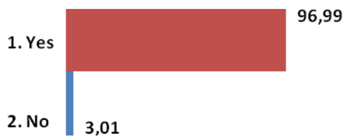
9.11 Glass House:



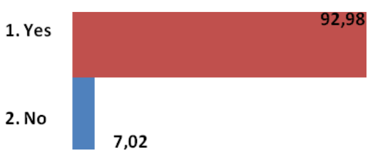
9.12 Fan:



10. Do you know that all of the above can help the family income?

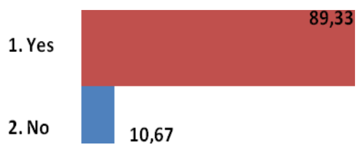


11. Do you know that all of the above can help our national economy to become independent from imported oil and natural gas?



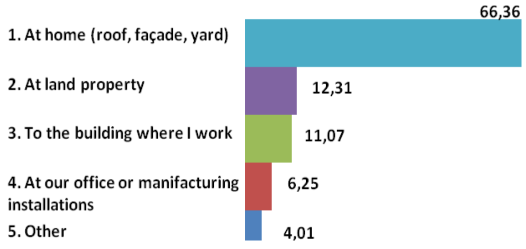
12. Do you know that all of the above can help to reduce environment pollution?

13. Do you already use any of the above?

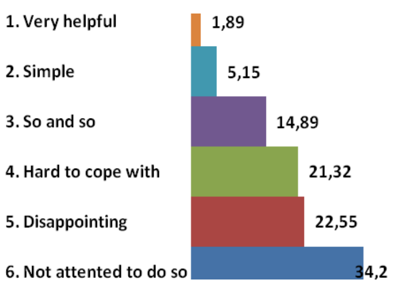


13.1 If yes, which one:

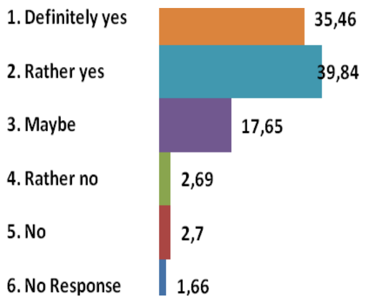
13.2 If no, would you like to install any of them:



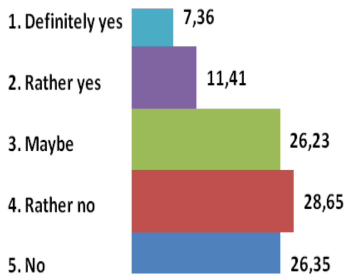
14. If you have already attempted to do so, what is your comment on the necessary beaurocracy?



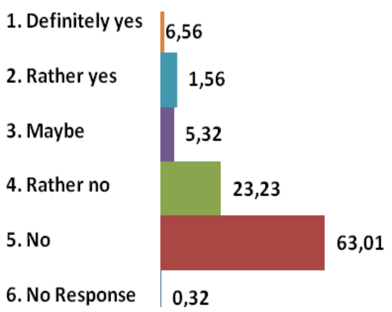
15. If you are reassured from the authorities that you will have definite economic gain, and a simple beaurocratic procedure, would you proceed to install any of the above?



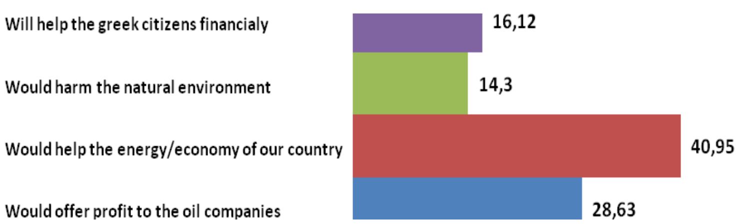
16. Do you think that the installation of P.V.S and W.G.S insult/destroy the aesthetics/natural beauty of buildings and/or the natural environment?



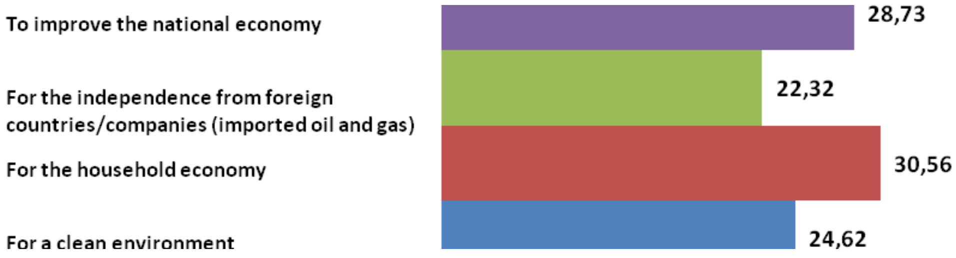
17. Would you accept a nuclear plant in our country?



18. We have learned that there are fossil fuels in our country. Do you think that their exploitation:



19. Finally, would you wish to see a wide use of R.E.S. for the following reasons:



Discussion and conclusions

The number of the participants to this research, and the answers that have been gathered, permit us to point out several subjects of interest.

1. Both male and female, and also all age groups, have been covered satisfactorily.

2. The educational level and also the occupation of the participants, have also been covered satisfactorily.

3. The cognitive level regarding Renewable Energy Sources, seems to have significally improved regarding our previous relative surveys . Both the general questions regarding R.E.S. and the specific questions regarding partial subjects such as PV, or WG, or parks to mention some, seem to be "well enough" known by the public.

4. For example, to the question about PVs the "well enough" level from 30,7% in 2011, in this research, it has reached 40,89%. And regarding PV parks, the "well enough" from 25.20% has reached 32,41%.

5. Regarding WGs, from 25,72% in 2011 we find now 37,01%, and in WG parks, from 22,40% today it has reached 34,98%. In conclusion, the campaign by the media seems to be achieving its aim.

6. Geothermy does not seem to be well known. Contrary to Biomass (wood blocks and pellets) that due to the high prices of oil and natural gas, seems to become very popular (from 17,99% to 72,57% !).

7. Regarding the economy point of view, several interesting remarks can be pointed out: Most people seem to have understood that R.E.S. can help both the family income and the national economy.

8. Among the people that already use some of R.E.S., Photovoltaics and especially Biomass are ahead.

9. People who would like to install R.E.S., are interested to do so firstly at home, and then to a farm or land property.

10. A very important point that has been underlined, is that since August 2012 a new laws have decreased the income from the installation of PVS, and it seems that this policy will continue. This legislation has a negative effect to the interest towards new installations of PVs.

11. Regarding bureaucracy, which seems to be a major problem in Greece, people seem to be disappointed, but in case the state should establish simple and clear rules and also some guaranteed economic gain for the citizens, R.E.S. applications should definitely increase.

12. Another interesting subject, is the change of the attitudes towards the aesthetics of the environment concerning the installation of R.E.S. all over the country. During two previous surveys (e.g. 2007,2009) people seemed to be firmly against large scale installations, arguing about the natural environment preservation. Nowadays, most people seem more interested in installing R.E.S. in their property, since 55,01% declare not to be disturbed by the PVs and/or W.Gs.

13. Regarding the possibility of the construction a nuclear plant station in Greece, people point out the seismic activity of the area and the danger of severe pollution, and seem to be definitely against such an idea (87,00%)

14. Recently, it has been known that in Greece there are large amounts of fossil fuels, oil and gas. Of course, people are not precisely informed, but anyway they consider that in case these fuels are exploited, firstly it would help the economy and the energy problem of this country, but also that it would offer profits to the (foreign) oil companies.

15. Finally it is interesting to see the general attitudes of the participants towards the wide use of R.E.S. firstly, for the protection of the environment, secondly for the improvement of the national economy, but also for the independence from imported fuels, and the less energy cost for each household, though the last recently seems to fade away.

16. Comparing the educational level of the participants with their views towards the environmental subjects, in brief we can observe that the higher the degree, the more they know about R.E.S., they are more reluctant to contribute financially to the state attempt for R.E.S. applications, they have faster been adapted to the idea of PVs and WGs around them, and that they also point out as their main interest, the need for the protection of the environment, through the use of R.E.S..

Concluding Remarks

1. Unfortunately, greek people have turned towards wood and oil for heating, due to the cold winter and the economic crisis.
2. Despite the economic crisis and a rather hard future, people seem to be well informed and very interested regarding the subject of R.E.S..
3. People are interested indeed for the protection of the environment, for the national economy, for the release from imported fuels, and finally for the personal/family economic profit from the application of R.E.S., but they are also disappointed from the new economic policy applied to R.E.S..

Acknowledgments

Many thanks are due to the members of K-eco projects co. and the students, postgraduates and PhDs, and most of all to the Greek people that have willingly participated to this research.

Abstract: By the end of 2015, more than 36,000 battery storage systems in combination with PV systems had been installed in Austria and Germany. As yet, these battery storage systems are mainly used to increase the on-site consumption of local PV generation. However, charging the battery without considering the current generation of the PV system and the current state of the grid means that this application is of little benefit for the grid, e. g. regarding control and stability, reliability, power quality or security. Alongside the use of battery storage systems to limit a PV system's maximum grid feed-in, several other grid and/or system-relevant applications for battery storage systems are possible. One strategy is to use autonomous systems to even out a building's load peaks, mainly caused by heat pumps or other electric heating or cooling systems. Forecast-based operation strategies are required. The research project Spin.OFF uses a self-learning artificial neural network (ANN) to predict the energy demand of buildings. In addition to local autonomous strategies, some system- and/or grid-relevant applications require coordination by third parties. The second strategy, presented in research project MBS+, provides a decentralized micro-grid concept for the optimization of Distributed Energy Resources (DER) in the form of a Battery-Storage-Network (BSN).

Keywords: battery storage systems, battery storage network, grid-relevant applications, artificial neural network, social implications

Introduction

By the end of 2015, more than 36,000 battery storage systems in combination with photovoltaic (PV) systems had been installed in Austria and Germany (Kairies et al, 2016). Investment subsidies and the desire of private households for energy self-sufficiency are the main drivers for this trend, which is most likely to continue to increase in the future. These systems are mainly used to maximise the on-site consumption of the local PV generation. However, charging the battery without considering the current generation of the PV system and the current state of the grid means that this application is of little benefit for the grid or the energy system (Weniger et al, 2016). Taking into account the public subsidies for such battery storage systems, it seems to be economically feasible to also use these battery systems within a defined scope for system- or grid-relevant applications, because the inter-connection of a rapidly increasing number of Distributed Energy Resources (DER) to the grid causes more and more problems of control and stability and also raises concerns about reliability, power quality, and security. One potential grid-relevant application is the use of these battery storage systems to even-out the PV system's grid feed-in. This application is mandatory in the German support programme for battery storage systems, where the maximum PV feed-in is limited to 50 % of the nominal PV power (since 2016) to ensure that PV peaks are always eliminated (Weniger et al, 2016).

System-relevant applications for decentralized autonomous energy storage systems

A grid-relevant application for battery storage systems is currently being investigated in a case study of an office building under construction in Vienna. The study implements an Aqueous Hybrid Ion (AHI™) battery storage system and answers questions concerning technical planning and dimensioning issues, ecological evaluation concerns, as well as its instrumental utilization to minimise power grid peak load or to maximise in-house consumption by means of an energy management system based on a self-learning artificial neural network approach (Maul et al, 2017). This section of the paper is concerned with first results of implementing and priming the energy management system with historical data from a comparable neighbouring office building.

In general, the energy consumption of office buildings can be divided into two parts. Tenant consumption, which is not a concern of this study, and the costs of operating the building, which are mainly caused by heat pumps or other electric heating or cooling systems, lighting, etc., but are also reduced by photovoltaic (PV) installations in the overall infrastructure of an office building. This mixture creates the need for energy management systems for the intelligent combination of resources, without changing the aim of evening-out load peaks and allowing for self-optimization. This case study implements a cradle-to-cradle certified battery implementation and 33 kW_{peak} PV system, reflects the scenario described above, and tries to answer all the issues arising in implementation. It also opens the possibility of retrieving data which can be used for further research. After installation, a tenant survey will be conducted to study the social impact and acceptance of this type of system. Lastly, an ecological analysis including a lifecycle assessment will be carried out to highlight the advantages of AHI™ battery storage systems and compare the result with other battery systems, such as Li-ion, Vanadium, Zinc-Iron and Redox Flow in terms of ecological footprint.

The energy management system was based on the use of a self-learning artificial neural network (ANN), not possible to realize with traditional grid-connected converters and their limitations in their applicability to dynamic systems, lack of processing power and missing interfaces. An ANN is a computational model made by a number of simple, highly interconnected processing elements, which process information by their dynamic state response to external inputs. It was developed as a self-learning feed-forward artificial neural network (FF-ANN) to predict power consumption (D'Andrea et al, 2012). An analysis of the electrical and architectural concept of the battery system was conducted within the technical and regulatory limitations. The performance of electrical security devices during isolated operation is being investigated to confirm that these devices respond accurately, since currently this is still uncertain. The energy management system implemented was primed with data from a comparable neighbouring building, and battery performance is currently being analysed to acquire new data regarding the energy flow, power ramps, power availability and power quality to gain insights into the physically achievable flexibilities offered by the new AHI™ battery storage system to create a model predictive control (MPC) system, as a second part, to manage the battery storage. The FF-ANN uses solar radiation, net energy consumption, building temperature data along with a day categorization system as inputs, the purpose of which is to predict short-term net building power consumption, hence the energy demand of the office building, and the MPC, based on the consumption forecast and PV production forecast, will create a charging/discharging schedule for the battery storage system.

Once installed in the office building, the system will be periodically retrained (the optimum frequency is yet to be determined) to include changes in the energy use behaviour of the building due to occupancy changes and various changes in the building structure, for example, more energy-efficient windows, or retrofitting more solar panels for increased local energy production.

The ANN model developed, presented in (Xypolytou et al, 2017), different input combinations were examined during the design of the FF-ANN. The parameters that affect the performance of the ANN are types of input and their pre-processing, the number of hidden layers used, the size of the hidden layers, the transfer function that creates non-linearity between the layers, and the time window that determines the samples used for the training. In addition, it is very important for the retraining period to be chosen in such a way as to allow adaptability to new conditions without affecting the performance of the FF-ANN.

The selection process of the inputs was based on various simulations and a comparison between architectures (see Figure 1). Mean Square Error (MSE) between target data and simulated data of the comparable office building was used as a benchmark (Tofallis, 2015).

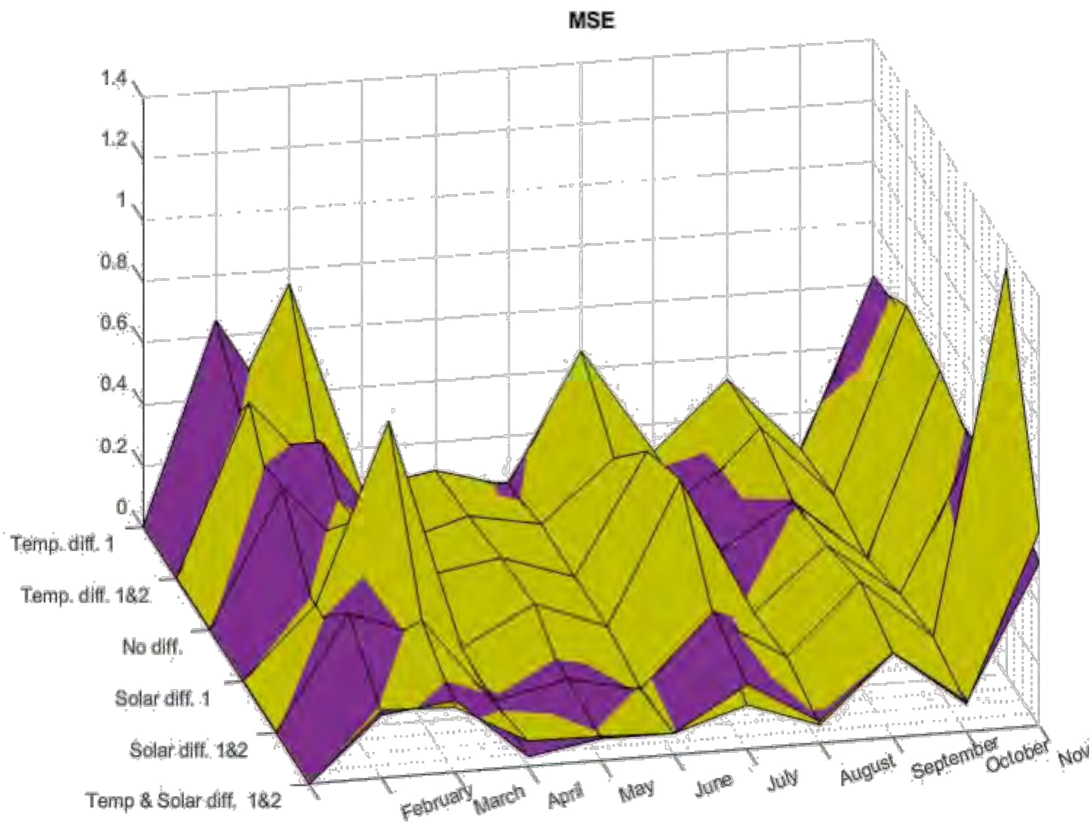

Figure 1. MSE comparison of 3 hidden layers (gold), size 7 neurons with 2 hidden layers and better performing (lower MSE) size 5 neurons (purple)

The current optimum set of inputs and pre-processing can be seen in Table 1.

Table 1. Input types and pre-processing

Input	Pre-processing / Type of input
Past energy consumption	Moving average of 4 hours
Solar radiation	Moving average of 1 hour
1st derivative of solar radiation	Moving average of 1 hour
2nd derivative of solar radiation	Moving average of 1 hour
Temperature	Moving average of 2 hours
1st derivative temperature	Moving average of 2 hours
2nd derivative temperature	Moving average of 2 hours
Date	Specific day of week, month, and holiday
Time	Hour of day

This FF-ANN consists of two hidden size 5 layers. The input layer has the 9 inputs shown in Table 1, while the output layer has size 1, which is the moving average of the next 4 hours. Each neural network layer has an integrated weight matrix (W) and bias vector (b). The transfer function of the hidden layers is the hyperbolic tangent sigmoid transfer function (tansig). The output layer is driven in a Log-sigmoid transfer function (logsig). The training time window used was 23 days. The Matlab® graphical representation of the current form of FF-ANN is shown in Figure 2:

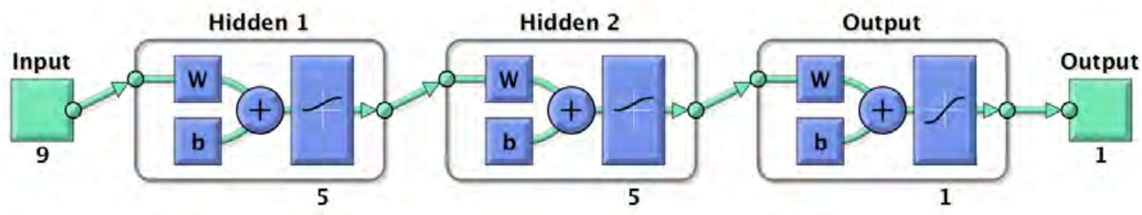

Figure 2. The current FF-ANN architecture in Matlab®

The power consumption projected by the FF-ANN and the actual consumption available in the historical test set is shown in Figure 3 below:

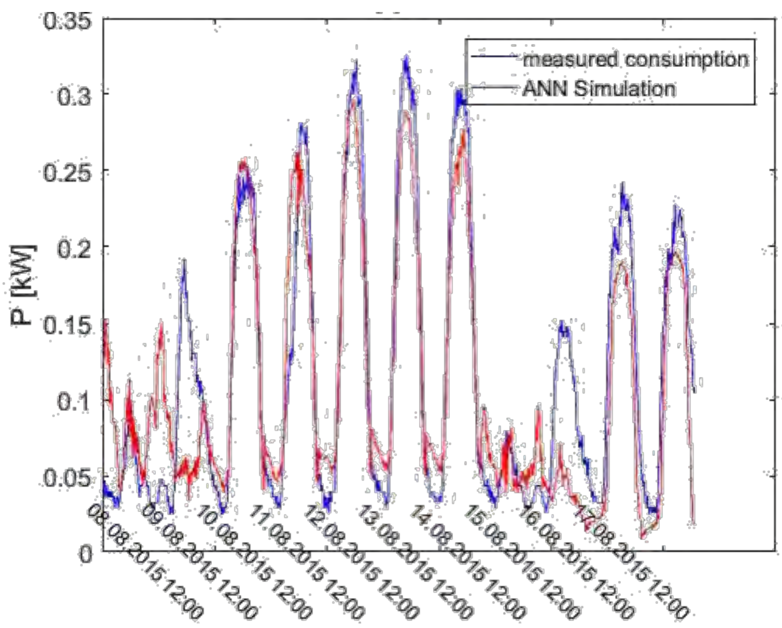

Figure 3. FF-ANN results on an exemplary 10-days test set

The system reflects choices made to create an FF-ANN the purpose of which is to predict the consumption of a building. It has the ability to be re-trained periodically. To achieve this, a local data storage will be integrated to save historical data. These data are a valuable source for the conduct of future studies which can further optimize local controllers.

Technical implementation

The technical approach involves connecting single battery storages (located in different households) to form a BSN. While these storages are connected to the power line, an additional communication network is required to enable these distributed storages to communicate and exchange information with each other.

To date, no or only limited support is available for collaboration among participants of a balancing group to utilize distributed storage devices for balancing generation schedule deviations. In particular, owners of PV systems and (private) battery storages are not able, e.g., to autonomously and jointly decide how to fulfil the requests of a balancing group officer (BGO) by using their aggregated battery storage potential.

Several approaches are considered feasible for fulfilling the given requirements of a decentralized BSN. Among them, peer-to-peer (P2P) technology (Oram, 2001; Fattah, 2002) represents quite an obvious choice. It is not only the notion of a computing architecture that does not rely on a central (server) component that makes P2P systems feasible for the envisaged BSN. In fact, there is an analogy between early P2P computing systems and the current discussion on the use of private and distributed PV systems and battery storages in a P2P manner. According to (Shirky, 2001), P2P applications take advantage of previously unused resources – storage, computing cycles etc. –, which allows them to make new, powerful use of a large number of devices that have been connected to the Internet. It is similar with the distributed components in the energy domain, like battery storages, PV systems, electric cars etc.

In addition to P2P systems, studies of multiagent systems (MAS), e.g. (Shoham and Leyton-Brown, 2009), have investigated concepts with specific relevance for BSNs. With MAS, autonomous (network) entities are called agents. In our BSN, single participating households or household devices are modelled as agents. These households, or even the battery storages in the households, regularly communicate their potential utilization at 15-minute intervals to their BGO. With this information in mind, the BGO then requests the whole BSN to provide/consume a specific part of this potential to/from the grid to keep the group balanced. At this point, the BSN participants jointly decide how to fulfil this request through distributed consensus finding. MAS provide a number of algorithmic options for the BSN participants, e.g. distributed constraint optimization, negotiation, auctions, voting or mechanism design.

A further, nascent technology – called blockchain – represents an apparent symbiosis of P2P and MAS technologies, and is currently gaining in importance in the energy domain (EventHorizon, 2017). A blockchain network represents a P2P network with a distributed consensus algorithm at its core. Additionally, through the abstraction of 'smart contracts', network participants are able to cooperate as is the case with MAS. Therefore, we are investigating the potential of blockchain as technology base for the envisaged decentralized BSN or if it is necessary to stick to more mature technologies.

A key constraint is the identification of a suitable solution for integrating the BSN-algorithms into – existing – household's energy or home automation system components. Hence, technologies that allow for the simple deployment of the developed BSN algorithms to these energy system devices are also part of the solution concept. In this aspect, container technologies like (Docker, 2017) and especially (Docker Swarm, 2017) for the realization of a reliable decentralized solution are complementing the concept.

Social implications

Especially if grid and/or system relevant applications require active coordination by third parties e. g. balance group managers or grid operators, one crucial aspect for the successful implementation and operation of such a BSN is the willingness and acceptance of storage operators (particularly private owners) to give access to external stakeholders. In order to assess this willingness of current and potential operators of home storage systems to participate in such a BSN, an online survey has been conducted. This assessment should serve as a proxy for the social implications of a BSN for system and/or grid-relevant applications.

The survey form contains up to 8 mainly closed-ended questions focussing on social aspects like motivation, risks, opportunities, framework conditions and incentives, as well as additional demographic and technical questions. With the support of the Vienna and Styria funding agencies [1] as well as of the national "Climate and Energy Fund", the survey was distributed to about 20,000 operators of home storage systems and/or a PV system.

Within 3 weeks, the survey had been completed by about 2,300 respondents, of whom 257 PV operators already owned a battery storage system. This meant that about 11 % of the PV owners originally contacted were included in the study sample. The data were analysed mainly using descriptive statistical analysis using Excel and SPSS.

The results of the survey show a high willingness of PV operators (with or without a battery storage system) to participate in a BSN for system and/or grid-relevant applications, although subject to certain conditions. While only 10 % of the sample would participate without further conditions, almost 75 % would agree to participate only under certain framework conditions. This result emphasizes that the development of these framework conditions is a crucial factor for the success of such a network.

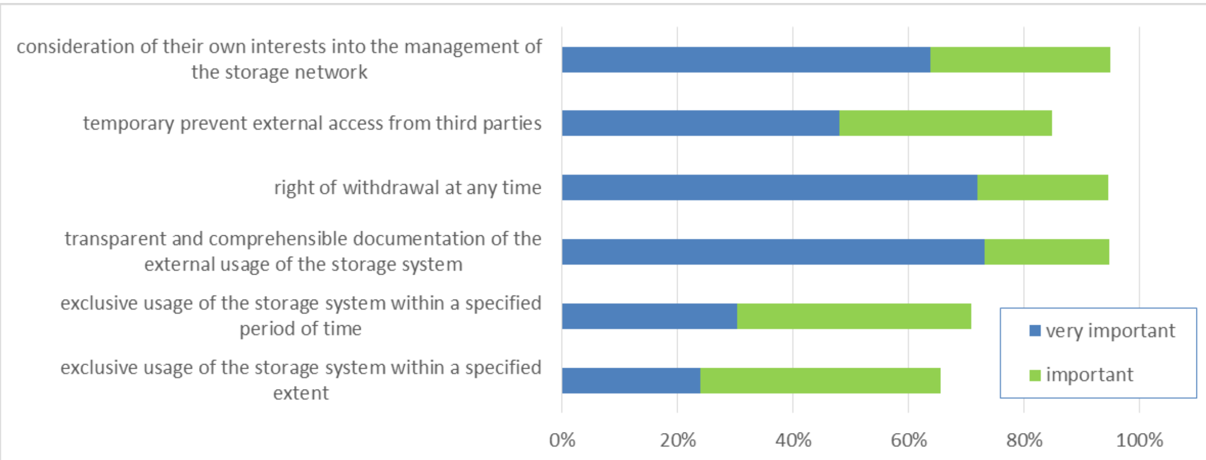

Figure 4. Importance of selected potential framework condition for the participation in a grid- and/or system-relevant BSN

Those 85 % of the sample who stated that they were basically willing to participate (even though only under certain framework conditions) were asked about the importance of selected framework conditions, their motivation and possible (financial) consequences regarding a potential participation. As displayed in Figure 4, the right to withdraw at any time,

[1] Vienna: Municipal Department 20 - Energy Planning, Styria: Department 15 Energy, Housing, Technology

as well as a transparent and comprehensive documentation of the use of the storage system were ranked by a majority of respondents as ‘very important’ (72.01 % and 73.12 %) conditions, shortly followed by their own interests being considered in the management of the storage network (63.74 %). Asked about their motivation to participate, top-ranked answers were the contribution to ‘increased security of supply’ (42.65 %), and ‘a higher share of renewable energy in the overall system’ (40.62 %). In contrast, additional earnings opportunities were considered to be ‘very important’ by only one quarter of the respondents (25.71 %).

The study also gives insights into the relevance and suitability of different incentives and financial compensation for the additional use of their own storage systems and the associated (financial) impacts on the owner. Regarding additional incentives for participation, 80 % of respondents seem to consider financial compensation for additional costs or foregone revenues to be sufficient for participating in such a BSN. This confirms that financial interests are not a decisive factor for participation. This is particularly interesting in contrast to the responses of battery storage owners’ statements about their initial motivators when buying the storage, in which ‘improvements in the profitability of their PV’ plant was stated by 97.5 % to be ‘very important’. Further analysis will therefore focus on the differences and similarities of respondents with and without their own battery storage.

Conclusions

Beside the usage of battery storage systems to limit the maximum grid feed-in of a PV system, several additional grid- and/or system-relevant applications for battery storages are available.

A case study of the impact of using a decentralized autonomous energy storage system, utilizing only local data for training a neuronal network as consumption forecast input, will provide more data to allow a better consumption prediction of wider application areas (residential, industry, different geographical areas, etc.). The objective of the system so far is to improve the coordination of system planning and to even out load peaks. A more advanced system could be designed to allow multiple objectives or to work on multiple buildings. A different objective could be to provide additional services such as trading between buildings in a micro-grid, or emergency functionalities to always allow building evacuation or energy redundancy for safety critical systems. A future integration in building management or smart home systems, an industry which has been progressing substantially in the last decade, can be considered very likely. The rapid advancements of both software and hardware solutions specialized in machine learning in recent years allow faster training of small neural networks. Although the development of self-learning systems able to predict energy demand is still a challenge, it is now computationally feasible to create a self-learning system on cheap off-the-shelf hardware. Cloud-based high-performance computing enables multiple models to be created in parallel, in which parameters of the models can be optimized with various methods (Grzesiak et al, 2007) (Goodfellow et al, 2014) in feasible time windows. This allows more generic systems to be designed, dynamically optimizing the parameters in parallel with the flow of new data. Available data for research is the biggest limitation for the use of deep learning techniques in energy consumption estimation (Mocanu et al, 2016).

Especially if grid- and/or system-relevant applications require active coordination and external access to the home storage system by third parties, one crucial aspect for the successful implementation and operation of a BSN is the willingness of storage operators to participate. In this context, the results of the survey show promising prospects for the successful implementation of a BSN for system- or grid-relevant applications. In total, almost

85 % of the sample would agree to participate, even though the majority only under certain framework conditions. Furthermore, the results emphasize the importance of transparent and comprehensible framework conditions and well-designed instruments for its implementation and management from the operators' perspective. Participation is predominantly ideologically and technically motivated (contribution to the energy transition and to a high supply service), financial aspects only play a minor role. Further analysis will discuss the results of the survey in relation to relevant framing conditions, as well as potential bias within the sample due to characteristics of the participants as 'early adopters' in the study, or effects of social desirability in their response behaviour.

Design to Thrive

Engineering applications of solar energy – the most potent renewable resource

Professor Tariq Muneer

Edinburgh Napier University (ENU), Edinburgh, UK

Abstract: Solar radiation is the most potent renewable energy resource. The amount of radiation striking the earth on an annual basis is equivalent to 15,000 times that of current global energy consumption. Although photosynthetic energy capture is estimated to be ten times that of global annual energy consumption, only a small part of this solar radiation is used for photosynthesis. In contrast engineering applications of solar energy offer significantly higher efficiencies, i.e. for thermal applications the efficiency may easily exceed 50% mark while for solar photovoltaics an efficiency of over 15% is possible. This article will cover the six areas of research and application of solar energy. The research was undertaken at Edinburgh Napier University (ENU).

Keywords: Solar radiation, renewable, enginnering

Introduction

The design and modelling of solar energy applications demand (a) an accurate assessment of the incident solar radiation which will vary in a diurnal and well as annual cycle, and (b) an understanding of the physical processes that are encountered in solar energy exploitation systems. This article shall present the two of the above constituent elements. Under the ‘application’ strand four low-carbon technologies are presently included and relevant examples are also presented.

Solar radiation data

Solar radiation data are essential for the design of solar energy exploitation systems. In response to the above demand posed by industry, CIBSE (2015) has provided hourly time series of global and diffuse irradiation and illuminance data for 14 UK locations. The author served as the co-ordinator fo the latter activity and a synopsis of the relevant procedures is provided here for the benefit of the reader who may extend this work for other global locations.

For any given country the most commonly available measured solar data are the horizontally measured global radiation. These are available for a limited number of locations and that too at a significant cost. From an early work of Cowley (1978) we note that the solar radiation regime can change significantly over a distance of just 50km. However, through the work of NASA (http://eosweb.larc.nasa.gov/cgi-bin/sse/retscreen.cgi?email¼rets@nrcan.gc.ca) it is now possible to obtain daily-averaged irradiation data for virtually any location in the world. The author’s research team has undertaken an accuracy assessment of the NASA’s satellite-based data which is shown in Figure 1. The latter plot is based on measured data for the period 1981–1983 (three complete years) for a location that is in near proximity to West London. The statistics within the latter figure shows that there is a close concordance between the satellite-based NASA irradiation and the UK Meteorological Office measured data set. Figure 2 presents the computational chain that is required to obtain components of solar radiation and illuminance. Algorithmic details are provided in Muneer et al (2014, 2015) and Muneer (2004).

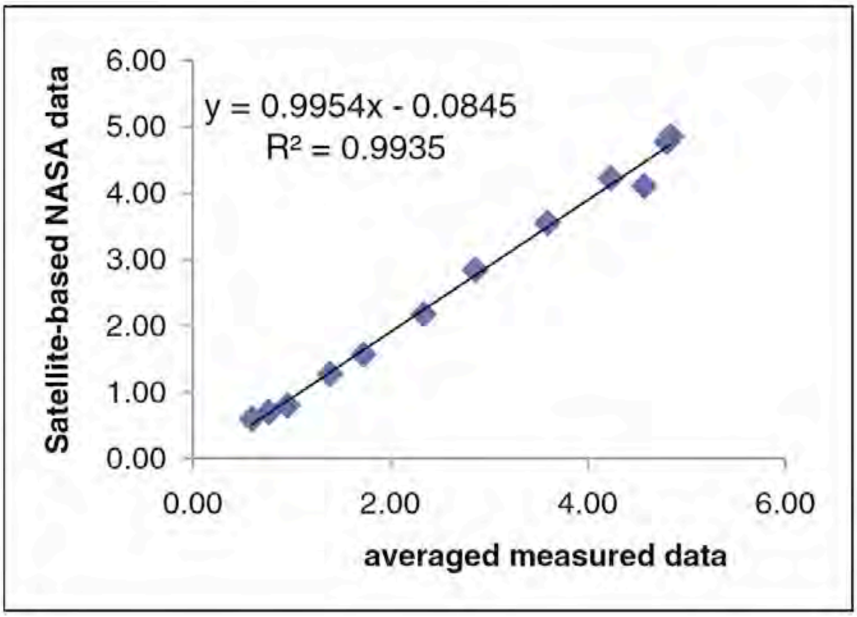

Figure 1. Comparison between NASA reported irradiation data and ground-based averaged measured data for Bracknell, England.

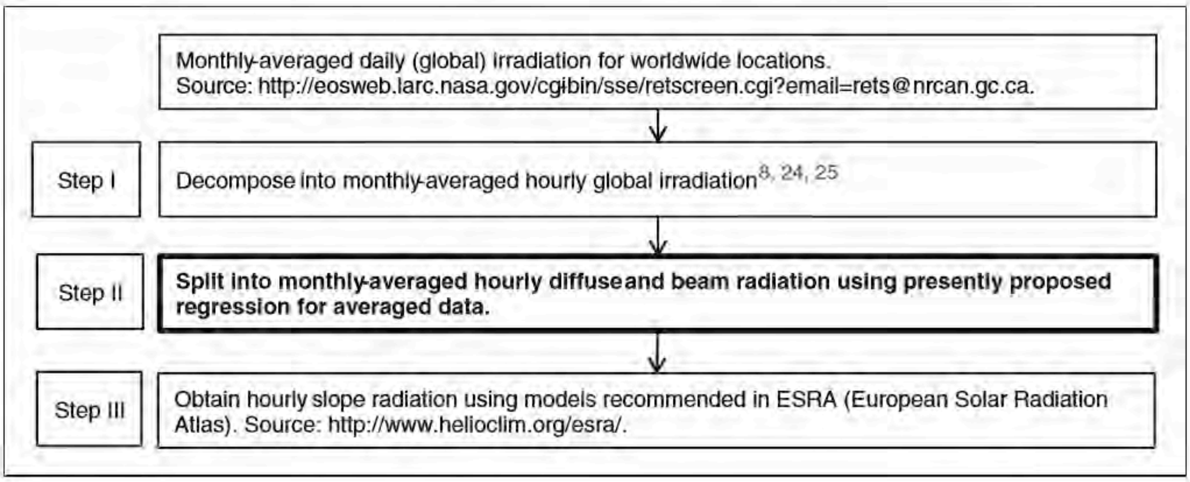

Figure 2. Computational chain for obtaining secondary solar data

Solar space heating

Buildings in the western world typically use–up at least 50% of the national energy budget and at least three-fifths of that is needed for space heating. A further fifth is needed for heating water. The key to space heating efficiency, capture and use of incident solar gains has long been identified to be high-performance glazing. Within the last 40 years we have seen the single-glazed windows with a loss-coefficient, U of 5.7W/m^2-K drop to 0.4 of the latter units for triple-glazed, Xenon-filled units. A factor 14 reduction! To prove a point in the year 1994 a solar conservatory was built at Edinburgh Napier University and its performance is shown in Figure 3. If the exterior surface of new-build is cladded with the latter units it will remove nearly all space heating demand for the majority of high-latitude locations.

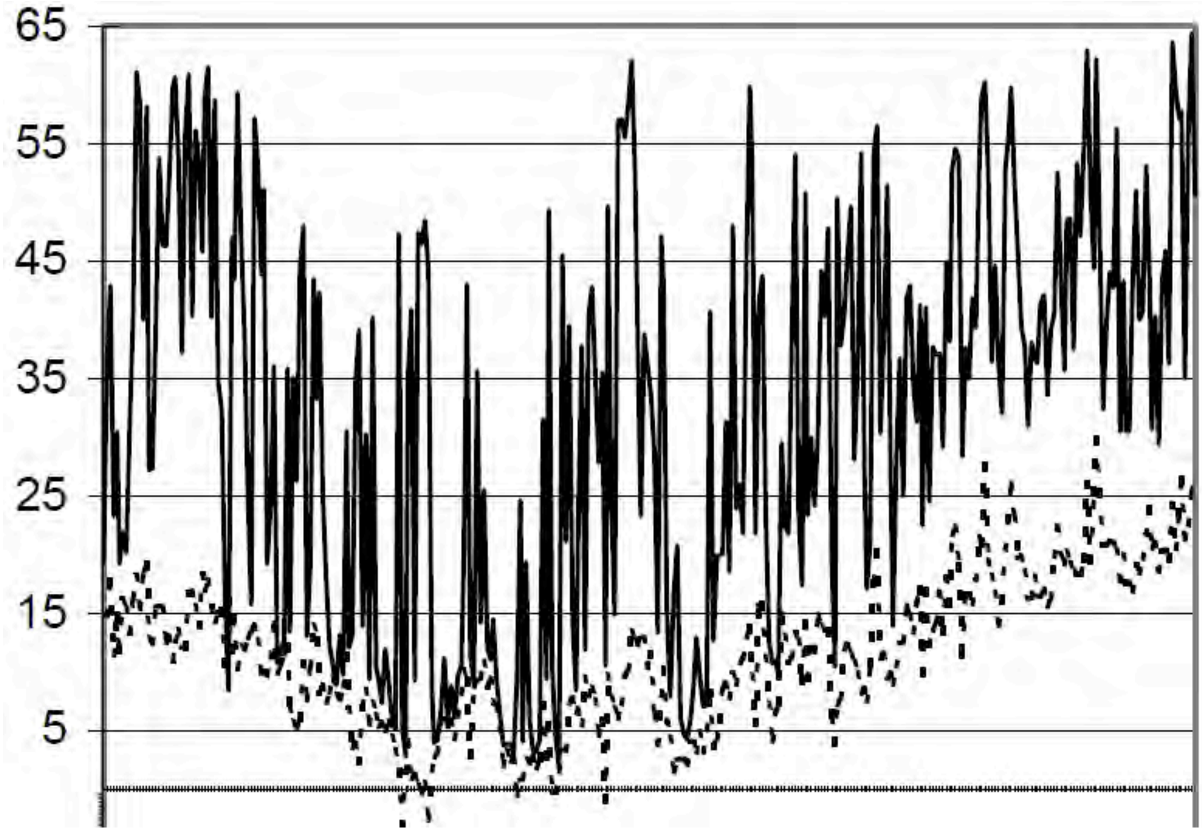

Figure 3. Annual performance of a solar conservatory using super-insulated glazing, Edinburgh. The heating season in the UK typically lasts between 9 to 10 months and this rather extended period works in the favour of solar energy economics due to the high utilisation factor. The super-insulated solar conservatory was built in August 1995 by Nor-Dan on a design produced at Napier University. At the heart of this design is a high performance triple-glazed window that acts as a thermal diode, i.e. the window admits solar energy into the sun-space but restricts the leakage of outgoing heat. Two window designs, both using specially coated low-emissivity glass have been tested. Hourly temperature profile using Argon-filled glazing is shown. The respective energy loss indices (centre-glazing U-value, W/m2-K) of the above mentioned windows are 0.73 and 0.4. These indices are in sharp contrast to the U-value of a normal double glazed window that lie around 2.8W/m2-K. Shown here are maximum daily temperatures (Celsius): solid line (sun-space), dashed line (outside ambient).

In the latter context following the earlier work of Owen (1982), and using Eq. 1 Table 1 has been prepared for Edinburgh. Note that the effective U-value takes into account the thermal balance which includes the irradiance as well as the outward heat loss from any given glazing.

$$U_{effective} = U - [1000 f_u \, \tau \, F_d \, I_w / (24HDD)] \quad (1)$$

Where f_u is the utilisation factor (= 0.6), τ the window transmission, F_d the dirt factor (= 0.8), I_w average irradiance (W/m2) and HDD the heating degree-days.

Table 1 Effective U-value for Edinburgh. Heating season: Sept – May (Heating Degree-Days = 2500)

Glazing	U-value	U-effective East/West	U-effective South
Single	5.7	3.9	2.6
Double: low-emissivity with air in-fill	1.8	0.3	-0.7
Double: low-emissivity with Ar in-fill	1.2	-0.3	-1.3
Triple: low-emissivity with Ar in-fill	0.7	-0.4	-1.1
Triple: low-emissivity with Xe in-fill	0.4	-0.7	-1.4

Solar water heating

In the western world hot water demand consumes some quarter of all energy used in buildings. Within the developing countries, though hot water demand is considerably less within buildings the latter saving is over-compensated due to the needs of the industrial sector. One area of rapid growth has been the textile industry which has seen an exponential rise within countries such as China, India, Indonesia, Pakistan and Turkey. The main use of water heating systems is for dying processes and currently the demand met with the use of fossil fuels. Within Pakistan's textile industry, which offers good employment prospects it is certainly the case. Pakistan's and Turkish solar climate can handsomely contribute towards the latter duty though to good effect. The author had the occasion to work with the textile industry of the two latterly mentioned countries (Muneer et al, 2006 and Asif et al, 2007) and a synopsis of that experimental work is presented here. Two different designs of built-in storage water heater - plain and a newly designed finned type heater were constructed to compare their thermal performance. One year's experimental data were collected for the two heaters. Figure 4 and Table 2 present those results.

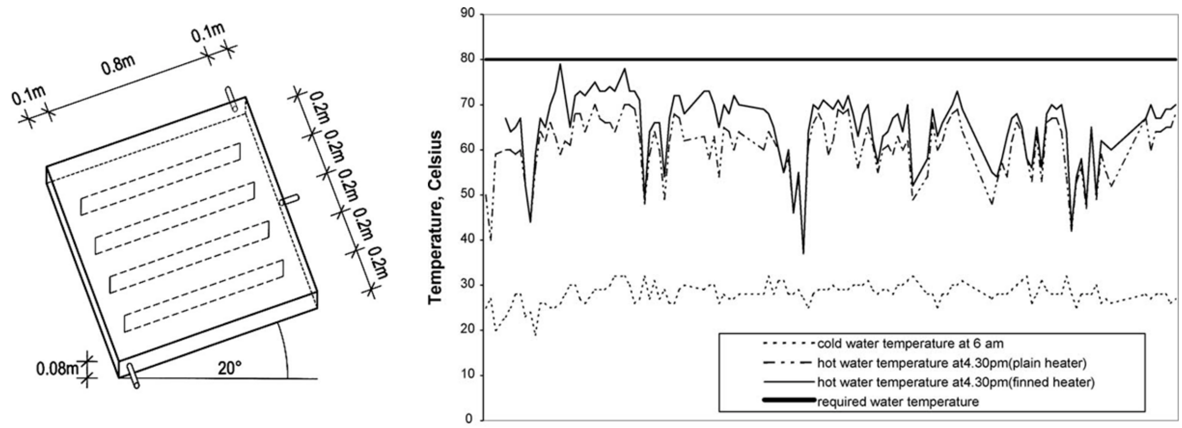

Figure 4 Isometric view of finned, solar water heater (left) and its daily performance to meet the 80^{o}C hot water demand required to wash cotton looms in textile industry.

Table 2 Comparison of Stainless steel (SS) and Aluminium (Al) solar water heaters (unit square meter frontal area)

	SS	Al
Annual-averaged temperature lift, Celsius	32.9	39.2
Life-time energy output, 20 years (MWh)	16.5	21.3
Thermal efficiency, %	47	61
Carbon payback, years	<1	<1
Economic payback, years. Fuel = gas	9	3

The technology under discussion is one of the most potent examples of what can be done with immediate effect to decline the release of greenhouse gases to atmosphere. The fabrication is low-tech, ideally suited for developing countries which also has a quick payback time in monetary and embodied energy terms.

Solar photovoltaic

In year 2015 the world electricity consumption was 21.7 Trillion kWh. This is equivalent to a constant load of 2.5TW. Between the years 1970 and 2014 the global-averaged per capita electricity usage had increased from 1,200 to 3,144kWh, a per-annum increase of 162%. This phenomenal growth will continue to rise with the advent of electric vehicles which are now being incentivised by governments as an instrument to combat kerb-side pollution. In terms of greenhouse gas emissions the latter will only be sustainable provided the renewable-sources based electricity increasingly displaces its fossil-fuel counterpart. Towards that end we note:

- Presently, 23% of world electricity comes from renewable sources.
- The cumulative wind power installed capacity at the end of year 2015 was 433GW.
- Likewise, solar PV capacity now stands around 368GW.
- The annual-averaged capacity factor for solar and wind energy are at best around 14- and 20%.
- The price drop per Watt of solar PV has been USD 7667 to 49 US cents in 40 years, a factor of 156.
- Likewise, the price drop for wind power has dropped by a third during the last four years to £97/MWh [Financial Times (2017)].
- Scotland is on track to generate 82% of its electricity from renewable sources by the year 2022.
- Globally speaking, by year 2050 solar energy is expected to become the largest source with PV and Concentrated Solar Power (CSP) respectively providing 16% and 11% global electricity. Likewise, wind power is expected to carry a 17% share thus making a total wind-solar contribution of 44%.
- Several years' worth of solar PV and roof-top wind turbine research was undertaken at author's own institution (ENU). Figure 5 shows the PV installations at ENU. With the price of solar and wind fast approaching the levelised cost of electricity (LCOE) the main question will be the payback period for embodied energy. Table 3 presents the analysis that was undertaken for ENU PV installation and reported in Muneer et al (2007). Despite contrary claims it was found that even with a predominant overcast solar climate the payback period for PV in Edinburgh was only 8 years. With a 20-25 year life for PV modules it is likely that the PV technology will payback its embodied energy 2.5 to 3 times over.

Sustainable transport

Transport represents a crucial sector in today's economy and society, having a large impact on growth and employment. From a societal point of view, the importance of leisure and its related activities in modern societies makes transport an essential activity for the normal development of human relations.

Table 3 LCA for the Edinburgh Napier University 15kWp PV installation

Thermal energy audit		Embodied	CO2
Element/Material	Mass, kg	energy MWh-th	released kg
Total spigots, Steel	200	3.3	440
Total vert. rails, Steel	2000	33	4400

Cables, Copper	150	2.8	760
TOTAL		230	11000

Electrical energy audit		Embodied	CO2
Element	Mass, kg	energy MWhe	released kg
Inverters (2 IG60) Mixed	40	2	1700
Inverters (2 IG20) Mixed	24	1	700
Operation		2	1100
TOTAL		5	3500

Table 4 Energy, Environmental and Monetary economics for an electric vehicle

Energy used (kWh/km)	0.164
Energy used (kWh/mile)	0.262
Monetary economics	**pence/mile**
Electricity cost	3.15
Battery cost	0.78
Servicing cost	0.04
Vehicle depreciation cost	33.16
Total economic cost	37.12
CO2-emissions	**g/mile**
Charging based on UK grid	142
Charging based on Solar PV	12
Charging based on Nuclear, Hydro and Wind	3.3

Means of transport have evolved a great deal over time. The use of cars has become widespread in view of multiple advantages they offer. Amongst all means of transport, the car is considered the most convenient. The use of the car is flexible, is fast and agile and seems to be the only means of transport able to connect quickly with different locations, when offices, shops, hospitals, schools or sport facilities are far away from homes. In terms of safety, which is a top concern, driving a car makes us feel safer than for example driving a motorcycle, cycling or walking. A car is a solid and robust object that gives protection to drivers and passengers in car crashes and can withstand impacts. Due to all the aforementioned benefits, nowadays the car has become a necessity, and in the past decades the transport sector has experienced a significant growth in the world economy.

The number of cars on the planet has now crossed the billion mark and is increasing fast and 75 million units were forecasted to be added in year 2016 alone. The sales are expected to exceed 100 million units per annum by 2020 (Statista, 2016).

However, the pollution-related aspects of automobiles, in particular the diesel engine propelled vehicles, are now coming under focus. In this respect an extract from one UK newspaper (The Times) is quoted below:

- UK-wide there are 146 nitrogen dioxide monitoring stations
- A total of 26 of them breach EU/WHO guidelines
- From 2019 the Mayor of London, Sadiq Khan will create “ultra-low emissions zone” and diesel drivers will be charged £24/day to drive within city limits
- There is a growing call on government to introduce diesel scrappage scheme

Electric vehicles offer a zero (kerbside) emission and low greenhouse gas generation solution if the electricity is sourced from renewable energy means. Within the UK and other EU countries e-vehicles were introduced in a significant manner around 5 years ago and now represent 1% of auto population. In contrast we note that Norway’s proportion of electric and hybrid vehicles has reached 25%.

At Edinburgh Napier University a programme of research on electric vehicles was introduced fours ago with four charging stations installed at its three campuses. A further 12 charging stations will be added by the end of 2017. Table 4 presents the research findings of nearly four years of driving experience of a 100% electric vehicle, a Renault-Zoe (Figure 5 refers).

Figure 5. A 15kWp PV installation at Edinburgh Napier University which has been operational since 2005. The car in the foreground is University’s electric vehicle used daily since 2013 (left). A 35kWp PV roof was added at University’s Sighthill Campus in year 2015 (right).

Future low energy architectural design will need to address the incorporation of solar PV and electric vehicle parking bays on a micro- and community wind power projects on a macro scale.

Investigating Optimal BIPV Energy Yield in consideration of Daylight and Thermal Performance in Residential Buildings

Bao Quan Ong, Dr Abel Tablada

Abstract: Singapore faces potential risk of an energy crisis due to her high dependence on imported fuels. Building Integrated Photovoltaics (BIPV) on building facades is an ideal alternate source of renewable energy, considering the strategic geographical location of Singapore with relatively constant high solar irradiance year round in all orientations. This paper focuses on the optimisation of BIPV shading devices on residential building facades (North and South) based on three performance indicators, (1) solar energy yield, (2) indoor daylight conditions and (3) solar heat gain. DIVA-for-Rhino plugin was used to perform the simulations on three experiments. Experiment 1 compared three shading device tilt angles, at 3m intervals. Experiment 2 compared two shading devices angles with a smaller interval of 1.5m. Experiment 3 proceeded to compare three shading devices lengths calculated based on 1/3, 2/3 and 3/3 arcs, by evenly dividing the lowest sun angles into three sectors. The study concludes that 30° tilt angle, double-spaced, 3/3 length BIPV is optimum for façades in Singapore's residential buildings taking into account net energy yield, daylight conditions and solar heat gains. On the other hand, 0° incline, single-spaced, 3/3 length BIPV is only optimum for the top floor.

Keywords: Solar architecture, BIPV, Shading devices, Building performance,

Introduction

Singapore has a consistently high consumption of energy per capita and this demand is expected to rise further in the future (APEC 2013). Currently, 95.5% of Singapore's energy production relies on import of non-renewable natural gases (EMA, 2015). Despite many options of commercially available renewable energy worldwide, solar energy has established to be the most feasible source of renewable energy in Singapore (NCCS, 2016) due to the relative high solar irradiance throughout the year. Taking into account large-scale solar farms are not feasible in land-scarce Singapore's context, Building Integrated Photovoltaics (BIPV) is one of the few alternatives to increase domestic energy generation.

Commercially available BIPV has various applications such as curtain walls and fenestrations. This study focuses on BIPV acting as shading devices due to the dual functions it provides favourable. Firstly, the addition of BIPV can assist in converting solar irradiance to electrical energy for consumption. Secondly, it can also serve as a shading device to reduce the direct solar irradiance that enters the interior (Mandalaki et al., 2014). Providing shading on building envelopes is an essential strategy for tropical passive design.

A number of papers have studied the use of shading device in tropical and sub-tropical regions. In the tropics, especially near the Equator, there is similar high solar exposure for both North and South facades as a result of the high altitude sun path year-round. The cooling effects of shading devices on facades have been reported by Secondini et al. (2011). Temperature reductions of 1.3°C (unventilated room) and 0.5°C (ventilated room) were achieved as compared to the absence of any shading device in a high-rise building in Penang, Malaysia. In addition, it was found that mixed shading was the most effective shading device followed by double horizontal shading (Secondini et al., 2011). Another study by Wong and Li (2007) investigated horizontal shading devices and their effects on cooling loads. It was found that a 600mm and 900mm shading device reduce cooling loads by 5.87% - 7.06% and by 8.27%- 10.13%, respectively (Wong and Li, 2007).

There are also multiple papers conducted on BIPV as facades and shading devices. Sun et al. (2011) studied an optimal angle of BIPV claddings in Hong Kong by comparing its energy outputs. Saber et al. (2014) studied PV performance and energy yield predictions on the Building Construction Authority (BCA) Academy in Singapore. Through data-collection and simulations, they have found that 30° slope is the most effective angle for PV panels on facades in Singapore. Mandalaki et al. (2014) investigated BIPV shading device optimisation in relation to visual comfort and solar energy yield. They have found that brise-soleil and single-inclined shading have effective solar energy gain while maintaining indoor visual comfort. However, their study was conducted in a Mediterranean climate. Tablada and Zhao (2016) estimated the potential energy yield by using PV panels on the roof and as shading devices in a number of residential building typologies in Singapore. They have found that all facade orientations were feasible for the installation of BIPV, however, if building height is higher than 42 m and 33 m for point and slab block respectively full energy self-sufficiency cannot be achieved. However, to the author’s knowledge, there is no investigation on the impact of the shading device’s dimension and position on energy yield versus indoor thermal and visual comfort in the tropics. This is crucial in Singapore’s context where high-rise public housing (also known as Housing Development Board (HDB)) takes up approximately 16.9% of land area to house 80% of the Singapore population. Hence, results in this study may serve as reference to determine energy yield by BIPV in HDBs and its possible applications across Singapore.

Therefore, this paper aims to study the effectiveness of BIPV installed on North and South facades of new Singapore residential flats. Using computational simulations, this paper aims to achieve the following:

1. To understand the impact of shading device angle, spacing and length on solar energy yield, daylight autonomy and thermal heat gain.
2. To propose preliminary recommendations on the implementation of BIPV as shading device on residential building facades in the tropics.

Methodology

The study consists of three simulation-based experiments to determine the optimum BIPV shading device. Experiments 1 and 2 compare three different angles of single and double shading respectively on North and South facades in terms of its solar energy yield, daylight levels and thermal heat gains in the interior. Experiment 3 uses the results from above experiments to compare three different lengths for BIPV shading devices.

Performance indices and modelling tools

Solar energy yield refers to the total annual electricity ($E_{electric}$) generated from a BIPV system. $E_{electric}$ is calculated from annual global irradiance which incidents on the BIPV shading device and takes into account efficiency (η) as well as the performance ratio (P) of PV panels (Quaschning, 2010).

The Daylight Autonomy (DA) is a climatic-based index which denotes the percentage in which a minimum -user defined- illuminance level is achieved by daylight alone for a specific time interval (Reinhart and Walkenhorst, 2001). In this study, DA is set at a minimum of 300 lux for general illumination of the living room from 0800 hours to 1800 hours. Light sensors are placed regularly at 0.85m height and 0.425m apart from each other. When natural daylight levels are insufficient during the analysed period, electrical lightings (LED light) are activated to bring illuminance levels to 300 lux.

In Singapore, Residential Envelope Transmittance Value (RETV) is used to calculate thermal heat gains by facades in residential buildings (BCA, 2008). The components of thermal heat gains on facades include (i) heat conduction through opaque walls; (ii) heat conduction through glass windows; (iii) solar radiation through glass windows. Shading Coefficients of fenestration is determined according to the facade orientation.

Sky Exposure Factor (Zhang et al. 2012) is defined as the percentage of visible sky from a given point to the overall sky dome. SEF can be calculated using Grasshopper ray-tracing calculation from a point (McNeel, 2011). It is useful for evaluating visual connection to the sky, which changes according to plot ratio and different factors of BIPV shading devices.

Rhinoceros (v5.12) and Grasshopper (v0.9) are the primary tools used for generating the models for simulations. DIVA-for-Rhino is a plug-in to Rhinoceros that harnesses Radiance backward ray tracers and Energy Plus to evaluate environmental performance of buildings and urban forms (Solemma LLC 2016). Using ASHRAE International Weather for Energy Calculations (IWEC) Data (Department of Energy, 2013), solar irradiance on BIPV surfaces and daylight autonomy of interior space are derived from the simulations.

Model description and simulation settings

The simulations were done in a generic context to maintain adaptability for future applications of the study. A model abstraction and layout from the most recent residential developments in Singapore was developed and placed in a five by four rectangular array to factor in realistic site conditions. The unit plan follows a typical 4-room unit in the HDB. The simulations focus on the living room (3.6m x 4.6m x 2.8m) as it has the highest daily occupancy (Figure 1a).

Three plot ratios (PR) 2.8, 3.4 and 4.0 are selected to represent current typical and possible future densities in Singapore's residential areas. Among the three plot ratios, 5 cases were selected for simulation. Each case was given a number, Case 1, 2, 3, 4 and 5 (Figure 1b). From PR 2.8, level 3, 9 and 15 were selected, while PR 3.4 and PR 4.0 only level 3 was selected as each case has a different percentage of visible sky and irradiance.

Building materials used in the simulation follow typical materials used in constructions. CIGS thin film PV is selected as shading devices due to its higher performance on warm and cloudy, conditions typical for Singapore's climate. (BCA n.d.)(Saber et al. 2014) which has a calculated area-weighted diffused reflectance of 4.73% and an area-weighted specular reflectance of 2.97% (Jakubiec and Reinhart 2014).

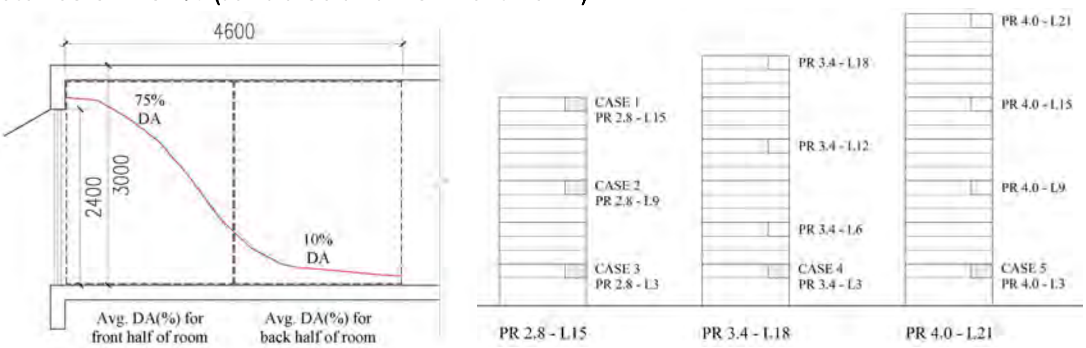

Figure 1: a) Cross section of living room and b) Section of housing blocks at Plot Ratio 2.8, 3.4 and 4.0 with position of cases 1 to 5

In this study, BIPV shading device was set to shade direct solar irradiance from 11:00h to 15:00h, which is the period with the highest solar irradiance and potential heat gain. Sun angles at 11:00h are lower than at 15:00h, therefore they are used for the dimensioning of the shading devices at different seasons. In order to determine the optimum shading device for North and South facades, several factors were considered (Figure 2). (i) Shading device angle (0°, 15° and 30°) (ii) Shading device spacing (1.5m intervals double shading and 3m intervals single shading) (iii) Shading device length (1/3, 2/3 and 3/3 arc lengths). The lengths are determined by equally dividing the lowest angles into three arcs. By taking the solstices as the limit, the different lengths shield different length of time in a year.

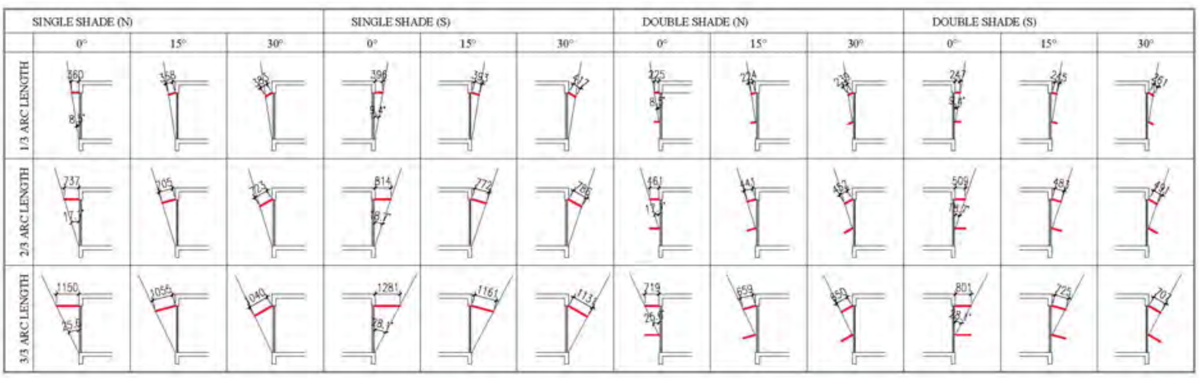

Figure 2: Matrix of possible shading devices

Results

Experiment 1

Experiment 1 aims to investigate the angle of BIPV shading device in relation to solar energy yield, daylight autonomy and thermal heat gains. The shading device spacing is 3m coinciding with floor to floor height. Sun angle is fixed at 17.1° for North facade and 18.7° for South facade (Figure 2: 2/3 Arc Length). Experiment 1 only simulates Cases 1, 3 and 5.

Solar energy yield increases as unit levels increase for both north and south facades and for all shading angles due to the higher SEF and solar exposure. North and South facades behaves similarly. However, North facades have lower energy yields due to the length of BIPV shading device for North facades being shorter than the South, as the sun angle in summer solstice is higher than winter solstice. Shadings with a slope at 30° achieve 10.2% and 9.3% higher yield than those with 0° for cases 3 and 5 respectively. Only for Case 1, 0° has higher solar yield than 30° due to its position at the top of the building with no surrounding obstructions as occurs for cases 3 and 5.

Regarding DA, 0° shadings have 26.7%, 29.6% and 28.6% higher DA than 30° shadings for cases 1, 3 and 5 respectively. This is expected as the SEF from indoors is higher when shading's slope is 0°. The differences between the shading slope angles are more accentuated for Case 1.

Energy used on electrical lighting to keep DA 100% (300 lux) is 1.8% higher on the South with respect to the North façade due to the slightly larger dimensions of the shading and the cloudier conditions of the sky from November till February. Taking into account both the BIPV energy yield and the energy used for electrical lighting, the net energy yield are calculated. The net solar energy yield from 0° is higher than 30°, for both North and South facades. In Cases 1, 3 and 5 the net solar energy after subtracting electrical lighting is lower for 30°. For Case 5, the net solar energy is negative, using more energy than the BIPV can provide. Thus, from experiment 1, 0° is a better option than 30° tilt angle.

Table 1 Net energy yield in Experiment 1 for North (N) and South (S) facades

Tilt angle	Case 1 (kWh)		Case 3 (kWh)		Case 5 (kWh)	
	N	S	N	S	N	S
0°	256.33	290.68	45.22	48.33	-1.13	2.98
15°	235.99	257.00	40.29	42.38	-2.91	-2.03
30°	207.94	226.55	36.66	37.24	-5.90	-5.48

Regarding the thermal heat gains by using RETV it is found that there is no difference between Cases 1, 3 and 5 since RETV does not consider site conditions. In terms of shading slope angle, 30° allows lower thermal transmittance (N: 29.8 W/m2, S: 30.6 W/m2) than 0° (N: 30.5 W/m2, S: 31.3 W/m2) for small margin.

Considering all results of experiment 1, it can be concluded that for single shading per floor, 0° shading device has overall better results than those with 30°. The net energy gain from 0° is higher than 30° while the higher RETV is not relevant.

Experiment 2

Experiment 2 aims to investigate the impact of reducing the shading device spacing from 3m to 1.5m. Only Cases 1, 3 and 5 are simulated in Experiment 2 and according to the results in experiment 1, only 0° and 30° will be simulated.

Solar energy yield is calculated through the summation of upper and lower panels. Similar to experiment 1, the higher the SEF and solar exposure the higher the solar energy yield for both north and south facades and for all shading angles. North facades have lower energy yields for the same reason as in Experiment 1. Shadings with a slope at 30° achieve 16.8% and 9.8% higher yield than those with 0° for cases 3 and 5. Only for Case 1, 0° has higher solar yield than 30°. Comparing experiment 1 and 2, double shading device gives 20.9% and 17.7% higher solar energy yield than single shading device for cases 3 and 5 respectively. However, energy yield from double shading in Case 1 on experiment 2 is lower than in experiment 1 due to the overshadowing effect on the lower slat.

Regarding DA, similarly to experiment 1, shadings with 0° tilt angle allows 7.5%, 15.5% and 10% higher DA than with 30° for cases 1, 3 and 5 respectively.

Energy used on electrical lighting to keep DA 100% (300 lux) is 2.9% higher on the South with respect to the North façade. However, comparing cases 1, 3 and 5 from both experiments, the benefit of using double shading device is substantial for 30° shadings and still evident for 0° shadings. Taking into account both the BIPV energy yield and the energy used for electrical lighting, the net energy yield is calculated. Comparing between experiment 1 and 2, less electrical energy is required in experiment 2 due to the improved DA. The net solar energy yield from 30° is higher than 0°, for both North and South facades.

Table 1 Net energy yield in Experiment 2 for North (N) and South (S) facades

Tilt angle	Case 1 (kWh)		Case 3 (kWh)		Case 5 (kWh)	
	N	S	N	S	N	S
0°	230.66	263.98	63.84	78.17	14.64	28.63
30°	249.62	267.13	81.53	85.79	25.40	30.10

Regarding thermal impact of shading tilt angle, RETV is lower for 30° in North and South at 28.8W/m^2 and 29.6W/m^2 respectively. While thermal heat gain is higher for 0° in North and South 29.5W/m^2 and 30.1W/m^2.

Overall, the results from Experiment 2 showed that 30° shading device performs better than 0° shading device as net energy gain from 30° is higher than 0°. Even though DA conditions for 0° is better than 30°, the difference in DA is less than the difference in solar energy yield. In addition, thermal heat gains for 30° is lower than 0°, showing there will be better thermal comfort.

Experiment 3

Experiment 3 aims to investigate the length of BIPV shading device in relation to solar energy yield, daylight autonomy and thermal heat gain. The results from experiment 1 and 2 determine that optimum shading device spacing is at intervals of 1.5m and BIPV optimum angle is fixed at 30°. The length (1/3, 2/3 and 3/3 arcs) was determined according to sun angle as explained in the Methodology section. All Cases 1, 2, 3, 4 and 5 were simulated in Experiment 3.

Shadings with 3/3 length achieve higher energy yield than those with 1/3 and 2/3 lengths as larger surface area receives higher total irradiation.

Regarding DA, 1/3 length shadings have higher DA than 2/3 length and 3/3 length shadings for all cases. This is expected as the SEF from indoors is highest when shading has the shortest length.

Energy used on electrical lighting to keep DA 100% (300 lux) is compared between different lengths. Table 2 shows that net solar energy yield from 3/3 is higher than 1/3 and 2/3, for both North and South facades. The reduction in DA in 3/3 is the least significant in reference to solar energy yield.

Table 2 Net energy yield in Experiment 3

Length (arc)	Case 1 (kWh)		Case 2 (kWh)		Case 3 (kWh)		Case 4 (kWh)		Case 5 (kWh)	
	N	S	N	S	N	S	N	S	N	S
1/3	133.6	137.4	67.7	65.7	36.8	35.5	18.8	14.7	1.7	-0.4
2/3	244.2	256.6	124.1	127.3	78.0	79.1	53.5	53.9	31.1	29.8
3/3	328.6	293.3	152.4	159.8	97.2	103.4	67.6	71.3	40.2	42.9

Regarding the thermal performance, lower RETV are obtained for shading with 3/3 length in comparison with 1/3 and 2/3 lengths (Table 3). Therefore, double 30° slope shading with 3/3 length is the optimal shading device for both North and south facades on all cases except for Case 1 in which single 0° slope shading with 3/3 length is the optimal option.

Table 3: RETV of BIPV shading device at various lengths

	RETV (N) (W/m^2)	RETV (S) (W/m^2)
1/3	30.99	31.81
2/3	28.83	29.57
3/3	27.49	27.59

Overall building production

Using the optimised configuration, an estimate of net solar energy yield per floor and facade orientation can be calculated according to the obtained exponential equations shown in figure 3. The entire net solar energy yield considering North and South facades were also calculated. The study shows that BIPV shading devices for North and South facades can produce 92 639.1kWh of the 281 534.4kWh consumed annually which equates to 32.9% of annual consumption of a single block (EMA, 2016).

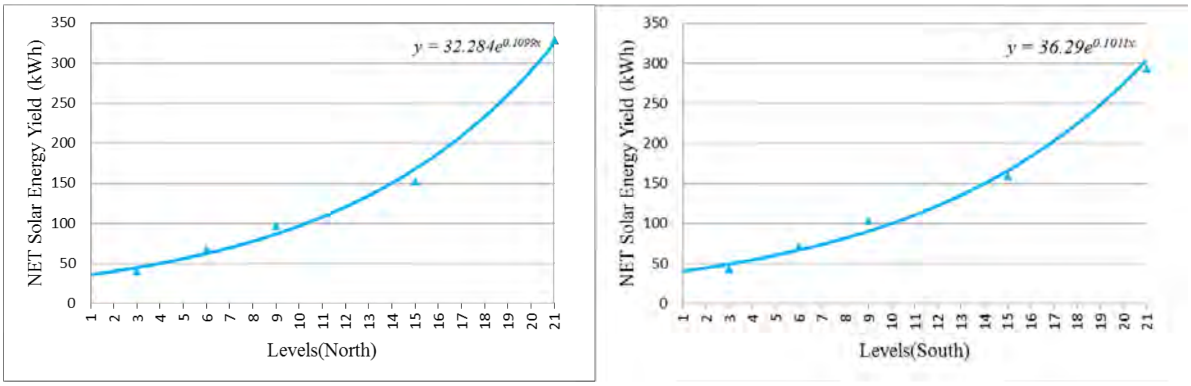

Figure 3: Net energy yield according to the position of BIPV shading devices (building level)

Conclusion

A series of experiments were conducted in this study to understand the impact of shading device angle, spacing and length on solar energy yield, daylight autonomy and thermal heat gain. These results were subsequently used to compare results of various shading device properties in order to optimise BIPV shading device. Experiment 1 compared different single BIPV angles while Experiment 2 compared between single and double BIPVs. Lastly, Experiment 3 compared the optimisation of various lengths of BIPV shading device.

In conclusion, the following guidelines can be determined from this study:

1. The optimum shading device is a double BIPV with 3/3 arc length (650-700mm) and 30° tilt angle. This may be applicable on new buildings or in retrofitting projects.
2. In the case where only a single shading device can be installed, 3/3 arc length, 0° shading device is preferred.

The total net solar yield amounts to 92 639.1kWh for North and South façade for a single block, which is 32.9% of electrical consumption of the block. When coupled with additional solutions such as roof PV arrays, it can provide an even larger contribution as a renewable energy source. Hence, findings in this study show significant energy yield through BIPV shading device and suggest feasible applications in Singapore HDBs.

Further studies will include the optimisation of BIPV dimensions and positions on East and West facades as well as other intermediate orientations. The effect of adding BIPV on facades with balconies and exterior common corridors will also be explored.

Solar energy in the urban vertical fabric

Harald N. Røstvik

Professor,
University of Stavanger, Norway. harald.n.rostvik@uis.no

Abstract: By using a recently completed Nearly Zero Energy Building (NZEB) house in Norway as a case, this paper discusses the chosen strategies and explores their wider potential. The case is an innovative compact house addressing the housing shortage through minimising area-, volume and building costs, while exploring the solar energy potential using BIPV on vertical walls in a Northern climate. Advantages and disadvantages are evaluated.

Keywords: NZEB, cost, housing, solar

Introduction

The case building is constructed 30 years after one of Europe's first modern NZEB designs was built in the same region. It is interesting to compare the technical solutions and the costs available at that time and now. Such history lessons are also useful for teaching university students of architecture and urbanism about advances in passive and low energy design, as well as the remarkable technological developments. The house 30 years ago was not as energy efficient as the new one is. It had a total energy need per m^2 more than double of the new house. In order to deliver so much energy it had to use a combination of solar PV, solar thermal, wind power and log fire (kakkelovn). It had batteries to store electricity and two thermal mass stores to store heat, one rock bed and one water tank. The many technical devices necessary led to co-ordination challenges between them. Grid connection was not possible at the time. It is interesting to observe that after all these years and with grid connection later having been widely used in NZEBs to balance the scattered delivery of energy from solar and wind, the tremendous advances and cost reductions in battery technology now again opens up for the possible future use of batteries to make buildings and neighbourhoods energy autonomous. But such a technological approach can only be successful if energy need is lowered through the traditional methods of passive and low energy design. In the following chapters a listing of the described methods are put figures to, after which the potential of delivering the energy need from solar is discussed.

The main advantage of such an all electric solution is that it is technically much more clean cut and avoids all the co-ordination challenges in solutions using several combined energy sources, as designed into the first NZEB.

Planning

All construction is energy demanding and produces greenhouse gases from the very start, excavation of the site, through material development, transportation, manpower and demolishing. The role of the architect is hence also to avoid planning larger areas and volumes than necessary. The goal of which is to reduce the resources going into the production of buildings, cities and infrastructure. A building that is compact and rational will always have a better chance of becoming energy efficient and a user of renewable energy. It is also cheaper. Total building costs for housing in Norway are on average NOK 70 000 per m^2 (GBP 64 000) including finance cost, project development and profits. This includes site costs of NOK 6 000 (GBP 5 500) per m^2 (Norsk Prisbok, 2014). To understand the cost structure is particularly important for architects and planners so that housing costs can be lowered to accommodate the needs of the young and the first time buyers.

In the particular case in Norway, analysing and questioning the area need with the client led to 45% floor area reduction, from 105 to 58 m^2. The process was very natural and the client afterwards expressed to nationwide media that he is very pleased with the result (Teknisk Ukeblad, 2017). He even expressed that the storage space and main rooms felt more generous than anticipated during the planning process. See Figure 1.

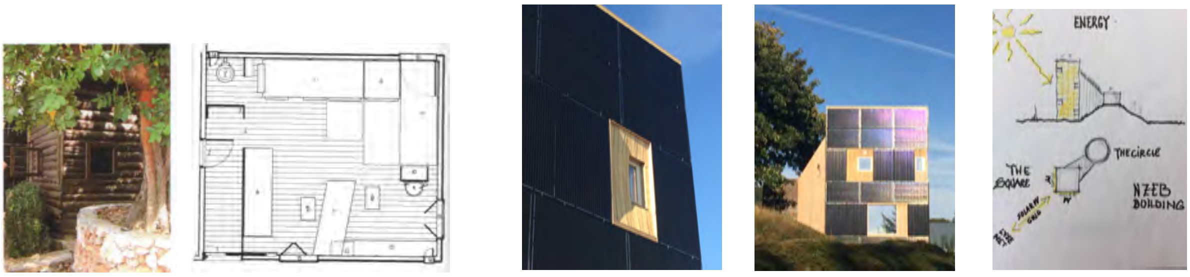

Figure 1. Left two: Plan, picture Le Cabanon. Ill: Byggekunst. Right three: Case house. Ill: The Architects.

The planning process started with discussions between the client and the architect where the first bubble diagram sketched by the client was analysed. The first example used was the fair life one can have in a caravan in a mobile situation. The client then rented one and went on summer holiday on the $8m^2$ with his young son. It worked perfectly well for them and based on this, new planning discussions took place, bringing the total area down to the as-built size. The second example used was Le Corbusier’s Le Cabanon at Cap Martin, in southern France (Byggekunst, 2007). Le Cabanon was only 16 m^2 and the famous architect and his wife lived there during the summers on $8m^2$ per person (Figure 1). The compact thinking had been inspired by Le Corbusier’s long haul flights to other continent. He had seen how compact the cockpit and the toilets were on board. Le Cabanon contained a combined living and sleeping room, toilet and a small breakfast kitchenette, as there was a restaurant next door, where they ate lunch and dinner. Showers were taken outdoors or by swimming. Le Cabanon was of course for the summer season only. The third example was that of world famous philosopher Ludwig Wittgenstein who wrote great works in a 59 m^2 log house on a mountain shelf in Skjolden by the Sognefjord in Norway (Stiftinga W, 2017).

In Norway, where the climate is harsh, the demand for insulated construction and more indoor space is of course pressing, to avoid people sitting on top of each other in the long dark Nordic winters. But still, there is a lesson to be learnt from Le Cabanon about compact, rational space planning. For every square meter one can save, land and monetary resources are saved, so is energy, both for construction and the running of the building throughout its life span. The case house is composed of a living square of 4,2mx4,2m internally and a wet room circle with a diameter of 3,0m. The compactness of the $58m^2$, two and a half person Norwegian case house, is in strong contrast to the constantly growing average *living area per person* in Norway, which has doubled since 1960 when it was $29m^2$ per person. In 2000 it was 51 m^2. It is now $56m^2$ (Statistisk Sentralbyrå). Simultaneously the *average household size* has become smaller in the period. In 1960 there were 3,3 persons per household, by 2000 there were 2,3. This is the same as in 2015. The *area size* of housing (the average figures for detached-, row- and flat housing) has increased dramatically in the period, in spite of the fact that households have been reduced. In 1967 there were $89m^2$ per household. Thirty years later in 1997, 114 m^2, an increase of 28% during a period where the household size has been reduced by 30%. The Norwegian case house of $58m^2$ for two grown-ups and a now 6 years old child, say 2,5 persons, is $23m^2$ per person. The question arising is hence if such a compact building strategy lowers the quality of living? The issues addressed in the following relates to this as it discusses the pros and cons of the compact solutions and the architectural and technical challenges it poses.

Daylight

A slim plan (compact) versus a fat plan (spread out) has advantages and disadvantages. A fat plan means that everything can be located on one floor, while a slim plan means the house or apartment may have to go vertical over several floors, to achieve the same total floor area. The consequences of this are many. A slim plan offers the possibility of placing several windows in a room and to orientate them in different directions on several walls, which increases the use of daylight and direct sunshine. A fat plan will be deeper and it is more difficult to daylight the parts of the rooms that are located far from window-walls. But the slimness' verticality poses universal design challenges with the stairs connecting floors.

Universal design

A house or flat on one floor only is normally seen as the best in a total life span cycle. If people want to live in the same place in spite of health related limitations of their ability to use stairs, this is an argument for the one floor fat plan. If, however, the need for more compact living is driven forward as an argument to densify cities, both arguments have to be balanced and counterweighted against each other. If the option of going slim and vertical is chosen, it will be the job of the planner to ensure that it is possible to function on one floor most of the time by having the living room, sleeping-, kitchen- and bathroom facilities on at least one floor. This can sometimes be challenging if not planned for in advance, but it is possible if planned from the outset. In the case of the Norwegian building, the first floor is planned with this in mind without alterations, provided a sleeping facility is accepted and the day-sofa in the living room is used as bed at night. At the ground floor, such autonomy can also be achieved by installing a very light kitchen facility. Everything else is already in place.

This leads to the issue of access. External access to the middle floor in the case house is ensured by the used on a long sloping ramp looking like a barn access bridge. This is also the main access to the house, as the section in Figure 1 shows. Internal access for everybody between floors, also the handicapped, is possible by installing a simple weight-based stair lift. The step between the floors is all straight runs without any bends that normally complicate matters anyway and increases future lift costs. The straight run allows the use of a fairly simple and inexpensive lift, if a lift later becomes necessary.

Insulation

In the Nordic climate a lot of insulation is necessary to make buildings energy efficient in winter. With the new EU Directive, Nearly Zero Energy Buildings (NZEB) introduced from 2020, the housing market is driven further towards demanding energy efficient buildings that use new renewable energy. In Norway total wall and roof thicknesses already reach 300 – 500 mm. This is highly material-, labour- and finance-demanding. It also demands a bigger part of the site, as walls get thicker (Figure 2). This challenge has been addressed in the case house where it has been a goal to reduce insulation thicknesses wherever possible in order to reduce the footprint on the site. This is particularly important in dense situation in cities where densification is a part of the overall environmental strategy. Therefore new insulation types have been tried out. The compact-insulation applied has led to a reduction of wall thickness from 500 to 150 mm. Described from the outside it consists of 100mm Kingspan foam, 30mm Rockwool and a reflective layer of plastic. An LCA analysis will be carried out.

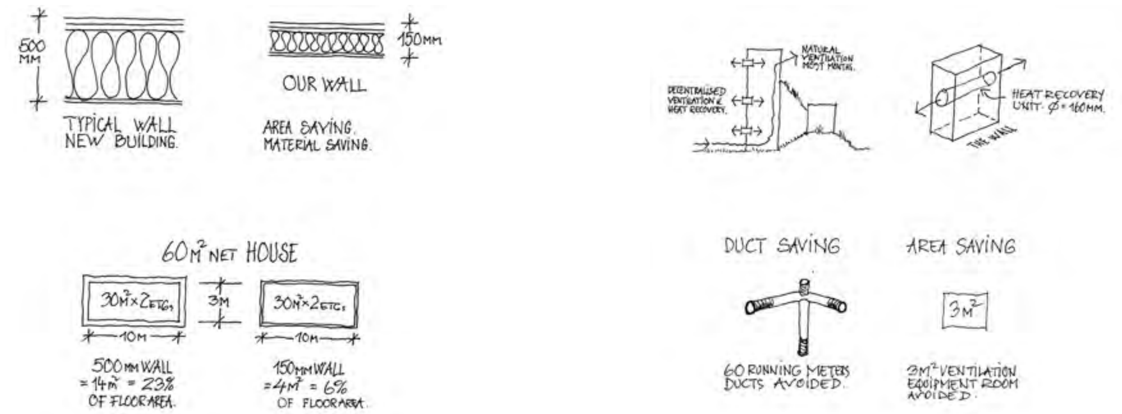

Figure 2. Left: Area, cost and material saving slim walls. Right: Decentralised heat recovery gains.

Ventilation

In order to achieve the NZEB standard, forced balanced ventilation and heat recovery is necessary. Most projects in Norway end up with that strategy. The case project has tried to question the need for such a heavy technology-dependent approach by leaning more towards a passive and low energy strategy. However, in the Norwegian winter months natural ventilation will not work without heat recovery, if a NZEB level is sought.

In the case project, natural ventilation is part of the strategy most of the year, normally 9 months. In the coldest three months of the year, forced ventilation with heat recovery is necessary. The applied heat recovery system consists of decentralised units mounted through the walls in a 160 mm diameter duct. Through this short duct, of wall thickness only, a fan in the duct extracts used indoor air. On its way out, the warm air passes through a ceramic cylinder that stores the heat. After ten seconds the fan switches air direction and sucks fresh outdoor air in through the same duct, thus heating the air when it passes through the warmed ceramic cylinder. There is one such small duct in each room, only a couple of rooms have two. They were very easy to install and are inexpensive compared to a centralised duct and air handling unit solution. A switch next to the light switch in each room can also switch them off manually any time and one by one. A centralised HVAC system is hence avoided. The saving is considerable: A traditional technical room for the air handling unit and the central heat recovery is eliminated. This is in itself a reduction of $3m^2$ ($8m^3$) per housing unit. In addition 60 running meters of ventilation ducts, that a standard centralised HVAC system would need, are avoided (Figure 2).

Through the combination of the strategies mentioned above, the energy need of the house is considerably reduced - to only 5 200 kWh per year. The following chapter will put this energy need into perspective and look at how renewable energy can deliver all of it.

Energy

The average energy need of a Norwegian single-family housing unit is 25 000 kWh per year and for a flat 12 000 kWh. Single family housing energy use is 80% electric energy and 20% wood or pellets (SSB, 2014). 99% of all electricity in Norway is hydropower-based, so it is considered clean. The energy need for the case building has been lowered to Passive house standard based on the mentioned energy efficiency measures. This led to a calculated annual energy need of 5 200 kWh, which is divided between the uses shown in Table 1.

Table 1. Energy need of case building. Source: E-tech

Domestic hot water	2 050 kWh/year
Space heating	1 050
Technical equipment	1 100
Lighting	700
Fans	300
Sum	5 200 kWh/year

Solar energy

The total energy need is delivered by a grid-connected Building Integrated Solar Photovoltaic (BIPV) electric system constituting the cladding of the vertical southwest and southeast walls. The PV modules replace other facade materials, so extra costs are minimal.

Angle of inclination

In countries close to the equator, the sun is high in the sky most of the day and year. In all the Scandinavian countries, however, the sun is low in the sky in that part of the year when energy requirements are greatest – in winter. Many international tables of radiation are therefore somewhat misleading, because they are calculating solar radiation onto a horizontal plane. Such tables do not allow for the fact that a considerable amount of solar radiation falls on vertical planes, e.g. walls of buildings, during winter the months (Røstvik 1992, 36-37). Table 2 shows the relationship between the angle of the solar collector to the horizontal for domestic hot water as well as for both space heating and domestic hot water. Although this is based on thermal energy delivery, the relationship to electric energy is comparable. It shows that in a Scandinavian situation a vertical wall integrated solar installation delivering space heating and domestic hot water will catch 97% (0,97) of the maximum, or considered the best 100% (1,00) that a 45 degree inclination delivers. This clearly shows that a vertical wall is an almost ideal location for solar modules, not least because it can also replace other, sometimes expensive, cladding materials.

Table 2. Inclination of the solar collector – relative change of degree of effect in Norway.

Angle to horizontal	0°	15°	30°	45°	60°	75°	90°
Domestic hot water	0,71	0,85	0,94	1.00	1,00	0,98	0,88
Space-heating and domestic h.w.	0,59	0,74	0,89	1,00	1,06	1,06	0,97

Table 3. Orientation of the solar collector, relative change of degree of effect in Norway.

Degrees from the south	0°	15°	30°	45°	60°	75°	90°
Domestic hot water	1,00	0,99	0,97	0,93	0,88	0,81	0,73
Space-heating and domestic h.w.	1,00	0,98	0,95	0,89	0,81	0,73	0,64

Source: Røstvik (1992).

Orientation

The directional orientation of the solar collector has less significance than most people realize. The best results north of equator are achieved if the collector faces due south, but slight deviations from this have little significance for the yield (Røstvik 1992, 37). Table 3 shows this. In the case of space-heating and domestic hot water where due south delivers maximum 100% (1,00), an orientation 45 degrees west of east or south will deliver as much as 89% (0,89). A west or east orientation, 90 degrees from south, will deliver 64% (0,64).

Lessons learnt in 30 years

The remarkable cost fall that have taken place during the last decade continues and solar PV systems will in due time become as cheap as most cladding materials. Solar PV modules are already cheaper than the more expensive marble and metal cladding facades. Reflection from neighbouring buildings and from snow will increase production. So will a well-ventilated façade. A gap between the rear side of the absorber and the constructed wall behind, secures an up draught that cools the solar cells and increased their electricity production. Construction detailing hence also becomes important.

The new Norwegian case house with its modest energy need is all electric and grid connected, it sells surplus electricity to the grid and buys back when it cannot deliver its own energy. The problem with this in Norway is that the selling of the house's surplus electricity generates very little income, only 20% of the normal cost of electricity per kWh when buying from the grid. So selling to the grid is not stimulated and does not pay off. This is contrary to many other countries that have introduced incentives by copying the initial German feed-in-tariff that encourages the selling of renewable energy to the electric utility's grid by offering payment way above the normal price per kWh. The consequence is that in Norway the lack of incentives stimulates the use of off-grid systems, totally energy autonomous solutions, where a kWh electricity produced by the house has the same value as the bought one by reducing or eliminating the need for buying electricity from the utility.

It is hence ironic that the electric utility companies that do not support and subsidise solar power delivered to their grid may undermine their own future by not paying properly for delivered solar electricity. With the fast development in battery technology, with falling prices and more compact solutions, battery storage may become a viable alternative both technically and financially, especially in neighbourhood solutions or village level local grids. The growing interest for smart buildings, smart neighbourhoods and smart cities underlines this and so does the growing interest in electric vehicles and bikes. 48% of all sold new personal vehicles in Norway during January 2017 were Battery Electric and Plug in Hybrids. They will be connected to people's homes and the vehicle batteries will share energy with the house and vice versa. This opens up a new world of opportunities that leads to community energy autonomy, while simultaneously evening out the peak load burdening the electric grid.

Discussion

Vertical solar facades may suffer from trees or neighbouring buildings casting shadows on the façade, but in locations where that is not the case, vertical facades may work very well. They deliver energy during the part of the year when the energy need for heating up north is highest. A solar PV façade, not a thermal one as discussed above, will achieve similar results. It may even deliver electricity during night in the most northern regions of Europe because in the summer the nights are very long. In some places the sun hardly sets in the summer. In latitudes around 65 degrees north the sun is up 21-24 hours a day during June and July. This is of course extreme, but it means that a solar absorber will deliver energy almost all through the night and can be orientated towards northeast or northwest, if energy is needed in the summer time.

The point here is that the efficiency of a solar absorber depends on many local factors. Vertical facades are useful producers and orientation does not have to be due south. Although the production is not maximum with such tilts and orientations, adding modules to increase the capacity of the system, with only marginal costs, can easily compensate the loss.

Conclusions

Verticalization and compactness are interesting measures to densify cities and as illustrated by the case building, compactness does not have negative effects only. There are many positive effects of densification, provided the distance between buildings is adequate. As the cost of solar is reduced and modules become competitive with traditional façade cladding materials and not only the more expensive ones, as the case is today, solar facades can become widespread. This will lead to less worry about performance. Until now, the solar advocates have been very particular at underlining that it is necessary to have unobstructed lines to catch sunshine. They argue for a stronger law that protects people right to sunshine. That is good from a health point of view and also to increase the use of daylight in buildings. Although this is true now, it is important to underline that this view is based on a situation where solar is so expensive that getting the most out of every module is a must in order to defend the solar equipment investment. This would call for stringent regulations and laws protecting a building owner against shade cast from neighbouring buildings. This may be a “truth” of the past, because sunshine is not only useful as direct sunshine, but also reflected. With verticalization and densification of cities it becomes impossible to control sunlight lines to prevent shading of solar modules. If we accept that shading will occur in dense cities, we should look at reflection from neighbouring buildings as an opportunity also. Sunrays are almost completely reflected from glossy white facades (think of glare in white vernacular urban settings) and reflective mirror glass in buildings. In the PLEA15 paper “Consequences of Verticalization” Paula Bregiatto et al showed how verticalization resulted in poor environmental conditions and accumulation of pollutants (Oliveira, P.B. et al, 2015). The paper described how the 2002 Master plan of Sao Paulo was updated in 2014 to reduce the massive exploitation of land. This is an example of planners using the master plan to adjust to changing conditions and experiences as time goes by. Such adjustments should also take place as regards the role of solar reflection when verticalizing cities. It is up to the planners to stay updated so that new technologies like solar is given the *best conditions possible,* as it can never be perfect.

In another PLEA paper "Comparing the solar performance of urban forms in London", Chatzipoulka, C. et al studied how urban geometry had an impact on solar availability in twenty-four urban forms in London (Chatzipoulka, C. et al, 2015). They found that solar availability on building facades in the urban setting naturally varied with deviation of building height and the sun's altitude: the lower the altitude, the greater the influence. Based on this general guidelines can be developed.

It does, however, appear that most studies are based on monitoring program software that does *not* handle uncontrollable reflection from neighbouring buildings. Instead they just study direct sunshine, which is only a part of the solar contribution. More precise models that include the consideration of reflection would be helpful and based on such modelling; more realistic guidelines can be developed.

Abstract: Taking into account that Brazil possesses 84% of its population living in cities and that transportation constitutes a significant portion of the urban cost matrix, balancing city growth, energy consumption and transportation (including maintenance and operation of the road system) represents a great challenge to be overcome. Though 65.2% of the Brazilian electricity mix is based on hydropower, the country has faced strong unfavorable hydrological conditions. This research hence had the overall objective of investigating solar energy potential to supply renewable energy for residential and public transportation end-uses. The method comprised a general analysis of the city of Londrina, in Brazil, and an indirect quantitative relational methodology of data constitution for computing energy consumption and generation potential. We followed the 'ecosystem approach' on sustainable urban development to establish present and future residential energy consumption scenarios for the studied city. Our calculations showed that, when the whole urban perimeter is occupied, installing PV arrays on 10% of the residential roof surface would produce a 75% energy surplus that, if added to PV generated by adoption of a massive local renewable energy production (MassREP) system, Londrina would be able to also supply a new, renewable electricity-powered smart mobility transportation system.

Keywords: Urban Metabolism, Energy Urban Planning, Solar Energy, Distributed generation, Smart Mobility.

Introduction

As of 2008, over 50% of the world's population lived in urbanized areas (UN, 2014). Due to a car-dependent development culture, urban sprawl and high agglomeration of built environment, people and economic activities in one place, urban settlements represent bulk resource (energy, water, land and materials) consumers, generating immense amounts of waste, high thermal capacity material surfaces and heavy emission of pollutants to the immediate and global environments (Bai, 2007; Niemelä et al., 2011; Pincetl et al., 2012). Such negative tracks are expected to worsen as urban areas play their protagonist role in population growth forecasts and the dark path we witness today concerning the problems of pollution, resource scarcity, climate change and extreme poverty become more critical. Hence, sustainable urban planning approaches that regulate a balanced view of future developments must be increasingly consolidated.

The relationships among city growth, energy consumption and transportation represents a great challenge to be overcome in Brazil. Over 84% of the population lives in cities (IBGE, 2010), meaning that at least 168 million people use some kind of urban transportation, private or public, individual or collective. Transportation also represents a significant portion of the urban cost matrix. Though 65.2% of the Brazilian electricity mix is based on hydropower (BEN, 2015), the country has faced strong unfavorable hydrological conditions, which restates the importance of investigating other potential renewable energy sources to sustain transitioning towards a less dependent or fossil-free society. This research hence had the overall objective of investigating solar energy potential to supply renewable energy for residential and public transportation end-uses for the city of Londrina. Such symbiosis constitutes an innovative urban energy ecosystem and an important enabler for Brazilian eco-cities in the near future.

The method comprised a general analysis of the selected city and an indirect quantitative relational methodology of data constitution for computing energy consumption and generation potential. We followed the 'ecosystem approach' on sustainable urban development to establish present and future residential energy consumption scenarios for the studied city. A top-down methodology was applied to estimate current energy consumption for each residential typology defined. Next, a bottom-up approach was applied to derive consumption for future typologies defined by the existing city zoning plan. Finally, we assessed the potential to not only counterbalance such consumption, but also to feed a new smart mobility transportation system, through adoption of a massive local renewable energy production (MassREP) system.

The Ecosystem Approach

Amid all movements and strategic views towards sustainable urban development, the 'ecosystem approach' stands out for its comprehensiveness and systemic thinking. This theoretical approach helps to frame the chaotic web of existing variables and relationships by essentially enabling partial analysis of a system without losing sight of the broader context in which it appears and by which it is influenced (van Bueren et al., 2012).

Within the ecosystem approach's scope, different 'sub-approaches' frame the built environment as an ecosystem that needs to balance its inputs, outputs, use and extraction of resources and, by doing so, enable provision of methods and tools for environmental assessment. The 'flows sub-approach', in particular, defends that city survival requires constant resource inputs and outputs flowing through it, at immense transportation and energy expense to sustain such 'metabolic' work. By seeing cities as quantifiable entities, in which the inputs and outputs of materials, resources, energy and information are measurable (van Bueren et al., 2012), concepts such as 'Urban Metabolism', 'Circular Metabolism' and 'Carrying Capacity' emerged and gained traction in the past years.

Urban Metabolism is the collection of technical and socioeconomic processes that occur in cities, and result in growth, production of energy, and waste elimination (Kennedy et al., 2007). Considered as fundamental to sustainable city development (Kennedy et al., 2012), such metabolic work enables system and technology management for reintegrating natural processes, increasing energy and resource use efficiency, and recycling waste (Newman, 1999). Shahrokni et al. (2015) further elaborated the concept of 'smart urban metabolism' (SUM), which aims at combining real-time user-generated data to offer knowledge on energy and material flows as close as possible to reality, and the use of calculation engines that can provide feedback related to sustainability indicators set by a city.

Smart Mobility

Mobility efficiency within a city, region or country is closely related to the economic and social development. Transportation facilitates access to work, services, education and leisure. In large cities, it constitutes a significant portion of the urban cost matrix. In some cities, the amount spent on transportation - including maintenance and operation of the road system - is larger than the share committed with basic public services such as water, electricity and sewage supply.

The term ‘smart mobility’ is embedded within the ‘smart city’ framework, which promotes the use of information and communication technologies (ICTs) to create *“a particular form of spatial intelligence and innovation, based on sensors, embedded devices, large data sets, and real-time information and response”* (Komninos et al., 2013), that helps more efficient functioning and maintenance of urban physical infrastructure, as well as managing natural resources wisely through participatory governance, all of which supporting a strong and healthy economic and social development (Caragliu et al., 2011). In that line, ‘smart mobility’ refers to logistics and new transportation systems which improve urban traffic and inhabitants’ local and international accessibility through ICTs (Giffinger, 2007). Smart mobility is usually associated with ‘green mobility’ standards, which aims at expanding public access and decreasing environmental, social and economic impact through the creation of a sustainable transport system that reduces air and acoustic pollution, greenhouse gas emissions, road congestion, accidents, and that also optimize territory consumption.

The Energy Issue

Transportation is vital to the survival, well-functioning, development and, particularly, to the quality of life in cities. In Brazil, the transportation sector is the second largest energy consumer in the country (32,5%), right after industrial consumption (32.9%) (BEN, 2015). Sadly, 82% of this consumption comes from non-renewable sources.

In 2014, the total anthropogenic emissions associated with the Brazilian energy matrix reached 485.2 Mt CO_{2eq}, from which 46% (221.9 Mt CO_{2eq}) were transportation-driven. The current scenario could be reversed if individual mobility is decreased; alternative renewable energy sources are taken into the sector; and massive investments in comfort, safety and quality are made in public mass transportation, since it consumes 5-10 times less energy per passenger.

The Brazilian electricity matrix represents 17.2% of the total end use and is mainly consumed by the industrial (38.7%) and residential sector (24.8%). 65.2% of it comes from hydro power plants. More recently, other clean energy sources have received encouragement, such as biomass (7.4%) and wind power (2%) (BEN, 2015). However, taking into account that only 0.04% of this electricity reaches the transportation sector; the huge solar radiation available in the country; and also the recent drought periods, solar thermal energy represents an interesting alternative to be explored, especially if we consider that dry periods are associated with increased solar potential due to low interference from clouds and more intense solar radiation. Furthermore, solar energy is considered as a renewable and inexhaustible energy source. While the PV panel production indeed has its own impacts, the electricity generation process does not emit SO_2, NOx and CO_2: all of them greenhouse gases contributors to global warming and with harmful effects on human health.

Our case study: Londrina

As a young city that has undergone rapid growth during its 82 years, Londrina is the fourth most economically influential city of Southern Brazil. Located 390 km from Curitiba, the state's capital, Londrina is one of the most dynamic cultural centers of the country and presents an important potential for future urban growth and development. The city has a population around 554.000 inhabitants, but also conforms a metropolitan area with over one million citizens and conurbative spatial integration with two neighboring towns. At an altitude of 608 m, the urban perimeter is set on a fertile land, containing five hydrographic basins with permanently protected areas of original bottom valley vegetation.

Londrina's urban form is characterized by two sites of high verticality, density, income and infrastructure (i.e. the city center and '*gleba palhano'* neighborhood); a region of medium density, income and infrastructure in the center outskirts; a region of low density, high income and medium infrastructure in the southwest, dominated by gated communities; and vast areas of peripheral neighborhoods in the north, east and southeast with medium to high density and medium to low income and infrastructure, housing several social projects and a few irregular occupations (Figure 1a). This reveals an evident urban socio-spatial segregation, result of innumerous unplanned developments and growth.

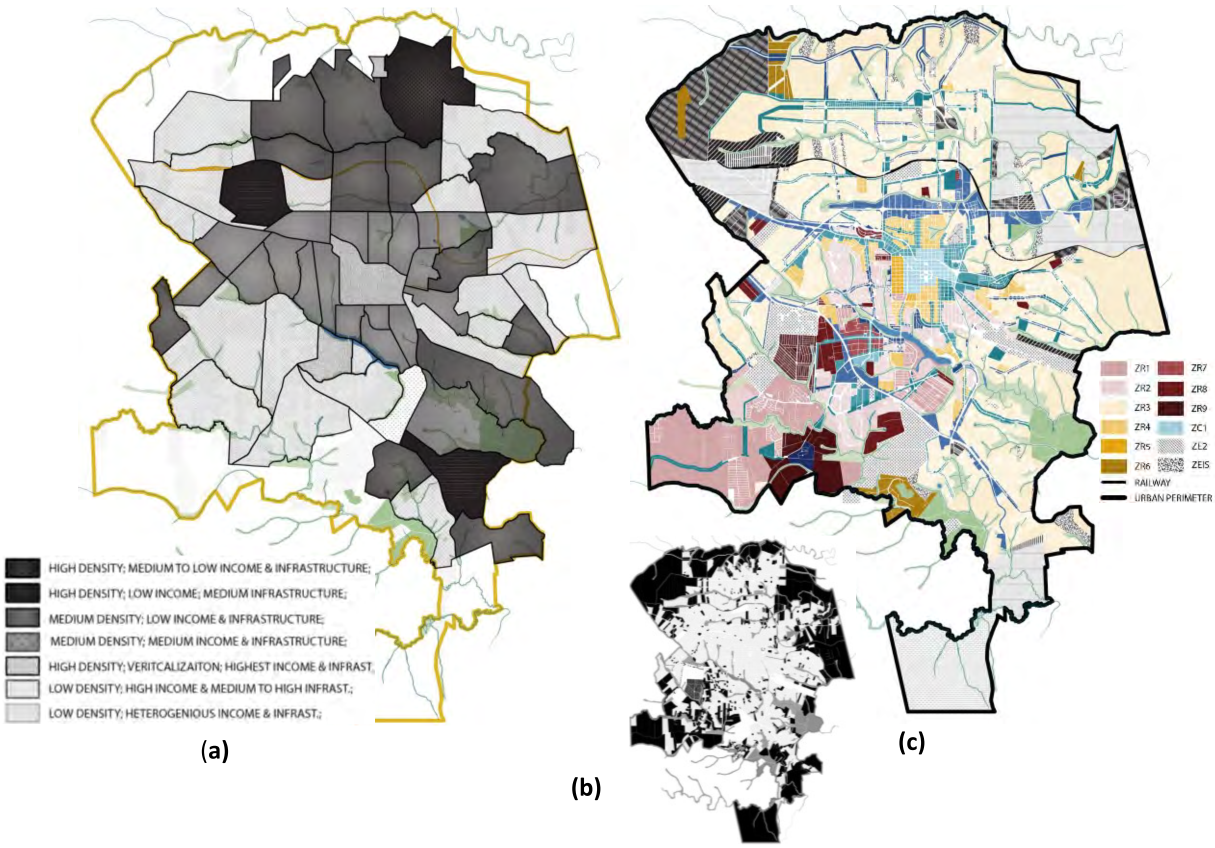

Figure 1: (a) Social, Economic and Infrastructural Synthesis Map adapted from Londrina Environmental Atlas (Barros et al., 2008); (b) Urban voids; (c) City zoning plan

Most of the services and shops are located in the central area and most industries are located in the few main roads that cross the city, consequently, so are the employment offers, the desired routs, the public transportation's passenger demand and the traffic jams in peak hours. This fact causes a considerable daily displacement due to the distance between jobs and residences. Additionally, the city has a comparatively low mobility rate and a high number of individual vehicles per person (0.65, according with CMTU, 2013). Furthermore, the few existing terminals are concentrated in the central, northern and southern regions, leaving the west and east uncovered, which result in loaded, less comfortable lines and larger displacements.

Londrina's energy consumption profile is basically composed by an *annual electricity consumption* of 1,356,129 MWh (in 2013), being roughly one third of it (429,974 MWh) demanded by the residential sector (COPEL, 2013); and by the *diesel consumed by public transportation*, which accumulated 27,002,508.03Km traveled in 2013 (CMTU, 2013). Considering an average consumption coefficient of 0.33 l/Km (Oliveira, 2004), therefore the annual diesel consumption by the urban buses would sum up to 8,917,444.14 liters.

Method

A literature review addressed concepts such as the urbanization process of Brazilian cities; the ecosystem approach; eco-cities; urban metabolism; smart and green mobility; public mass transportation systems; and energy issues within urban planning. Next, an empirical research process aimed at diagnosing the current state of affairs regarding existing mobility systems, energy consumption and the new zoning plan proposed for Londrina. Surveys and interviews were carried out with official governmental municipal departments, such as: the City Hall of Londrina, IPPUL (Institute of Research and Urban Planning of Londrina) and CMTU (Transit and Urbanization Municipal Company).

Computation of the current and future residential energy consumptions, as well as of their renewable energy generation potential, was accomplished through a mixed 'top-down' and 'bottom-up' approach, combined with an 'indirect quantitative relational methodology of data constitution'. The starting point was to create a typology table (Figure 2) based on the categorization of the 12 main residential building typologies (existing and future) extracted from the City Zoning Plan (Figura 1c).

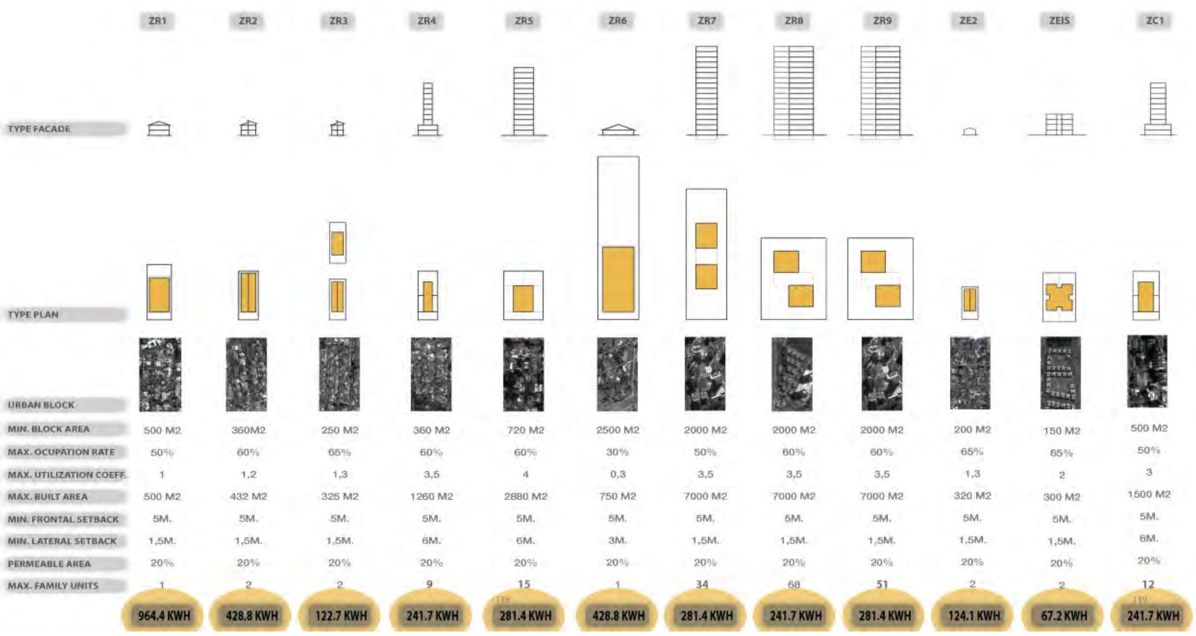

Figure 2: Typology Table with Energy Consumption by family Type

Since the currently enforced zoning legislation (Figure 1c) forecasts zone types for the complete (future) urban limits, an urban void map (Figure 1b) was created using Google Earth to distinguish areas already bearing the future zone type from those yet to be occupied. Both maps were combined over a GIS platform. The area occupied by each zone - and corresponding percentage relatively to the total urban area – allowed to finally infer the total number of families these areas could support. 'In loco' analysis of a number of chosen typologies coupled with information collected from the Parana Electricity Company (COPEL) directed categorization per social class, quality and quantity of electrical appliances and then divided into seven energy consumption ranges (Table 1).

Table 1. Energy Consumption Ranges

TODAY	Total Annual Consumption (MWh)	Total Number of Families per Consumption Range	Average Consumption per Family per Year (MWh)	Average Consumption per Family per Month (KWh)
Consumption Range 1 (0 - 100 KWh)	37428	46432	0.81	67.17
Consumption Range 2 (101 - 150 KWh)	62997	42326	1.49	124.03
Consumption Range 3 (151 - 215 KWh)	94898	44692	2.12	176.95
Consumption Range 4 (216 - 280 KWh)	77977	26,880	2.90	241.74
Consumption Range 5 (281 - 340 KWh)	45748	13547	3.38	281.42
Consumption Range 6 (341 - 580 KWh)	65295	12,689	5.15	428.82
Consumption Range 7 (> 581 KWh)	45631	3,943	11.57	964.39
Total	429974	190509	2.26	188.08

Estimation of average energy consumption of each type followed a top-down approach. From the number of household consumers, the 2013 annual energy consumption (MWh) and the percentage and number of families of each urban zone, we defined consumption ranges and estimated the average monthly consumption/family in each zone. Once we estimated the future number of families for each typology, we projected the corresponding energy consumption, considering full occupation of its urban perimeter.

Roof surface for each zone typology was calculated. The renewable energy generation potential assumed (1) that 300 Wp PV panels would be installed on 10% of the residential buildings' roofs; and (2) a global tilted irradiation value of 5,30 KWh/m^2 (Pereira, 2006) and manufacturer's data. Average energy generation capacity (KWh/month/panel) was multiplied by the maximum number of panels that each typology could hold and summed to estimate the city overall generation potential. Finally, included the massive local renewable energy production (MassREP), composed by the proposed solar farm and linear PV arrays along the two main highways that cross the city.

Results and Discussion

Our calculations showed that, when the whole urban perimeter of Londrina is occupied by its existing and future zoning types (always considering the most densified situation), the city would have about 688,286 family units, whose residences will consume around 1,743,926 MWh/yr.

Installation of PV arrays for distributed energy generation in 10%, in average, of the residential roof surface would produce 1.75 times the overall residential consumption. If PV generation along the *two main highways* that cross the city is added to that of a *power plant* suggested for the northwest future industrial zoning void (Figure 3a), Londrina would be able to also supply a new renewable electricity mobility system. This system could be composed by different public transportation vehicles types (e.g. regional train, light rail, tram) and be combined to walkable streets, slow mobility network and bike highways, ICTs and other solutions, connected by fifteen intermodal terminals fairly distributed throughout the city (Figure 3b).

Figure 3: Proposed (a) energy and (b) smart mobility masterplans for Londrina

Conclusion

Londrina holds a huge potential for solar PV generation and many additional eco strategies due to the combination of economic prosperity, strict enforcement of construction regulations and favorable solar radiation potential. Energy and smart mobility masterplans were developed to express the main guidelines for distributed solar generation throughout the city, allied to an intermodal electricity-efficient public transportation system.

Socio-economic and political aspects are in the very foundation of transitioning towards eco-city models, and become more challenging in developing countries contexts. Financial and structural difficulties for installing PV systems, particularly in low income areas; safety concerns that currently hamper public transportation use and car sharing; and prioritizing green policies such as tax incentives for acquiring PV systems coupled with construction regulations to make it mandatory are some of the issues that need to be addressed for this change to happen.

[3] Southampton City Council, Southampton, UK

Abstract: In parallel to major demographic change occurring in societies today, austerity measures in the UK have had a considerable impact on local authority budget including social care for the elderly. This work reports on novel research, which aims to harness the value and the power of sharing economy based on digital platforms augmented by surveys to support elderly people in the UK. The Elderly Support To Inspired Ageing (ESTIA) digital platform aims to help the elderly people achieve independent, comfortable living at their home for longer. The three tools of the project are: (1) A contact/scheduling board where all carers and clinicians can share information; (2) A sensing platform that collects data from the house and the supported person's activity; and (3) An on-demand service through which home care services and training can be commissioned. The ESTIA platform will provide a dynamic, shared-economy (Uber-like) market place for domiciliary care services. In essence, this project aims to provide more efficient care services with less administration cost. Finally, platforms such as ESTIA optimised for individual care, may demonstrate a structured transition from state supported to community supported care. This paper reports on initial analysis and the set-up of the ESTIA digital platform.

Keywords: Elderly support, Sharing economy, Digital platform, Domiciliary care, Independent ageing

Introduction

The EU and the UK are facing a major demographic predicament. The decline in birth rate, changes towards more healthy living (e.g. quit smoking), better working environments and modern medicine have all contributed to an increase in life expectancy (Population Estimates Team, 2016). The inevitable ageing of the current population stirs the discussion about the impact ageing has on different layers of the established social structure and systems.

Older people - persons 60 years or older - have invested a lot of money in their properties and they own a large share of the housing market, accounting for about 50% of the UK projected household growth to 2030 in the UK (Andrews, 2008). It is not a surprise therefore that almost all of them would prefer to stay and age at home instead of moving to care facilities (Barlow & Venables, 2004; Andrews, 2008). For this to happen it is necessary to adapt the current housing stock to the changing needs of their occupants and to also create sustainable communities that will support their well-being (Andrews, 2008). New social housing is typically required to conform to strict "lifetime home standards" but the housing industry is rather unwilling to voluntarily take on changes to their “business as usual” design and construction practice (Barlow & Venables, 2004).

In the period, 2013-2014, local councils in the UK spent £8.8 billion for the care of people aged 65 and over. 4 million people in this age band have care needs but only 850,000 qualify for formal state support. 1.5 million rely on informal carers to support them (BBC News, 2015). In 2011, 40% of the English population aged between 50 and 64 years old was providing between 1 and 19 hours per week of unpaid care (Figure 1). More importantly, the self-health of unpaid carers was found to deteriorate with the total hours of unpaid care they provided (Census Analysis, 2013). Carer stress is one of the main reasons that older people are moved to formal care institutions (Barlow & Venables, 2004). Informal and privately funded care is often misinterpreted by governments as cost free (Lipszyc et al., 2012). It is to be expected however that these 19 hours per week of unpaid care will eventually shift to formal care. This shift, in a region such as Greater London would cost an additional £16,000 a year for each person eligible for fully funded at home, support. In the case of residential care, the same cost would be even higher reaching up to £39,000 a year (UK Care Guide, 2016). It is likely that an increasing number of the informal carers will require health services from the NHS before the age of the 65 and/or they will end up with increased care needs at some point after this age.

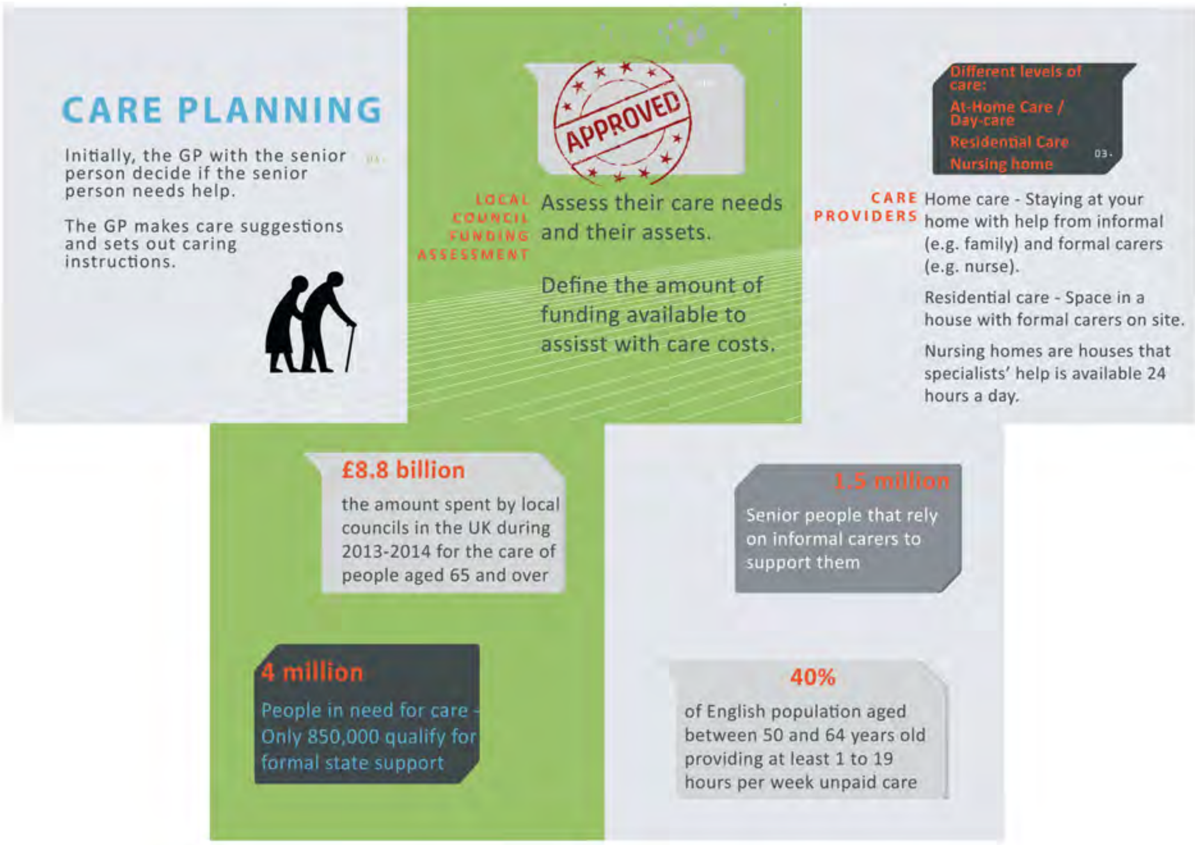

Figure 1. Stages of care planning, cost and market potential in the UK. Data references in text.

In April 2020, a £72,000 cap will be introduced on the lifetime private expenditure for care. In addition, anyone with private assets below £118,500 will be entitled to some sort of care subsidy or funded care from local authorities (AgeUK, 2017). This new policy will give more people access to different levels of formal care (NHS UK, 2015) putting more pressure on local authorities' social care budgets. This budget is further strained by increases in the fees asked by home care providers. Home care providers usually employ staff on an hourly basis and pay them the minimum wage (Jarrett, 2017). The introduction of the 'national living wage' led to a £0.80 per hour wage increase (from £6.70 in 2015 to £7.50 in 2017 (UK Government Digital Service 2017)) for 40% of the home care employees (Jarrett, 2017). In addition, the profit margins of the care providers are also affected by a nationwide shortage of nurses. To cover their nursing demands, care providers are currently hiring agency staff at much higher pay rates (Jarrett, 2017). The increasing cost of care services, the shift of more people from informal to formal care and the support for the elderly currently in private funded care (they usually pay higher prices than the fees negotiated by councils) will challenge the viability of home care providers. Part of the increases in cost will need to be passed down to the customers; in this case, local councils with budgets already under great strain.

The research questions may be formulated as follows: Can a digital platform based on a sharing economy paradigm extricate elderly care support from rigid, high cost care plans? More importantly, can it promote independent, comfortable living for longer?

This paper argues that the development of a digital care platform can tap the social capital (e.g. neighbours, family) and enable informal carers to integrate their resources to achieve enhanced patient centric care. When it comes to formal care and traditional health providers, digital technology should not be seen as a competitor. It can be a useful tool for physicians and home care providers that will enable cost effective residential care and flexible care plans customised to the real time needs of their "clients".

The Elderly Support To Inspired Ageing (ESTIA) digital platform aims to support and promote independent living for the elderly by integrating three critical features in an easy to manage dynamic care platform:

(1) A contact/scheduling board where all carers and clinicians can share information, keep notes, raise concerns and create reports about the wellbeing of the supported person;
(2) A sensing platform that collects data from the house and person's activity and creates profiles of daily routine, alerts and proposals to the person of interest and its carers;
(3) An on-demand service through which the person and family can seek telehealth services, get advice through physicians or commission home care support services and training.

Approach

Tele-health platforms were the first to set an example of an "Uber" like, health related sharing economy application with real time on-demand services (Miller et al., 2016). The benefits for practitioners are flexible working hours and an increase to their income while people in residential care will pay competitive market prices for personalised advice from the comfort of their homes (Miller et al., 2016). The challenge however is to traditional care providers that need to be proactive and adapt their operations to the emerging telecare market rules (Miller et al., 2016). The first steps toward this direction have been made with care agencies piloting a system that enables them to talk through the television set with the person in need. The new emerging market, if it is properly regulated has the potential to lower the cost of formal ad-hoc residential support services, helps informal carers to cope with their tasks and allows elderly people to live at their houses for longer.

Health care platforms learn from the sharing economy paradigm of telehealth but their main advantage is the full integration and inclusion of the social capital. The success of such platforms would be to re-enable vulnerable and socially isolated people in need for care to be part of larger community schemes that have access to advice and care services. From a market perspective, care digital platforms such as ESTIA can provide the means to involve charities and volunteers and take some work away from the carers (Figure 2). Informal carers could benefit from having fewer responsibilities, less stress and access to guides and training. Formal carers will have the opportunity to restructure their services and optimise the use of their capacity and income. Most importantly, it is a significant opportunity for social care policies to include non-directly paid services and integrate them with the paid packages to achieve cost-effective, high value care plans.

Several approaches and efforts have been made to facilitate active ageing, promote social inclusion and provide tools for assisted living for the elderly (Grguric et al., 2010). Most of the efforts focus on the development of smart house applications and on house technological-fixes and sensor packages (Rocha et al., 2013) that send alerts, reminders and prompts and track activity profiles (Libal et al., 2009). ESTIA taps on the experience of existing Ambient Assisted Living (AAL) technologies and moves towards transforming the environment of Electronically enhanced Assistive Technology (EAT) (Barlow & Venables, 2004) into a sociable, interactive and dynamic people-centric care platform. The ESTIA digital platform works across different clusters and levels of information from individuals to hospitals and ambulance services. It is designed to introduce innovative ways for the coordination and commissioning of different levels of care services according to the person-specific expectations and requirements for elderly care provision.

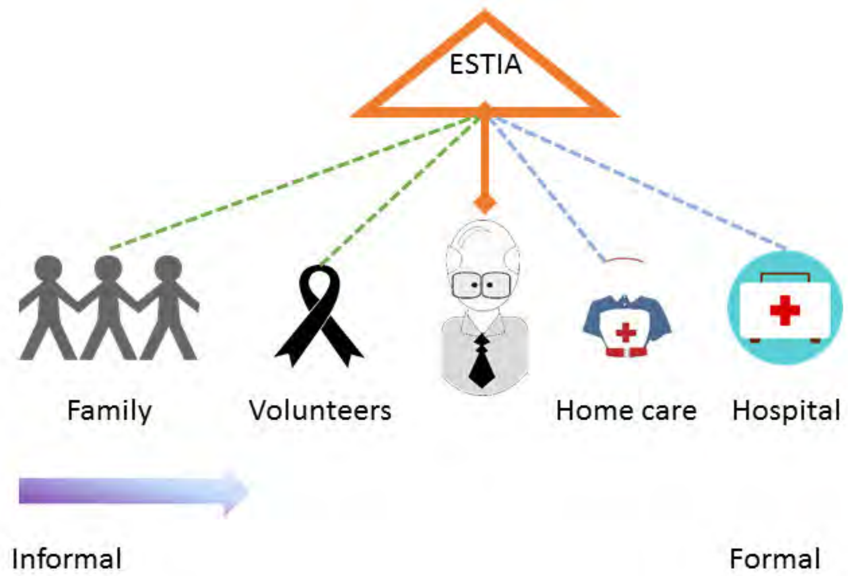

Figure 2. ESTIA platform and its interaction with typical informal and formal stakeholders in the care of elderly people.

The platform has adopted a clustered client based architecture with context aware communications (De Backere et al., 2017) between Communications, Domain and Database cloud servers. It enables multiple implementations of the same simple web interface. The primary objective is to have virtualisations of secure cloud clients running through smart television sets and allow the elderly to browse and access the available services with the remote control of the TV (Figure 3). It has been found however that such web based approaches may result in low response times and loss of services due to incompatible updates and software (Grguric et al., 2010). In order to ensure the flexibility of the system and uninterrupted and wide spread applicability of the services, a second client (e.g. a tablet PC) that runs a local API, standalone application will be installed in the house and it will periodically connect with the scheme's cloud servers. Ideally, there will be a small charging station that has an integrated Ethernet and GPRS connection and the tablet PC that will rest on this hub most of the time. The local API client will be open to communicate with a series of well-tested sensor interfaces and extend its capabilities as a traditional assisted living system such as proactive sensing hubs.

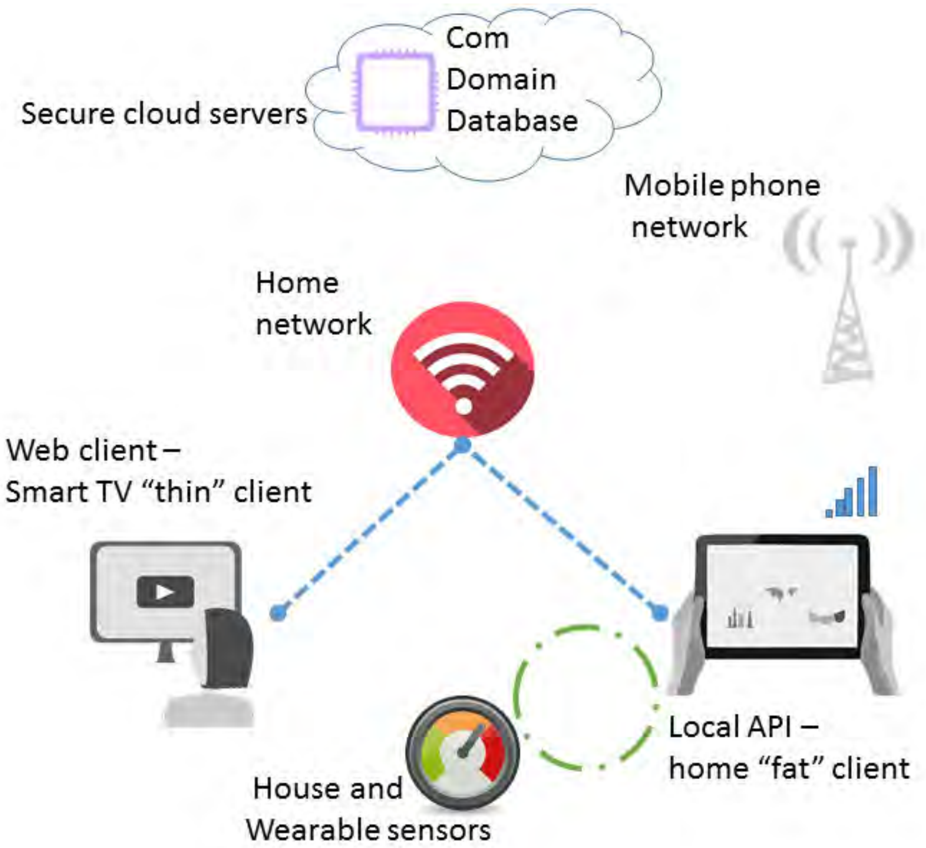

Figure 3. Network layout of the different components and connections of the ESTIA digital platform.

The interface will include three distinct layers of services (Figure 4):

1) The communications board; this board will have menus to access the health records; the care instructions and the care plan details. It will also provide a news feed, reminders about scheduled activities, send message updates to the listed carers and work as a generic chat/forum to share information. The board will support video and sound communications. It could also support video and sound monitoring services (with a function similar to baby monitors) if the people involved consent.

2) The sensing hub; the role of this hub is to allow the integration of passive sensing solutions to trigger "soft" alerts and active sensing to track emergencies and alerts triggered by the person in care. The hub could run from the local client and connect to the GPRS – mobile network. The sensing hub will track the profile of daily and weekly activities and the environmental conditions (e.g. indoor air temperature, carbon dioxide concentrations, etc.) in the house. Any deviations from the representative trend profile of the person in care will

flag events / warnings to the carers listed in this service. The warnings will also appear as prompts in the communications board.

3) The guidance and advice portal; the portal is a third layer of information and training services that can work as an electronic library. The library will contain instructions and advice for the carer and the person in care. Videos and interactive material can be part of the library. The training material can include exercise advice for the elderly and games that can help them stay mentally healthy (e.g. puzzles). This layer will integrate any on request tele-health and tele-care services and it will ideally be activated and navigated with voice commands.

Figure 4. Different layers of services accessible through the ESTIA interface

Challenges and conclusions

One of the biggest challenges of this project is the data governance and the framework for data sharing. This issue needs to be regulated and clearly define the rights and obligations of all digital services and their users. Confidentiality and data protection are paramount. It should be clearly defined who needs the information and what information the different stakeholders require. Different teams and individuals produce and demand different types and levels of data. For example, activity logging may be of value for the family. Medication administration and nurse services are of interest to formal care providers. It is important that all the people involved in the care of a person understand and consent to the use of any available services. The consent of the individuals and confidentiality have a growing importance as people envision and try to move towards smart cities with monitoring of all daily activities, identification of personal behaviours, "detection" of possible emergencies and targeted personal communications (Paolini et al., 2016).

One of the biggest dangers is the replacement of invaluable personal forms of care with impersonal technology features (Barlow & Venables, 2004). The social context and background of a senior person are critical to support his engagement with the community and avoidance of isolation.

Now there are several layers and structure of help from different teams with separate budgets. Community agents and charity organisations can train, coordinate and guide local networks of volunteers. A single point is required to gather information and coordinate the services to tailor help in a "personal sphere" context. This single point -“navigator” will be able to link statutory organisational bodies with private and social organisations.

We believe the biggest barrier to achieve the maximum engagement in the care of the elderly and high-level integration of the social capital resources is personal liability. Informal carers are stressed and they do not want to take responsibility of making decisions for the people they care for. The acuteness of a medical condition is very difficult to be assessed and the “safest response” is to look for health services from hospitals or formal care providers. Digital platforms could have an active role by providing a fast, reliable, first contact point for advice. Emergency tele-health service in combination with sensed data and the help of informal carers could reduce the events when senior people use the ambulance, emergency room or 15 minute response care services. In addition, training material (e.g. videos) and instructions could reduce the carers’ stress and make it easier to maintain a healthy, organised daily routine for the senior person. Exercise instructions, diet advice and mental health games can all promote the senior people’s wellbeing.

Lastly, the medical background and information about the person who needs care at the moment are segmented pieces of information and data spread across a variety of archives and secured with different levels of access. Formal carers would greatly benefit from having the health records, medication plans, care instructions and the care plan in a single source online repository.

The successful implementation of the ESTIA platform and its longevity are entwined with the macro economy of the emerging market ecosystem. Primary focus is given to addressing problems that can deliver the maximum value. We identify that fast, enhanced communications and information sharing is crucial for the successful development of any care-share application. All the stakeholders have an important role to play but it is the informal carers – the social capital that mainly needs to be engaged, trained and supported in order to be actively involved in peer-to-peer care support. We recognise the monetary but mostly the intangible value of this resource. Lifetime homes, ageing neighbourhoods and cities, social structures and market, all have direct and collateral benefits from caring for the elderly to keeping them healthy, active and happy at home for longer.

Resilience and older people: My home my life

Catherine Bridge

Enabling Built Environment Program, Faculty o the Built Environment, University of Sydney, Sydney, Australia, C.Bridge@unsw.edu.au

Abstract: There are both challenges and opportunities for urban design and housing regarding the uptake of 'livable home' design. in the context of both an ageing population and a greater likelihood of major weather events and global warming impacts. There are a number of key factors that shape the way that 'livable home' design in Australia has been developed and adopted. For instance, there has been insufficient policy attention paid to home modification or housing retrofit so as to ensure that older peoples housing is capable of substituting for community care and facilitating the option to age in place. This was a very real issue in 2011 when devastating floods over 75 per cent of Queensland caused great distress for many older people and meant many were unable to remain at home. Additionally, the lack of integration of climate and accessibility features potentially creates a triple jeopardy situation with older people being more vulnerable due to both climate events, physiological factors and increased likelihood of living in poorly adapted homes. This highlights the social and environmental injustice involved, in reflecting on the structural and attitudinal impediments that need to be addressed for housing form to increase the resilience of older people.

Keywords: Population ageing, home modification, climate change, urban density, lifetime design.

Introduction

Bringing together climate change and universal design principles for ageing has become a critical challenge for older people, urban planners, housing and infrastructure policy makers alike. The policy mantra is that everyone would be better off in smaller homes; and in denser suburbs, so as to facilitate less natural resource usage and greater public or active transport options. But what does this mean for 'ageing in place' and life quality for our burgeoning older population in Australia. Indeed, there appear to be a multitude of overlapping or contradictory standards that are applied to housing both at the design stage and in terms of its adaptive reuse. Part of the problem appears to be that, older people, designers and local government have quite different ideas about what is necessary, usable and comfortable. This is despite the fact that the core concept of sustainability concerns not just conservation of natural resources, but social good and economic viability over time. The problem in balancing and integrating sustainability dimensions stems from the primary focus resting on ecological concern with social sustainability being less valorised. Further, housing developers and builders are not responding to the needs of older people as they say there is little or no demand (Nishita, Liebig, Pynoos, Perelman, and Spegal, 2007). This view is reinforced by research that found that new buildings were no more likely to be accessible than those built in the mid-1990s (Chan and Gould Ellen, 2017).

A critical driver is density. For example, Australia is one of the most urbanised Nations in the world and Sydney the city with the largest population has recently established minimum lot sizes as low as $125m^2$ for housing in its middle ring to curb suburban sprawl (Department of Planning New South Wales, 2016). Smaller lot sizes and minimum frontages for dwelling houses and dual occupancy dwellings are required to improve sustainability and affordability but there is an inherent tension as those on aged pensions are the very people most likely to benefit from better integrated design and planning solutions. The failure of differing design and policy agendas to coalesce is of critical import given the large and increasing proportion of Australians who are over the age of 65 years and who are ageing within the increasingly fragile and unpredictable Australian climate ecosystem. For instance, summers are now longer and hotter and with a resultant increase in extreme weather events including flooding, extreme heat and longer fire seasons.

Importantly, a detailed report on the impacts of climate change on coastal areas of Australia, found that up to 247,600 houses were at risk from flooding from a sea-level rise of 1.1 metres (Department of Climate Change, 2009). Older people represent a significant group not only in numbers but in terms of housing ownership and financial resources available to choose their housing composition. As they experience the typical effects of ageing they can become more vulnerable to difficulty or injury due a climate change combined with reduced income and a lack of supportive features in housing design placing them in triple jeopardy. Unfortunately, the needs and desires of older people are underrepresented in the climate change debate and to a large part in sustainable home design initiatives. This indicates a potential for more integrated practices and presents possibilities for innovative products to be developed through careful understanding of the issues involved.

In January 2011, Brisbane, Australia, experienced its first significant flooding in almost four decades, this brought the tensions between 'livable housing' and climate extremes to a head. The findings from Brisbane are similar to those found in other post-disaster research and many Brisbane residents stated their surprise at the impact of the flood and even that such a flood could occur (Box, Bird, Haynes & King, 2016). Additionally, the limitations that underlying social vulnerabilities such as age and low income can present to flood preparedness left many at risk and the resultant criticism of government preparedness and actions left no appetite for widespread implementation of initiatives such as 'livable housing' in new build as it was at odds with the traditional Queensland flood and climate solution a raised home (Kennedy, Hockings, & Kai, 2005).

Changing demographics

Population ageing is expected to have implications for aged care and health, size of the working age population and housing (ABS 2016). In line with trends in other developed countries Australia's population is ageing due to increasing life expectancy and continuing low fertility (AIHW 2014b). Life expectancy by 2013 was 80 years for men and 84 years for females, indeed the proportion of Australians aged 65 and has risen from 12.0% to 15.3% between 1996 and 2016 (ABS 2014a). Critically the proportion of people aged 85 and older is projected to continue reaching 5% of the population in 2061 (ABS 2013). Growing older often comes with limitations and the financial sustainability of care services is already causing concern. Thus moving healthcare and social-care services into the homes of older people is attractive, especially given modern technologies such as home automation that can be used to create an innovative living environment. Universally designed housing within Australia is increasingly being badged as 'livable housing' a concept that blends universal design intent with that of other initiatives such as sustainability. Livable housing design is intended for everyone and should be a part of all new build, but unfortunately it is still predominantly viewed as being primarily for those people with a disability.

A smart home on the other hand is a home capable of responding to an older people's needs and activities by compensating for and/or adapted to reduced cognitive and physical ability. In the case of both the 'livable' and the 'smart' home, there is an inherent tension in regard to ecological sustainability. This is because of the increased expense and the need to retrofit. For example, removing internal walls to increase circulation spaces for wheeled mobility can decrease energy efficiency ratings, while automatic environmental controls and air conditioning also increase energy load and costs. The 'livable housing' design guideline's concern housing with as few as six simple design features, such as reinforced bathroom walls, a flat entry to the house and wide corridors and doorways. The fact that livable housing and ecological sustainability are poorly aligned, results in a failure to address the home as a vessel to provide protection to a more vulnerable occupant at times of extreme climate events such as prolonged hot spells or in floods. Indeed, there is little or no consensus regarding the definition of universal design features or of those critical to ecological sustainability and thus the use of concept such as provision of level access a core component of 'livable housing' are continuing to prove problematic as the rest of this paper sets out to demonstrate. The current lack of integration of these concepts, runs the risk of bringing less accessibility, safety and comfort to older people.

Home modification: consumer survey results

Level access is an sustainability adaptation concern given the fact that traditional housing design has included stairs at entries to prevent flooding, but stairs can be a barrier for those with limited mobility, assistive device users and a tripping hazard and fall risk for older people more generally. An exploratory research survey regarding home modification uptake and outcomes was mailed to all consumers who received a home modification organised by Hunter New England Area Health Service in New South Wales, Australia upon discharge from hospital in 2011. Consequently, three hundred and ninety-five health clients were invited to complete the home modification survey. Eighty-three surveys responded to the question concerning the type of modification, this response rate representing a response rate of twenty-one per cent, a good response for a postal questionnaire targeted at an older population. The donut graphs (below), shows that many of the respondents required an access modification to help them in moving through the home (70%). This is unsurprising given the voluntary nature of 'livable housing' design in Australia.

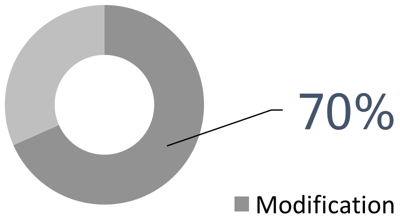

Figure 1. Access modifications required as a proportion of all home modification interventions undertaken in the Hunter New England Area Health Service upon discharge from hospital in 2011.

The relationship between caregiving and design is important as design may not only support care-giving but substitute for it. For instance, found that design directly substituted for care (Carnemolla, 2015). Informal care was the most sensitive, with reductions in care forty-one per cent for moving about the house but the greatest reduction was in formal care. These results clearly indicate that care is sensitive to design with a forty-seven per cent overall reduction in the care provided. This is a significant finding given previous research, compared costs for people care in various housing settings with those receiving residential care identified that where care can be provided in the home, the cost saving to government is significant (Bridge, Phibbs, Kendig, Mathews & Cooper, 2008).

Flooding events and level access

The most frequently cited argument against level access is around flooding and drainage strategies. These issues are traditionally overcome in 'livable housing' with the addition of cover. The entry design most often promoted for new build of single dwellings provides a level access via the carport as illustrated in Figure 2.

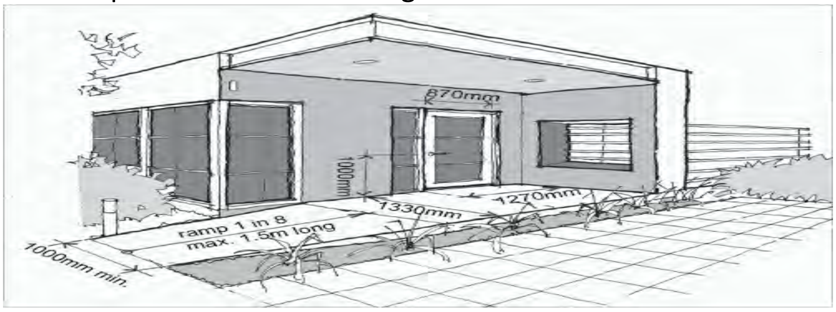

Figure 2. Level entry design (Palmer& Ward, 2013).

Nevertheless, qualitative responses to this same survey revealed that water ingress and slipping may not be ameliorated or even fully addressed after home modification interventions as this survey respondent says "*We found that the covering over our car port (ramp is under car port) is inadequate and we now have rain coming up on ramp - very dangerous at times*" (respondent 33, home modification follow-up survey)[1]. Where the risk of water pooling increases as in tropical climates where large volumes of water fall in a very short period or where only limited side and roof coverage is provided, then consideration of lipless or level drainage channels with accessible grate are also necessary. Figure 3, illustrates one such relatively low technology solution known to effectively reduce the risk of flooding and water pooling.

Figure 3. Drainage grate to prevent water ingress

Another advantage of the design afforded by an integrated roof and sidewall extension is reduction in the risk of flooding and/or water pooling on very wet or windy days. This is because water falling on the roof will be carried off by a standard guttering system and

[1] The sampling frame for this exploratory research survey was all consumers who received a home modification organised by Hunter New England Area Health Service in New South Wales, Australia upon discharge from hospital in 2011.

because the overhang is sufficient to prevent wind driven rain penetration. However, the more traditional covered porch solution where sides are unprotected as in Figure 4 is less effective in reducing the risk of wind driven rain penetration.

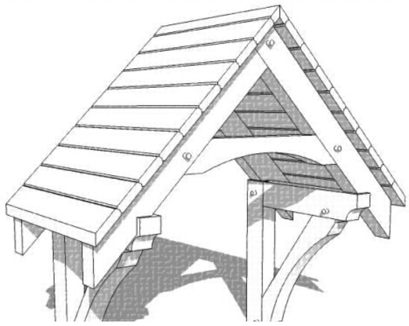

Figure 4. Door canopy to prevent water ingress

An underutilised but more climate friendly design in areas prone to flooding or likely to have significant water ingress is an earth berm and bridge entry design. Such a design consists of a retaining wall and walkway graded at a slope of 1:20 or less up to the entry level. A level bridge, in combination with a deck or porch, spans the distance between the retaining wall and the building entrance. The "moat" thus created enables rainwater drainage away from the building and can be filled with gravel or suitable plant specimens (i.e., plants for wet areas).

Importantly, landscape modification can successfully overcome inaccessibility, reduce modification cost and make for a less stigmatising and ecologically sustainable outcome in some if not all residential homes (Carnemolla & Bridge, 2012). The feasibility of modifying the residential landscape is determined not only by the type of homes, in particular the building's relationship to the streetscape, but also site features including available land area, existing site, vegetation, topography, hydrology and soil conditions. For instance, research conducted by Chan and Gould Ellen (2017) found that homes within buildings with more than fifty units were found to be more accessible than those with less units, reflecting the lack of an elevator in smaller multifamily units.

Despite these specific limitations, where landscape modification is considered a technically feasible access solution, it brings with it a number of benefits in addition to providing immediate access between garden path and front door. Landscape modification can be designed to sensitively blend with existing architecture, thereby maintaining perceived house values and reducing stigma. an underutilised alternative access solution to ramps and lifts. Findings such as these require additional research examining the comparative costs of accessible landscape modifications, consumer responses to landscape modifications and examination of current industry practices and skill base in order to better integrate sustainability objectives within a community care and 'livable housing' policy framework.

Housing and income

Older homeowners want to age in place and this decision making relates to their housing location, which reflects connection to community and proximity to services (AIHW 2013; Boldy et al. 2011). But most people are best placed financially around retirement age to make changes to their housing configuration of their own choosing that will support them in the longer (AIHW 2013; Quine & Carter 2006; Productivity Commission 2011). However, there is a strong tendency to avoid planning for retirement and ageing (Olsberg & Winters 2005). Unfortunately, the majority of ageing Australians do not have sufficient superannuation to support themselves through retirement and will be dependent to varying degrees on the age pension (Malcolm 2012). However, the ease with which a property can be structurally modified to support either sustainability or ageing in place, can be traumatic especially where issues of title and finances are problematic (Ward et al. 2012). Additionally, there is evidence that Government supported home modification schemes are underutilized by eligible people (Bridge & Gopalan 2005). This may be due to complexities in the application and eligibility process or individuals not perceiving a need in their environment, choosing instead to adapt their behaviour to cope (Bridge, Phibbs, Gohar, & Chaudhary, 2007).

While financial resources could be made available through refinancing the family home there is a reluctance to do this unless absolutely necessary (Bridge, Adams, Phibbs, Mathews, & Kendig, 2011). Additionally, the design and construction industries are insufficiently prepared to deliver 'livable housing' let alone accessible housing that is ecologically and economically sustainable for a vulnerable lower income population. The value of age-friendliness in renovation or new building projects is not always obvious to the public or to older homeowners, and clear guidelines for the execution and financing of such projects are scarce, so targeted action and greater investment is much needed (Ruddock, 2016). The absence of a National regulatory framework has resulted in a plethora of approaches; creating confusion and undermining universally designed housing as a viable option for older people wishing to age in the same locale (Bridge, 2012). Lastly arguments and lack of government incentives, have traditionally been perceived as a barrier to more widespread implementation of both sustainable and universally designed housing features.

Conclusion

Failure to understand the interaction of inclusive design elements with those that better protect vulnerable older people in the face of extreme weather events such as fire and flooding are a missed opportunity. These are significant contributors to the quality of a dwelling and the risk is that living environments will be degraded without them. If more inclusive design practices such as routine consideration of level entries are viewed from a more integrated sustainability and climate change perspective, their value becomes obvious not just in regulatory compliance for public buildings but also in injury prevention and in improving ease-of-use and efficiency for all building users. Human comfort is a concept that embraces and potentially unites diverse aspects of both 'livable housing 'which is trying to achieve accessibility, usability, adaptability etc. and ecological sustainability which is trying to achieve better thermal comfort, humidity and air quality etc. Design for sustainability is a complex issue involving several complex processes and integrating 'livable housing' design as a methodological extension for sustainability is challenging, but failure to address it in a timely manner will compromise not just quality of life for older people but add significant additional economic and ecological burdens to societies with ageing populations.

Acknowledgments

The survey research results reported was supported by a grant from the NSW Department of Family and Community Service, Ageing, Disability and Home Care.

Designing Housing Decision-support Tools for Resilient Older People

Bev James[1] and Kay Saville-Smith[2]

[1] Director, Public Policy & Research Ltd, Wellington, New Zealand, bevjames@xtra.co.nz
[2] Director, Centre for Research, Evaluation and Social Assessment (CRESA), Wellington, New Zealand, kay@cresa.co.nz

Abstract: Critical to maintaining independence as we age, is the ability to make informed decisions about challenging questions concerning housing choices, dwelling performance and resilience, and residential movement. Over the last nine years the New Zealand-based GoodHomes research teams have worked with older people and community organisations to investigate issues around housing, ageing in place and resilient communities. Out of that participatory research has evolved evidence-based decision-support tools to help older people maintain independence. All tools have been co-designed and tested in homes and in charrettes with older people and with service and housing providers supporting older people. These tools help older people identify priorities and information requirements, as well as assess the diverse factors involved in home-related decisions. These decisions encompass not only the dwelling, but also the neighbourhood and physical environment, health and support needs, social connections, resource needs and constraints, and cultural preferences. The tools are: The Good Home Tool for home repairs and maintenance assessment and solutions; the Resilient Homes Tool and Selecting a Site for Your Home Tool enabling better dwelling and location choices; and My Home, My Choices, a decision-support toolkit for making housing decisions.

Keywords: Ageing-in-place, Housing, Resilience, Decision-making, Participatory design

Introduction

Homes that are warm, in good repair, can weather adverse events and enable residents to move around safely are crucial to ageing well and enabling older residents to stay living independently in their communities. It is well known that older people are potentially more at risk or vulnerable to harm from adverse natural events, such as storms, floods, bushfires, land erosion, coastal surges and earthquakes. In normal times, too, the home can pose a threat to safety and wellbeing. Poor home repairs and maintenance can exacerbate older people's vulnerabilities to harm in good times and bad (James and Saville Smith, 2010). Equally, poor choices by older people around the siting and design of the dwelling they live in can expose them to both risk and expense. Housing that fails to meet older people's needs reduces their personal resilience and independence, but there has been little attention given to building age-friendly, resilient housing in New Zealand or enabling older people to make good housing choices.

This paper reports on three research programmes focused on how older people's resilience can be supported and increased, despite inadequacies in the New Zealand housing stock and a pattern of under-performing and under-maintained housing often sited in vulnerable environments. Those research programmes incorporated three important elements. First, they were committed to understanding the experiences and perceptions of older people within their built environments. This involved using a range of research methods: surveys, interviews and focus groups. Second, the research was multi-disciplinary bringing social scientists, natural hazard scientists and building technologists together. Finally, the programmes were solutions focused and oriented to enabling older people. This was accomplished through explicit, purposeful and participatory design activities involving older people themselves directed to developing evidence-based decision-support tools. During the latter phase of tool and solutions design in each programme, older people reviewed research findings and technical knowledge.

Four of the tools generated by those research programmes are reviewed here. They are: Good Homes, Resilient Homes, Selecting A Site for Your Home, and My Home, My Choices. All tools are found on the website www.goodhomes.co.nz. The paper firstly examines 'older people' and 'vulnerability'. It then describes the research activities, the key findings underpinning each tool, and describes the tools. Then the participatory design approach is discussed. The last section comments on the usefulness and impact of the tools in supporting older people's resilience and choices.

Older people, vulnerability and ageing well

While the population aged 65 and older is diverse in health and disability status, living arrangements, financial and housing circumstances, older people can be particularly vulnerable to poor housing conditions. Cold and damp housing can cause or exacerbate illness such as respiratory problems, asthma, hypertension, and coronary and cerebral thrombosis. In New Zealand people aged 65 and over are especially vulnerable to excess winter mortality, which is higher than the European mean. Levels of heating, thermal performance and indoor air pollution have all been suggested as contributing factors to this excess mortality (Davie et al, 2007). Dwellings in poor repair, or lacking in accessibility features can cause injury, which in turn leads to premature entry into aged residential care (Bridge et al, 2006). There is also considerable evidence that older people are more vulnerable to natural hazard risks and this can be exacerbated if their housing is not robust enough to protect them. Older people are more likely to die, be injured, or to worsen chronic conditions during or after adverse natural events (Greenberg, 2014; Carswell, 2010; AARP Public Policy Institute, 2010). In part these vulnerabilities are due to age-related frailty, declining health or physical impairments. Also, other factors, such as financial constraints, reliance on others for transport, the extent of connections to local supports and services, and living alone affect vulnerability.

The Research Programmes

The three research programmes at the centre of this paper are: *Ageing in Place,* which addressed the role of poor house performance and the burden of repairs and maintenance; Community *Resilience and Good Ageing,* which investigated how older people can be supported to help themselves and their communities to manage and recover from adverse natural events; and, *Finding the Best Fit,* which focused on the realities, costs, risks and benefits of downsizing for older householders.

Ageing in Place

This multi-method research included surveys, interviews, dwelling condition surveying and a systematic review of repairs and maintenance programmes targeted to older people. The research found that owner-occupiers aged 65 and over were even more likely than other age groups to under-invest in repairs and maintenance (Saville-Smith et al, 2008). Even if they could pay, older people often delayed repairs and maintenance. They often over-estimated the costs of repairs and were frequently overwhelmed by managing the process of procuring repairs and maintenance. They also under-estimated the impacts of failing to undertake repairs and maintenance. The components of older people's houses that were in worse condition than the dwellings of younger householders were: inferior ceiling insulation and poorer condition of windows, roof claddings and steps/ramps. These components are implicated in cold, damp and unsafe dwellings. Using these findings, the *Good Homes Tool* was developed to support older people to be more confident and prepared to assess their home repairs and maintenance needs and to identify a range of solutions, so that they can maintain their homes as safe and comfortable places.

Three versions of the tool emerged; a 'self-help' tool for the older householder, a version for providers of social and support services, to check that their older client's home is safe and in good repair, and a technical version for owners or managers of housing for older people. The householder and service provider tool is in the form of a booklet consisting of a checklist and solutions covering key components inside and outside the dwelling, e.g.: outdoor and indoor lighting; pathways; ramps and steps; decks/balconies; roofs; walls; windows; piles; doors and handles; floors and coverings; ceilings; plugs; hot water; heating. Components are assessed room-by-room, e.g.: kitchen, bathroom, bedroom.

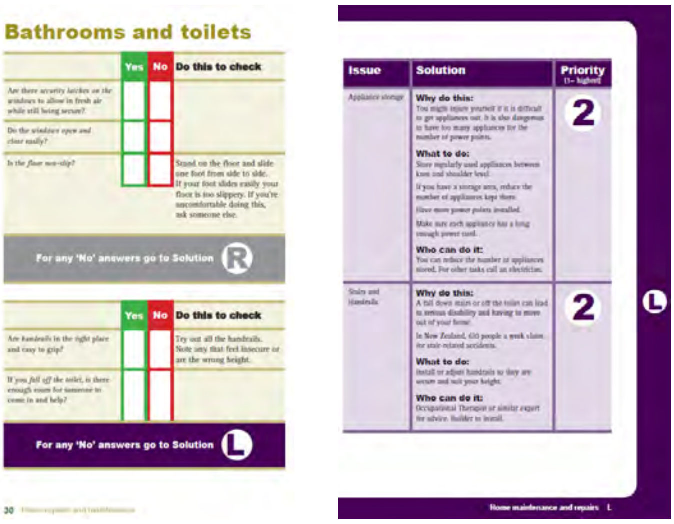

Figure 1. Good Homes Tool: Part of Bathrooms and Toilets Checklist

The tool helps to identify repairs and maintenance that need to be done, safety issues, the best person to do the work (e.g. if a registered tradesperson is needed), and the priority of the job. The tool is written in plain language, with step-by-step instructions. Diagrams and pictures illustrate technical terms where required. The tool encourages older householders to feel confident about assessing their home by explaining that the room-by-room assessment can be done as time permits, and with the help of a friend. The technical version for housing providers and property managers provides a robust set of home diagnostics. This tool comprises a hardcopy and an accompanying electronic spreadsheet, which prioritises the work, providing solutions to remedy each issue as well as indicative costing information.

Community Resilience and Good Ageing

This multi-method programme included a national survey of 631 people aged 65 and older who had experienced an adverse natural event, hazard risk mapping, analysis of councils' emergency management documents, in-depth interviews with 28 older people affected by floods, and focus groups with over 110 older people living in natural hazard-affected communities. The research found that an adverse natural event can be a 'tipping point' for an older person to remain living independently. Damage to house or property, or having to move residence, are likely to increase older people's needs for support, decrease their sense of wellbeing, and potentially make them worse off financially (Saville-Smith and Fraser, 2013). Research participants, while reporting stress and disruption, also reported that they learned new skills and gained confidence in managing challenging situations, and made contributions to the preparation for, and recovery after an adverse natural event. However, they were critical of a lack of information about emergency preparation tailored to older people's needs, inadequate inclusion of older people in emergency planning, and poor information to enable older people to make informed choices about residential sites, resilient building design and materials (James and Saville-Smith, 2014).

Two tools were developed. The *Resilient Homes Tool* provides guidance on identifying dwelling design, materials and systems features that pose a risk in storms or floods. The guide covers roofs, skylights, verandahs and decks, windows, walls and wall cladding, exterior doors, wiring and electrical systems, as well as resilient lighting, heating, cooking and water features. The *Selecting A Site for Your Home Tool* enables a quick assessment of a residential site and provides information about where to find out about site vulnerability to natural hazards. The guide covers wind, flooding, landslides and changing land use.

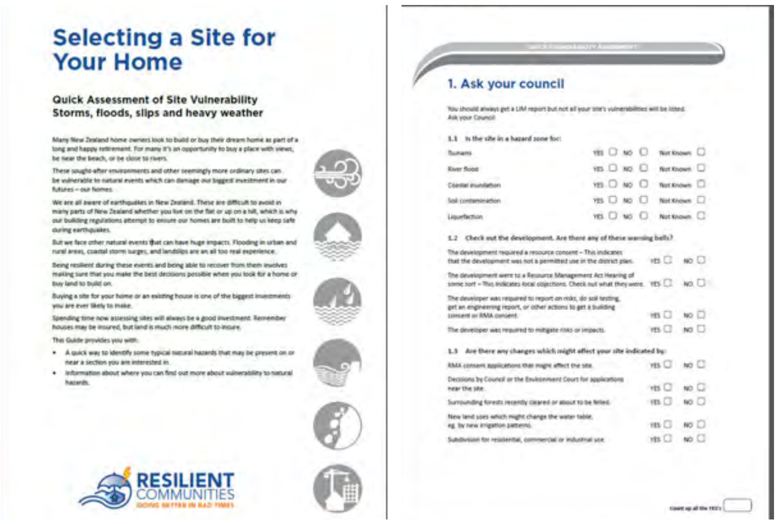

Figure 2. Pages from Selecting a Site for Your Home Tool.

Finding the Best Fit

This multi-method programme included regional housing market analyses, a national survey of 571 people aged 65 and older, a survey of 617 retirement village residents, and interviews and focus groups with over 220 older people and over 70 providers of services for older people. The programme found that for most who downsize, the amount of equity release is modest, if any. This is because the supply of small, affordable dwellings is constrained, and most people move within the same housing market. Furthermore, often realised equity is used to deal with debt or everyday living costs (Saville-Smith et al, 2016).

Clear housing preferences were expressed for a home that maintains independence, is warm and easy to maintain, easy to move around in, affordable to buy or rent, has cheap running costs, is compact but has sufficient space for activities and visitors, is close to services and has an outlook (Saville-Smith and James, 2016; James, 2016a). Participants identified a wide range of information needs about dwelling price, location, tenure and amenities. They also sought information about services supporting people in their homes.

My Home, My Choices was developed in response to concerns about poor information provision. It is designed to help older people identify what is important about their home environment, and decide whether to stay in their current home, to make changes to their home, or move. The tool is available in both hard-copy and as an interactive website. The tool describes over 60 options, including advantages and disadvantages of each option. Individuals can work through the tool at their own pace and compare different options. The 'answer' is not provided, instead suggestions are made about where individuals can find information on the issues and options they wish to investigate.

Figure 4. My Home, My Choices Tool: Hard Copy and Web Version

These three research programmes found a strong desire among older people to be actively involved and to maintain control over decisions around their housing and home-related needs. The programmes also found that older people as consumers did not have sufficient, relevant and impartial information, either to know the range of options available to them or to make informed choices (James et al, 2016; James, 2016b). The programmes identified similar challenges for older people. First, home-related decisions are complex. It is not only about whether to stay or to move. It is also about household products, dwelling materials, natural hazard risks. location and support services. Financial implications need to be understood, as does whether a decision taken now has long term implications that could limit future options. Second, information sources tend to be fragmented, sometimes confusing and not easy to access. There is poor coordination across different agencies and sectors. Third, it is difficult to access impartial information in some areas such as housing products, services and materials, and information is seldom available in age- and disability-friendly formats.

Participatory design approach

The three programmes used a participatory design approach, which is not only about actively involving older people in the research process underpinning tool development, but also about meaningful engagement in design and testing of tools (Spinuzzi, 2005; Bridge et al, 2016; Dewsbury et al, 2006; Haak et al, 2015).

All tools were designed, developed and tested over several stages, outlined below. Participants assisted in various ways at all stages. Older people hold important knowledge through their life, community and work experiences. Their knowledge, lived experiences, needs and aspirations were valued and used. Participants' pre-occupations, concerns and priorities were of primary importance in guiding the tool development, so that the tool is relevant to the user. Participants were pivotal to identifying both the problems and the solutions that resulted in the tools. There were mechanisms for participation that allowed people to iterate the tools, through workshops/charrettes, as well as local and national advisory groups. Furthermore, participants tested the tools in their homes or applied them to real-life situations and provided feedback, which was essential in improving the relevance and user-friendliness of the tools.

A range of participants were involved so that different experiences were drawn on to test the tool's usefulness and applicability in various situations. Across the three programmes, people aged in their late 50s to early 90s participated, including people with disabilities; those living alone, as a couple, or with younger family members; and living in large urban areas, provincial towns and rural locations. The majority were owner occupiers, although some in licence-to-occupy units and rentals also participated.

Brainstorming and prototype development

Testing research findings and brainstorming ideas for tools was done in feedback sessions with those who participated in the data gathering stages. The researchers had not formed a fixed idea about tools that might be developed. Instead participants were instrumental in generating ideas. The idea for a 'checklist' to help older people manage their home repairs and maintenance came from participants. Older people in the *Finding the Best Fit* research wanted a tool that would help them find information to support their decision-making about their home-related needs. The idea for the two resilience tools came from participants' interest in information that would have helped them to better identify natural hazard risks. Many believed they had exercised due diligence when they bought their property, yet there were risks they were unaware of (Saville-Smith, 2014).

Older people were less involved in prototype development. After the brainstorming, the researchers undertook tool development, based on the research findings and participant feedback. Prototype development of the *Good Homes Tool* was led by a building scientist, supported by other research team members. The two resilience tools were developed through workshops with experts in natural hazards, engineering and building technology. There was considerable debate among those experts about how to compile guides for the lay person, and the several prototypes produced reflected those tensions. A hard-copy prototype of *My Home, My Choices* was developed by the research team through a review of five overseas tools to help older people assess their housing situation and explore housing options, and a workshop with an expert advisor.

Testing the tools

The *Good Homes Tool* went through several iterations. An early version of the householder tool was trialled by three older people in their homes. An early version for experienced housing assessors was workshopped by staff of a community housing provider. Feedback from both trials was used to improve the tool designs for trialling at three charrettes, where participants worked through the tools in detail. Charrettes included older people, health and social service providers, older people's advocacy groups, repairs and maintenance providers, housing providers, councils, Māori organisations, church groups, and service clubs. After revising the tool in response to charrette feedback, over 150 older people used the revised tool by themselves at home, or were helped by a service provider to use the tool. Eight housing providers tested the tool on their properties. Written feedback from those testers was used to further refine the tool.

The challenge for the two resilience tools was to ensure that the technical guides were easily understood and relevant to the needs of older householders. Three workshops with older people were used to test the prototypes developed by the technical experts. Their responses resulted in considerable rewriting of both tools, to make them simpler to understand, with more pictures, and an easier check list to record potential hazards.

The hard-copy version of *My Home, My Choices* was tested with over 100 people in eight workshops. Older people, health and social service providers, older people's advocacy organisations, housing providers, Māori organisations and policy agencies were among those involved in the testing. Over 80 suggestions were received from the tests. Over two-thirds of those suggestions were used to refine the tool. The interactive web tool was then developed from the hard-copy and tested by six older people. Based on their feedback, further adjustments were made to the tool.

Positive impacts

All the tools were designed for, and with the active involvement of, older people living independently in their communities. Their contributions to tool development show how research can facilitate older people's participation in building their own and their community's resilience. The research shows, too, how solutions-focused investigation can address the persistent information asymmetry found within the design and delivery of the built environment.

The tools are having a positive impact in helping older people to make informed choices, to plan and to take action. Evidence for the impact of the *Good Homes Tool,* which has been available since 2012, is most apparent. This tool has been picked up by over 50 organisations. Implementation pathways through local organisations and media as well as national bodies, resulted in six national stakeholders placing the tool on their websites or referring to it in publications, dissemination of the tool to older residents by three councils, use of the tool by three neighbourhood regeneration / repairs and maintenance programmes, endorsement of the tool as a way of reducing falls at home, and one district health board (DHB) integrating the tool into its public health programme. The DHB evaluated the tool and found a high level of interest among volunteers supporting older residents to use the tool, as well as older householders themselves. Overwhelming feedback was that the tool was useful. Householders identified jobs to do, both immediate and planned. Some used the tool to talk with tradespeople about needed repairs, and tradespeople reported that the tool improved clarity of communication with clients. Jobs completed included painting of steps, cleaning out gutters and water pipes, making a fire/emergency plan, checking and installation of smoke detectors, repairing ranch sliders, installing hand rails and pruning overgrown trees. Service providers noted their clients' confidence in managing their home had improved through using the tool.

Interest in the two *Resilience* tools, launched in September 2014, has been mainly from organisations concerned with improving dwelling quality, such as the Building Research Association of New Zealand, and community housing providers. The *My Home, My Choices* tool was launched in August 2016. To date, around 150 tools have been taken-up, mainly by organisations, including councils, local Age Concern offices, Māori health providers, Iwi organisations, Community Advice Bureaux, an organisation supporting older people to age-in-place, local budget advice services, legal services and financial advisors. Training sessions in using the tool have been provided by the researchers.

Sustainability and Resilient Homes for the Older People in Natural Adverse Events

Roman Jaques[1] and Kay Saville-Smith[2]

[1] **BRANZ, Building Research Association of New Zealand,** Roman.Jaques@branz.co.nz
[2] **CRESA, Centre for Research Evaluation and Social Assessment,** kay@cresa.co.nz

Abstract: Resilience has become the 'new black' among policy advisers, practitioners, researchers and academics. From individuals to cities, organisations to buildings, and industries to ecosystems, questions are being asked about their ability to function, adapt and perform well in the context of changing circumstances and when subjected to significant shocks. This is concerned with the intersection between resilience and sustainability and its implications for older people. It explores the current knowledge base around the performance of the most fundamental of components in the built environment – dwellings. Specifically, dwellings designed to be sustainable in the context of adverse natural events. It shows that, while there is an overlap between some elements that are sustainable and those that are resilient, frequently the characteristics of what have become accepted as sustainable are assumed to deliver resilience as well. Key ways in which the sustainability and resilience of dwellings can be enhanced to protect older residents during adverse natural events, reduce the damage likely to be caused by adverse events, and assist the recovery process subsequent to adverse events, are examined.

Keywords: Ageing, resilience, sustainability, adverse events

Introduction

Resilience and sustainability are the 'new black' for policy advisers, practitioners, researchers and academics (Wingfield *et al*., 2006). Broadly the concept of resilience refers to the ability to adapt to, perform during, and regenerate from adverse events. By contrast, sustainability refers to the ability to function in the long term by minimising the importation of resources from 'outside' the system and the impacts of the system on the environments in which it operates. From individuals (Bencze and Tilotta, 2010) to cities (Peng *et al*., 2012), from organisations (Building Seismic Safety Council, 2006) to buildings (Mejia, 2008), from industries (Bowker *et al*., 2007) to ecosystems, questions are being asked about their ability to function, adapt and perform well in the context of changing circumstances and, in particular, when subjected to significant shocks. Across the natural, physical and social sciences as well as in public policy, questions are being asked about the factors that protect in the context of adverse events and the pathways and mechanisms that encourage successful adaptation. Those questions become especially important in countries experiencing ageing populations, especially where older people, as they are in New Zealand tend to be housed in areas vulnerable to adverse natural events such as river and coastal flooding, coastal surges and storms (James and Saville-Smith, 2014a; Bell and Wadha, 2014).

For older people concepts of resilience and sustainability can appear abstract. Yet all older people have an interest in homes that protect them during adverse events and also provide them with comfort and amenities that minimise resource use and costs. In the New Zealand housing market there is increasing emphasis on the sustainability of houses and the use of accreditation tools such as HomeStar and LifeMark. The question that arises is whether sustainable homes are also resilient homes. This paper explores the current knowledge base around the performance of dwellings designed to be sustainable in the context of natural adverse events. It shows that, while there is an overlap between some elements of sustainable homes and resilient homes, the assumption that sustainable homes are resilient homes is largely untested. Moreover a careful review of features promoted respectively as sustainable or resilient shows misalignment between the two. This paper identifies ways in which sustainability may be brought together to protect older residents during natural adverse events, reduce the damage likely to be caused by adverse events, and optimise the recovery of the dwelling itself and the daily lives of older people subsequent to those events.

Sustainable Homes and Resilience

Despite the widespread branding of homes as sustainable, 'green', environmental, 'earth-friendly', 'off-grid', or 'eco' there are no formalised definitions. In New Zealand, the Beacon Consortium coined the term NOW Home® (Beacon Pathway Incorporated, n.d.) for dwellings that could be delivered into the mid-price housing market while simultaneously minimising water and energy consumption, and materials and operating waste, and maximising thermal performance. The New Zealand Green Building Council is accrediting homes under its HomeStar system (www.homestar.org.nz). Other countries show a similar plethora of nomenclature around sustainable dwellings. None of these labels are entirely synonymous, typically they refer to dwellings designed, built, operated, maintained or re-purposed to significantly enhance the dwelling's lifetime environmental performance.

Performance in those domains is purposefully prioritised compared to existing homes and new homes delivered through the mainstream building industry and increasingly, accreditation tools are used to signal a sustainable home. Those tools are very diverse in their mechanics, ranging from the very simple checklists specific to a particular region through to the very complex and comprehensive international green building frameworks. An example of the former is 'Build it Green' (www.builditgreen.org), designed for use in Oakland, California. This contrasts with the International Initiative for a Sustainable Built Environment (IISBE) SB Method and SBTool (www.iisbe.org) which has a global approach. One of the very earliest formal green building assessment methods, BREEAM (www.breeam.org), was introduced by the UK's Building Research Establishment (BRE) in 1990. Through its approach, BREEAM became a template for many other international tools that followed, such as LEED from USA and Canada (www.usgbc.org/LEED), DGNB from Germany (www.dgnb.de/en/), CASBEE from Japan (www.ibec.or.jp), and HomeStar from New Zealand (www.homestar.org.nz). The domestic assessment version of the scheme – BRE Global EcoHomes – has now morphed into the Code for Sustainable Homes (BRE, 2013) which is mandatory for all newly built homes in England and Wales. More recently, comprehensive, consortium-driven sustainable building guidelines and standards have emerged, such as the 2012 International Green Construction Code (ICC, 2013).

Despite their diversity, sustainable homes accreditation tools all tend to focus on similar domains, themes or parameters: energy, water and material efficiency; thermal performance; protecting occupant health; reducing waste; and environmental protection. The idea that sustainable homes will be resilient homes able to endure and recover from adverse natural events largely resides in the emphasis in sustainable homes on reducing the import and export of resources. Broadly, accreditations for sustainable dwellings are framed around two considerations. The first is the quantity and sustainability of the resources used to build and maintain the dwelling. The second consideration is the systems associated with living in and operating the dwelling. In most sustainability accreditation systems, where the expected consumption and import of water and energy is minimised, dwellings are likely to score higher on the sustainability measures included in the accreditation. This is also the case where the export of waste and external impacts are minimised. Dwellings with off-grid energy generation, independent sewerage, on-site stormwater management or on-site water collection are typically placed very highly by sustainable homes accreditation systems. Figure 1 shows how HomeStar provides credits along what might be broadly described as a sustainability continuum.

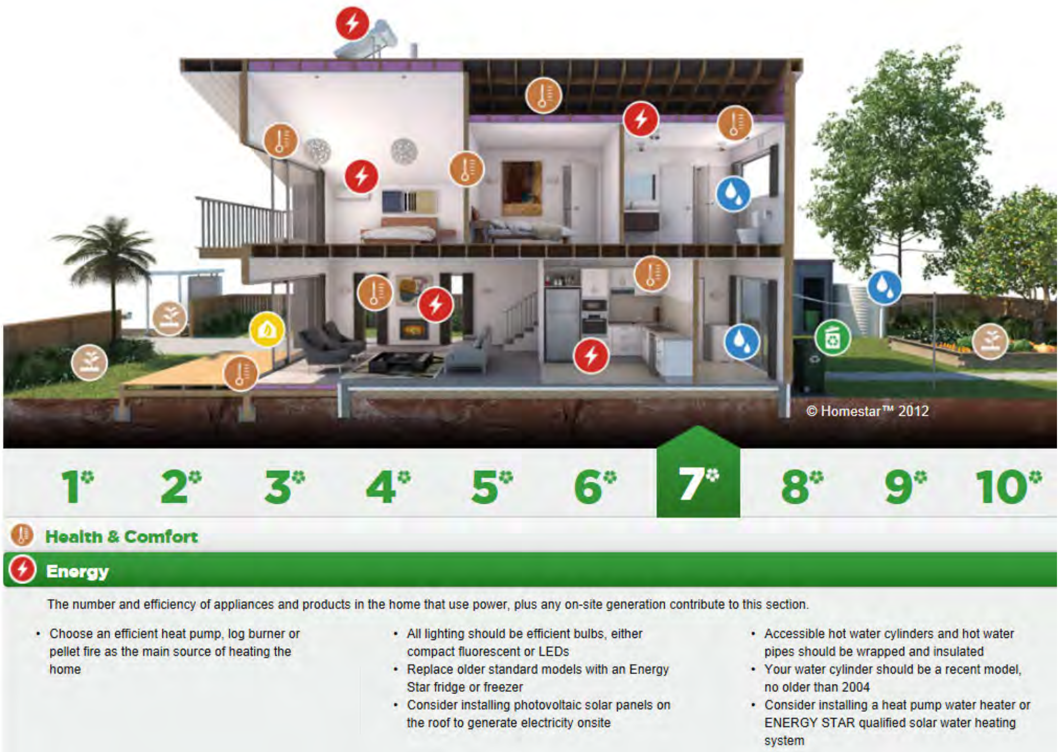

Figure 1: HIGH END SUSTAINABLE BUILDING (Source: www.homestar.org.nz)

This 'hardware of independence', which tends to detach dwellings from centralised and attenuated infrastructure, often leads to assumptions that sustainable homes are resilient homes. However, few of the sustainable homes accreditation tools actually incorporate a robust concept of resilience into their assessment procedures. Those that do tend to do so only cursorily or have a very narrow focus. Take for instance, the UK's Code for Sustainable Homes (CSH), which makes accreditation dependent on attention being given to flood risk. The accreditation tool provides for detailed drainage system design calculations, flood risk and consequential impact assessments to be undertaken. Resilience to other adverse natural events are given only cursory consideration.

Accreditation tools for sustainable homes do make opportunistic connections with resilience. Take for instance, the Portland Cement Association and the Institute for Business and Home Safety (IBHS) which have a sustainable building standard entitled the *High Performance Building Requirements for Sustainability (*Szoke *et al*, 2010). Written in mandatory language amending and appending to the *International Building Code* (ICC, 2009), there are claims that the sustainability features enhance disaster resistance and set more stringent durability requirements. Indeed, the then director of the IBHS claimed that "using these requirements will give forward-thinking communities not just more efficient buildings, but more sustainable communities that have the ability to resist and recover from disasters when they occur" (PRWeb, 2010).

In reality, considerable uncertainty exists around the extent to which the sustainability 'hardware' results in delivered resilience benefits. Three issues arise. First, the durability and functionality of independent micro-systems such as energy generating technologies under adverse conditions. Second, there is the issue of whether they deliver to the critical needs of individuals during and after adverse events. Third, there are questions as to whether sustainability hardware and materials encompass the critical elements of sustainable dwellings that are likely to protect, reduce damage and facilitate recovery among residents. Much of the reporting about the performance of sustainability technologies under adverse conditions has focussed on the durability of products. There appears to be little reporting of their functionality during and after adverse events, or the costs of recovery.

Some data is available; for example, William Young has presented case studies around photovoltaic panels which show high rates of survival. Of 20 systems located in the Florida hurricane pathways, only three were subject to damage and the damage was minor (Young & Haggard, 2006). Similarly, Hurricane Charley, which struck Charlotte County, Florida, particularly fiercely in 2004, left 25 of 32 monitored solar systems both undamaged and operational (Young, 2005). There is, however, a notable silence in the literature about how functional these technologies were during and in the recovery period subsequent to an adverse event in terms of the actual delivery of light, comfort provision and cooking. Examples of practices promoted in green buildings which clearly pose resilience challenges include: vegetated roofs providing additional dead-loads, and the use of roof-mounted photovoltaic systems creating extra wind loading.

There are, of course, some features of dwellings that achieve credits in homes rating schemes that clearly provide positive value to both the resilience of the dwelling and its household. For example, minimising impervious surfaces allows for better stormwater management, while appropriate berm arrangements (Gromala, 2010) allow for level entries necessary for people with compromised mobility to evacuate their dwellings if necessary. Similarly, the installation of properly secured and substantially-sized water tanks has positive impacts for both the sustainability and the resilience of a dwelling and its household. In relation to sustainability, water tanks reduce the waste of potable water when non-potable water is required for gardening and cleaning. In relation to resilience, water tanks provide stores of water useful for firefighting. They also provide a source of relatively uncontaminated water which can be made potable when water supply infrastructure fails in floods or earthquakes. Nevertheless, the failure to map resilience actions for adaptation to hazards is illustrative of the considerable gap between the approach to and measurement or rating of sustainable dwellings and the issue of actually delivering resilience.

Resilience through Fortified Dwellings

Resilience primacy is at the core of the FORTIFIED (www.disastersafety.org/fortified/) building movement, launched in 2010 in the United States by the Insurance Institute for Business and Home Safety (IBHS). It is a voluntary, national programme aimed at incorporating building techniques into both residential and commercial construction to provide a higher level of protection against a variety of natural hazards. FORTIFIED Home^{TM} operates as a third-party verification programme designed to help homeowners strengthen it via a tailored evaluation, inspection, and retrofitting process, to meet the challenges of specific, regional natural hazards. Hazards addressed are: flood, interior fire and water damage, earthquake, wildfire, high wind, and severe winter weather. In 2008, the initiative was battle tested by Hurricane Ike on the Bolivar Peninsula in Texas. Thirteen FORTIFIED homes survived a direct hit from the hurricane, including a 20-foot storm surge (Peng *et al*., 2012). These 13 homes were the only structures left standing in the immediate vicinity. It was postulated that their specific design feature to withstand extreme wind and water damage was the reason for this durability.

Unfortunately, details on the FORTIFIED homes' post-event functionality, in terms of service provision and comfort, are sparse. They are only described as having been 'left standing'. This leaves unanswered a myriad of questions. Were the buildings habitable? Did they provide a reasonable level of utility for their occupants? What was the resulting condition of the affected building materials? Did recovery require subsequent replacement of materials? What was the degree of remediation required? Was there a strong relationship between the designation level of fortification and the resulting utility post event? Little details around these questions appear to be provided in the public domain. Similarly, there is little detail regarding the costs of builds, the operating affordability or the amenity and comfort provided by these buildings to occupants prior to an adverse event.

It has been claimed that the most sustainable buildings will also be the most resilient buildings – "a truly disaster resistant building would be a zero energy home or building that ensures a high level of energy security…" (Young & Haggard, 2006, p. 4). The reality is, however, that the vast majority of 'zero energy homes' are no more likely to be able to provide added energy-based utility post event than more traditionally powered homes. Apart from the issues of the durability of the hardware previously noted, the vast majority of renewable systems in the 'western hemisphere' are grid-intertied photovoltaics. These are very unlikely to have any energy storage capability, mainly due to the very high purchase costs of batteries. In addition, for safety reasons, in an event, once the network goes down so too does the in-house electrical system, whether the solar system is generating or not. As Terry Brennan has stated in regard to the claimed resilience of buildings off-grid and on-grid: "If they lose only electricity, few buildings in the U.S. can provide as much comfort as my backpacking tent" (Wilson, 2011).

Sustainability, Resilience and Older People

In a sense, the debates about what precise sustainability solutions generate increased resilience do not matter for most of the older people of today. Much of the design and build work directed to sustainability or resilience is embedded in the new home market. Older people typically live in dwellings built prior to either the preoccupation with sustainability or the preoccupation with resilience. Most older people are confronted with dwellings deficient in both sustainability and resilience. At the same time, however, many older people are very vulnerable to adverse natural events. They are more likely to be frail or disabled that other members of the community and so the consequences for them of dwellings that fail to protect them during an adverse event or are difficult to restore subsequently can be profound. In addition, older people, in New Zealand at least, are often located in areas vulnerable to adverse natural events such as storms and flooding. Indeed, older people often select vulnerable, and sometimes isolated, landscapes near beaches, rivers or on elevated sites with views on retirement (James and Saville-Smith, 2014a). Coastal modelling in New Zealand clearly shows that older people are over-represented among the population vulnerable to coastal inundation (Bell and Wadha, 2014). The proportions of people aged 65 years or more at risk of coastal inundation can be considerable. Eight regions in New Zealand have in excess of 15 percent of their older populations living in coastal elevation zones of less than 3 metres (Figure 2).

Figure 2: Proportion of over 65 year olds living in costal elevation zones of 0-3 meters for selected regions

The vulnerabilities of already fragile sites can be expected to increase in the context of climate change and older people can be expected to bear the burden of those changes. In 2050, it is forecast that New Zealand will have 1.35 million older people. A million of them will live in settlements at risk of severe adverse natural events (Wright *et al.*, 2011; Smart and McKerchar, 2010; Walton *et al.*, 2004). The impacts can be profound for older people. Research in New Zealand (see http://resilience.goodhomes.co.nz/) and elsewhere (Cornell, *et al.*, 2012; Whittle, 2010) show that adverse natural events become a 'tipping point' between independent and dependent living. Older people's ability to care for themselves and participate in their communities is closely associated with the familiarity and comfort of an older person's home surroundings. Once home is disrupted, even for a short period, it can mean a decrease in the ability to live independently. Older people's incomes are often constrained and easily drained by the expenses associated with temporary accommodation, repair and remediation even where insurance is adequate. Community connections become attenuated and sense of belonging and home can be distorted (James and Saville-Smith, 2014b). The private and public costs, consequently, of older people's losses, including their loss of independence, can be considerable.

Unlike younger people, older people do not have time in their life course to 'make-up' what has been lost. For older people, then, resilience has three aspects. The first is protection during an event. The second is the ability to stay well and survive the immediate post event conditions which might see them isolated from others in their own community or their communities isolated from services. The third, is restoration – the ability to repair their homes and, often, their gardens and resume a more normal life. Those imperatives require a different sort of integration between sustainability and resilience to that seen to date. If older people are to access the benefits of sustainability and resilience, they need solutions to the challenge of retrofitting their existing homes, not simply accreditation of new builds. They need to understand their current vulnerabilities and be provided ways to protect themselves including options such as: designs for affordable garden swales to reduce flooding or fire risk; ensuring safe areas within dwellings which can be kept cool or warm in extreme temperatures; cooking and lighting; and, independent water supply and options for waste disposal when reticulated or other options are not available. Older people investing in new builds or moving home need to be enabled to understand the risks around site selection as well as the resilience of the building materials, designs and amenities they may choose for their homes. Most importantly, older people as well as designers, developers and builders need to understand the relationship between the 'kit' that is presented in the market as sustainable and its resilience under adverse conditions.

Design to Thrive

Population Ageing, Housing and Resilience in Australia

Bruce Judd

City Futures Research Centre, Faculty of Built Environment, University of New South Wales, Sydney, Australia, email b.judd@unsw.edu.au

Abstract: Population ageing is an international phenomenon with major implications for economic and social policy, and for housing and urban planning. A common policy response has been to encourage ageing in place by increasing levels of support in the home, to reduce burgeoning health and aged care costs and enable older people to remain for as long as possible in their home and community. However, this begs the question: ageing in what kind of place? In the long-standing family home, relocating to a more suitable dwelling, or in an age-segregated retirement village? In Australia, there are popular conceptions about ageing and housing which deserve to be questioned: that older people underutilise their dwellings, should downsize, and prefer to live in age-segregated retirement communities. Such stereotypes however do not stand up to empirical scrutiny. This paper draws on three research projects conducted over the last decade into how older Australians utilise their homes and neighbourhoods, their moving and downsizing behaviour, and multigenerational living, to address these perceptions from the perspective of resilience. It concludes with suggestions as to how the resilience of ageing Australians might better be supported through appropriate housing, planning and economic policy and improved industry practice.

Keywords: ageing, housing, resilience, Australia

Introduction

Population ageing is one of the most important social changes in the 21st century, though occurring at varying rates in different countries. Japan leads the world in population ageing with 33.1% of its population aged 60 and over in 2015, having grown by 9.0 percentage points since 2000, and expected to increase to 40.9% by 2050. Italy, the oldest country in Europe had 28.6% of its population 60 and over in 2015, predicted to grow to a similar 40.7% by 2050. The UK (23.0%) was close to the European average of 23.9%, and Australia was a little lower with 20.4% of its population 60 years and over, predicted to reach 28.3% by 2050, (UN, 2015). This presents many challenges to governments, placing stresses on the economy due to increasing dependency ratios (i.e. population 0-14 and 65+ to those 15-64), a reducing tax base, and increasing health and aged care costs (Productivity Commission, 2015). Australia, like many other countries, has introduced policies to address this including changes to the pension eligibility age and asset tests, compulsory superannuation, and encouraging ageing in place and community care to ease pressure on the demand for residential aged care. Accordingly, there has been a progressive increase in the level of aged care services delivered to the home, including for dementia care.

However, the emphasis on ageing in place begs the question: ageing in what kind of place? Most Australian dwellings are not considered suitable for ageing in place and attempts to introduce age-friendly adaptable or universal design for new dwellings have been largely unsuccessful. Even if mandated, new dwellings only represent a very small percentage of annual total dwelling stock, so change would be incremental. It is argued that older people underutilise their dwellings, should move to smaller dwellings and release their larger homes into the market for younger families. Retirement villages are often seen as an ideal solution, yet accommodate only a small proportion of the older population. Multigenerational living is adopted by some older people for financial, cultural, or care and support reasons but is not easily accommodated within conventional housing design. This paper will examine these issues from the perspective of resilience, using evidence from three studies conducted over the last decade. It will examine how housing contributes to the resilience of older Australians, and hence to positive ageing and social sustainability.

Resilience, Ageing and Housing

Resilience is a concept used in both the physical and human sciences. Its origin is from the Latin word *resilire*, meaning 'leaping back' and was initially applied in the physical sciences to materials and objects with "the ability to recoil or spring back into shape; elasticity", but more recently to include humans, being "able to withstand or recover quickly from difficult conditions" (Stephenson & Waite, 2011:1224). In the social sciences, the term has been applied to the ability of individuals and communities to recover from, or thrive in, the face of adversity; in the environmental sciences for species (including humans) to adapt to climate change and natural and man-made disasters; and has also been applied to housing and the built environment in terms of their ability to adapt to climate change, natural and man-made disasters and social change.

The earliest studies of psychological resilience concerned how children thrive despite difficult circumstances, focussing on protective individual personality traits, but has more recently been conceptualised as a more complex process drawing on a range of resources (Fletcher & Sarkar, 2011). It has also been more widely applied across the life span including to those of older age, in view of their exposure to ageing-related risks such as death of loved ones, sickness, accidents, disability, isolation, and so on. The two necessary components of resilience are some sort of risk (or stressor) and positive adaptation (Fletcher and Sarkar, 2011). The interest in resilience of older people reflects the important shift in gerontology from disengagement theory to successful ageing as conceptualised by Rowe & Kahn (1998).

Masten and Wright (2009:215) defined resilience over the life span as "patterns or processes of positive adaptation and development in the context of significant threats to an individual's life or function." However, resilience is not just about individual attributes, but as Janssen et al (2011:146) have noted, "…scholars increasingly acknowledge that positive adaption and development (resilience) is also is also influenced by external factors like families, communities and wider contextual circumstances". While psychology stresses the importance of the social environment as a resource for resilience, the role of the physical environment has also been acknowledged (Golant, 2015), consistent with the importance placed on person-environment (P-E) fit, meaning of home and attachment to place to healthy and successful ageing within the field of environmental gerontology (Ostwald et al, 2007; Rowles & Bernard, 2013).

A recent review of the concept of resilience notes the "overlapping and interrelated scales of household, family, neighbourhood and community resilience" and the different areas of resilience in later life: psychological, mobility, financial, environmental, physical, social and cultural (Wiles et al 2013:150-152), many of which are supported or inhibited by aspects of the built environment. In a review of the concept of resilience, Windle (2011:158) identifies four “layers of resources and assets that facilitate resilience” that include aspects of the built environment: individual, family and household (housing), neighbourhood and social context (environment and transport) and social policies (housing policy).

The role of the built environment as a resource for resilience is also being recognised in ageing and housing policy. A recent report commissioned by the South Australian Government (Windsor et al, 2015:58,59) identifies a “residence better suited to needs”, “better access to transport” and “lived in a better neighbourhood” amongst resources supporting individual resilience, and state that “community resilience often centres on infrastructure or the built environment” (Windsor et al, 2015:58,66). A recent issues paper prepared by the Advisory Taskforce on Residential Transition for Ageing Queenslanders (2016:7,9), identifies both individual and home resilience as important to an “individual’s propensity to explore transition options”, where home resilience includes “…the factors impacting the individual dwelling, such as its design, accessibility, proximity to services and transport, and the age friendliness of the local community”.

The Research Projects

This paper draws on three projects undertaken within the City Futures Research Centre: **Dwelling, land and neighbourhood use by older home owners** (Judd et al, 2010), involving analysis of 2006 ABS Census data, a national survey of 1604 older (55+) home owners administered via the *50 Something* seniors’ magazine, and 70 in-depth interviews in 5 Australian states, funded by the Australian Housing and Urban Research Institute (AHURI) and the Commonwealth Department of Health and Ageing (DHA); **Downsizing amongst older Australians** (Judd et al 2014), involving 2011 ABS Census data analysis; a national survey of 2767 older people who had moved since turning 50, again administered via *50 Something* magazine, 60 In-depth interviews, and policy workshops in 3 states, also funded by AHURI; and **Living together: The rise of multigenerational living in Australia** (Liu et al, 2015), involving analysis of 1996-2011 ABS Census data, an online questionnaire with 392 respondents from 318 multigenerational families in Sydney and Brisbane, 21 solicited diaries from 15 households, and 21 in-depth interviews, funded by an Australian Research Council (ARC) Discovery Grant.

Older Households their Housing in Australia

At the most recent 2011 ABS Census, a substantial majority of Australians 65 and over (84%) were living in either 1 (28%) or 2 (56%) person households, while 71% resided in detached single family dwellings, and 83% in dwellings with 3 or more bedrooms. Only a small percentage lived in attached/row housing forms (9%) and flats/apartments (10%). Even fewer (8%) lived in non-private accommodation, mostly comprising residential aged care facilities. Three quarters of all older Australians (76%) lived in owner occupied dwellings, comprising 67% outright owners and 9% mortgagees (ABS, 2012b), though outright owners have been decreasing in recent decades. Only 5.3% percent were living in retirement villages in 2010 based on industry estimates (Productivity Commission, 2011).

This broad picture of the housing of older Australians raises some important questions regarding housing and resilience. Why do so many persist in living in larger houses on large allotments that are not considered suitable for ageing in place? Do they really underutilise their dwellings? To what extent are they downsizing or moving to more appropriate housing, and why? And what are the ageing in place options that are positive resources for resilience?

Dwelling and Neighbourhood Utilisation

In the Dwelling, land and neighbourhood use study (Judd et al, 2010), analysis of the then most recent 2006 Census data (ABS 2006) found that 83% of Australians 55 years and older lived in 1 or 2 person households, a similar 85% in detached single family dwellings, and 83% in dwellings with 3 or more bedrooms. A similar 84% lived in owner occupied dwellings (either outright or with a mortgage), though outright ownership increased with age from 57% of 55-64 year olds to around three quarters of those in the 65-74, 75-84 and 85+ cohorts. Using a modified version of the Canadian National Occupancy Standard (CNOS), officially used in Australia to measure housing utilisation, a staggering 84% of dwellings of Australians aged 55 and over were deemed underutilised, i.e. with one or more 'surplus' bedrooms. However, 91% of our survey respondents regarded their larger dwellings as satisfactory for their household's needs. This brings into question the mismatch theory, which has also been challenged by previous scholars (Batten, 1999; Wulff et al, 2004).

One important reason for satisfaction with the size of the dwelling was the presence of 'temporary residents' in 25% of respondents' households (i.e. who stayed for at least 20 nights per annum but less than 6 months), not included in the Census household count. Temporary residents included: older children (37%), other relatives (20%), grandchildren (18%), elderly parents (5%) and tenants/boarders (1%). An important reason for maintaining a larger dwelling was the widespread use of 'spare' bedrooms either as guest rooms to accommodate visiting family and friends (27%), or for other non-sleeping purposes such as office/study (34%), hobby (12%), storage (9%), utility (4%) and reading rooms (2%). Some respondents claimed they needed more space post-retirement as they spent more time in the home, and some couples needed their own personal space. Maintaining social ties with family and friends, ongoing personal office or study activities and hobbies are considered important for positive ageing, and are recognised as resources supporting resilience.

A second focus on neighbourhood utilisation revealed the multitude of activities in which older people were engaged. Common daily-to-weekly activities included shopping (95%), recreation (79%), religious services (68%), visiting family and friends (64%), volunteering (58%) and community/social clubs (56%), while the most common monthly-to-yearly activities included medical appointments (92%), theatre and cultural activities (90%) and dining out (58%). Conversely, it was found that poor quality neighbourhood design (paths/crossings, street furniture and facilities, public open space, and transport infrastructure) could present real barriers to community participation. Such activities are also important resources for resilience, and suggest that a supportive built environment extends beyond the dwelling to the neighbourhood and the wider urban infrastructure.

Moving and Downsizing

Given the propensity of older people to remain in their larger homes, we embarked on a following project to investigate the moving and downsizing attitudes and behaviour of older Australians (Judd et al, 2014). Analysis of 2011 Census data (ABS, 2012) revealed that only 18% of older people (50 and over for this study) had moved within this five year period. Based on our survey data, it was estimated that only around half of these (9%) would have downsized (by number of bedrooms). Of these, the majority (71%) relocated to private housing in the general community, and around one fifth (21%) to retirement villages – though this did increase with age from 7% for 55-64 year olds to 54% of those 85 and over. A little less than half (43%) had moved into smaller detached dwellings, 28% to attached dwelling and 23% to flats/apartments, the latter two including those who had moved to retirement villages. The reduction in number of bedrooms was significant, from 3 and 4 bedrooms (42% and 62% respectively) to 2 and 3 bedrooms (47% and 33%) with correlating reductions in floor area.

When asked about the circumstances contributing to downsizing, 'lifestyle preference' (38%) and 'inability to maintain house or garden' (27%) were most commonly cited (38%), with secondary circumstances including 'children leaving home' (17%), 'retirement' (16%), 'relationship breakdown' (12%), 'death of partner' (10%), 'illness' (8%) and 'disability' (7%). Financial difficulties were only rarely cited (6%) compared to 'financial gain' (10%). The concept of 'lifestyle preference' is, however, difficult to disentangle from other factors such as reduced maintenance, retirement, or relocation to a more attractive area. Difficulties with maintenance can also be precipitated by negative shocks.

When looking for their new home, the most important considerations in moving were 'less maintenance of the home' (7(74%) and '…yard' (73%), a 'smaller dwelling' (67%) and once again 'lifestyle improvement' (67%). Location was common amongst second order considerations including 'closeness to shops' (55%), '…public transport' (49%), '…health services' (48%), '…children/relatives' (35%), and '…friends' (30%). In terms of dwelling and neighbourhood characteristics, a 'more accessible home' was important for 38%, 'a more attractive area' for 32%, and 'a more modern home' for 24%. Of the financial considerations, 'reduced cost of living' was cited by one third (33%) of respondents, a 'better investment' by one fifth (19%) and 'to discharge or reduce a mortgage' by only 14%.

When relocating, downsizers sought their information mostly from family (52%) and friends (30%) or real estate agents (27%), less often from financial advisors (14%) and rarely from health/aged care professionals (5%), government (4%) or seniors' organisations (1.2-1.4%). Three quarters (74%) of downsizers found the move either 'easy' or 'very easy', and a quarter (26%) 'difficult' or 'fairly difficult'. The most common difficulties encountered by the latter were 'availability of suitable housing type' (64%), 'cost or affordability' (45%), and 'suitability of available locations' (33%), with less common locational difficulties being 'distance from family or friends' (18%), '…retail facilities' (12%) and '…health facilities' (9%). While cost/affordability was flagged as a problem by close to half, difficulties arising from transactional costs (5%) and obtaining finance (5%) were rare.

Our policy workshops with ageing and housing organisation stakeholders identified three main barriers to downsizing: (1) inadequate supply of smaller, affordable, accessible dwellings located close to services; (2) financial costs including stamp duty, real estate fees, temporary accommodation and removalists fees, housing market fluctuations, and the potential impact on pension eligibility; and (3) psychological and practical barriers including attachment to the home and neighbourhood, and the stress of preparing for sale, decluttering and moving. Other recent research on downsizing (Adair et al, 2014) in Australia found that while 30% of people 50 and over had considered moving to a smaller dwelling, only 10% had done so, the major barriers being the effort of moving and finding a smaller well-priced home.

While for the majority, remaining in a larger home and familiar community appears to support resilience, for those finding maintenance difficult, particularly if accompanied by negative shocks, the dwelling can be a significant stressor precipitating an adaptive response of either home modification or moving to a more appropriate dwelling. However, moving and/or downsizing can, in turn, result in exposure to a new set stressors arising from the moving process (both psychological and financial), and dislocation from the familiar community, neighbourhood and services recognised as important resources for resilience.

Multigenerational Living

In the Living Together study (Liu et al, 2015), an analysis of 2011 Census data (ABS, 2013) revealed that while multigenerational households (defined as those with at least two generations, the younger aged 18 or over) comprised only 15% of Australian households, they represented one fifth (20%) of the Australian population (due to their larger household size) and had remained so since the 1980s (Liu et al, 2015). Most were living in detached dwellings (94% in Brisbane and 83% in Sydney), were homeowners either outright (36% and 31% respectively) or purchasers (42% and 45%), and around one fifth were renting (20% and 22%). Over half (59%) of participating households had at least one person aged 55 or over.

From our survey, the most common reasons given for multigenerational living were financial ones (38% in Sydney and 55% in Brisbane) including the active choice to support adult children at times of difficulty while undertaking higher education, or saving for their own future home, but also the inability of either generation to afford a sustainable housing option. The second most common reason was to provide care or support (19% and 28% respectively), whether for older parents, children or grandchildren, for cultural reasons, or to avoid unaffordable care services. Other less common reasons were adult children not leaving home (18% and 13%) or starting/continuing tertiary education (11% and 13%) and older grandparents moving in (11% and 9%) (Liu et al, 2015).

Our participating multigenerational households experienced a number of challenges. Most common amongst these were problems with privacy or interference (60% in Sydney and 58% in Brisbane) followed by impacts on intra/inter family relationships (19% in both), inequitable contribution to household chores (12% and 18%), space related issues (8% and 11%) and lack of flexibility or compromises (4% and 14%). Other less common challenges included financial arrangements, noise interference, inter-generational agreements or expectations, and the stigma of living at home for the younger generation (Liu et al, 2015).

Some of these stressors were exacerbated by the design of the home, notable those related to privacy, space and noise. Differences in lifestyle and preferences could be compounded by inadequate space, poor definition of generational territories, horizontal or vertical adjacency, and noise separation or insulation. Given the conventional design of Australian suburban detached dwellings, modifications to increase space and improve privacy could be difficult and expensive. Very few had made major modifications to improve person-environment fit, while others, expecting their multigenerational living to be temporary, had only made minor modifications using temporary room dividers or relatively simple garage conversions. Even fewer had adapted to multigenerational living by moving to, or building, a larger dwelling with more independent accommodation (such as a granny flat or similar) and others had contemplated this possibility but been daunted by the cost or ability to find a suitably designed dwelling (Judd et al 2017). While family support has been identified as an important resource for the resilience for either generation in the face of financial or circumstantial stressors, this was rarely supported by housing design that facilitated better definition of intergenerational territory and privacy.

Towards A More Resilient Built Environment for an Ageing Population

It has been established in gerontological literature that housing and the urban environment are important, if indirect, resources for resilience in older age, which is reflected in the residential choices of older Australians ageing in place. In conclusion, we turn to the resilience of housing and the urban environment in supporting Australia's ageing population and how this can be improved.

First, if the predominant housing choice of older Australians is to remain in larger homes in the general community, more needs to be done to ensure that new housing is suitable for ageing in place. Steps toward this in Australia have been slow and minimal. Australian Standards for accessible design have existed since the 1970s, but have not generally been required in private housing. The recent addition of a limited degree of accessibility within apartment buildings under the Disability (Access to Premises) Standards 2010 Act of the Disability Discrimination Act 1992 is welcome but minimal (common area access to one level). Recent attempts to introduce voluntary 'Liveable Housing Guidelines' (Liveable Housing Australia, 2015) have failed to attract wide industry support and meet proposed targets, suggesting that a mandatory approach within the Building Code of Australia is necessary. With over half of all private dwellings being renovated in 10 years, perhaps consideration could also be given to mandating adaptable design in this sector.

Second, it is important to recognise the diversity of the older population in terms of their circumstances and capabilities, which needs to be reflected in the housing options available. Unfortunately, this is not the case, with housing supply polarised around larger detached suburban dwellings and multi-storey inner-city/suburban apartments. Our downsizing interviewees noted a lack of dwellings "smaller, but not too small, single level, step free, with accessible design and a small, manageable garden." This 'missing middle' in the urban housing market has recently been recognised by Planning NSW who have introduced a Draft Medium Density Design Guide (Planning NSW, 2016) to encourage more diversity on the premises of both housing affordability and demographic change. This includes housing types more suitable for multigenerational households, such as accessory dwellings, but still relies heavily on two storey (town house) forms not suitable for ageing in place. Current economic disincentives such as stamp duty taxes and pension eligibility risks along with better information and support services also need to be addressed if moving and downsizing is to be encouraged.

Third, the Australian housing industry's focus has been too much on specialised, age-segregated housing (retirement villages and seniors housing) and needs to recognise that most older people, increasingly baby boomers, largely wish to live in the general community, some in multigenerational households, and thus represents a rapidly growing market sector.

Fourth, there is the need to recognise that successful ageing in place is not just about dwelling design, but also resilient neighbourhood design, facilities and infrastructure that facilitate social participation. Currently there is little coordination between different levels of government in creating age-friendly urban environments, with responsibilities split between national, state and local governments. As our research found, there is also enormous variability in the age-friendliness of neighbourhoods and infrastructure throughout Australia.

Finally, it should be noted that such resilient housing and urban environments are not only important to support successful ageing, but also provide diverse and inclusive options for the wider community.

Abstract: The morbidity rates in populations of older persons are rising in parallel with increases in life expectancy. Increases in the numbers of older persons, many of whom will be physically dependent, will challenge communities both economically and socially. To compensate for this health loss and the subsequent demands placed on the health care system, there is a growing demand for effective preventative public exercise interventions to enable the ageing population to maintain independence and enjoy a healthier lifestyle. The provision of age-appropriate playground and exercise equipment for older persons has been gaining international popularity and is expected to become increasingly popular among local governments as a direct result of rhetoric relating to the development of age-friendly cities. Using a multidisciplinary lens, this project maps desired rehabilitation outcomes with exercise equipment design and landscape architecture. It seeks to identify both physical and motivational strategies that are most successful in maintaining good health and well-being in old age. Findings suggest that there is demand for open public space interventions that can safely train balance, muscular strength, and cardiovascular fitness. However, there is a lack of health research examining the usefulness and the sustainability of currently available equipment. There is also a necessity to address participation barriers and manage potential adherence issues that prohibit older persons from engaging in beneficial physical activity.

Keywords: resilience, interactive outdoor space, therapeutic landscapes, elderly, playground equipment

Introduction

Older individuals have experienced an unprecedented increase in life expectancy (Mousourakis, 2013). This ageing population is a pivotal demographic shift that will greatly impact the way in which people design and experience landscapes. The global over 65-year-old population is expected to more than double by 2051, whereby the New Zealand elderly cohort is predicted to rise from around 15% in 2016 to 25% by 2051, diminishing the available workforce and expanding the disabled population (Mousourakis, 2013; Statistics New Zealand, 2013; 2000). Furthermore, the mandate for health services will be pushed by chronic diseases, which pointedly contribute to the ever-increasing health loss of people over 60, and particularly those over 85 years of age (Ministry of Health, 2016; World Health Organisation, 2011). Concurrently, these issues are expected to cause a significant fiscal crisis, potentially dwarfing that of the recent economic depression (Kowal, et al.,2014). In this ageing society, rising morbidity rates will become a priority for health professionals and planners, and the development of preventative measures will be imperative in minimising the significant demand on the health care system (Kowal, et al., 2014; Kershaw, et al, 2017).

Countless studies validate the abundant reimbursements of outdoor spaces for elderly people, who perhaps have the most time available to capitalise on these resources (Sugiyamao, et al., 2007; Kolt, et al., 2007; Grant et al., 2007). Benefits not only include increased participation in physical activity, but also the potential for increased social interactions. Natural settings foster stress recovery, decreased antagonism, and a documented reduction in developing neuropsychological illnesses (Sugiyamao, et al., 2007; McCormack, et al., 2014). Therefore, the importance for older persons to experience independence in 'natural' public space is potentially significant.

Traditional outdoor physical activity strategies such as leisure activities in parks, or in exercise groups, offer recreational advantages (Matsouka, et al., 2008). More contemporary strategies for engaging with outdoor exercise are through targeted fitness zones, which provide specialised equipment to facilitate cardiovascular, strength, and balance training (Cohen, et al., 2012; Volkanovski, 2015). Ever-increasing in popularity, these zones are increasingly being adapted for senior use to not only train for increased aerobic and muscular strength but also to improve motor functioning, balance and flexibility. These settings have the potential for improving overall well-being and increasing resilience to frailty (Kershaw, et al., 2017; Volkanovski, 2015). Developing an understanding of the effectiveness of these exercise strategies is essential to inform the development of future outdoor interactive spaces, which are effective at encouraging exercise participation for developing resilience, independence and well-being in older persons.

Method

The research method involved a review of the rehabilitation literature that examines both physical and motivational outdoor exercise strategies most effective in maintaining good health and well-being in older persons. The results of this were then compared against a systematic evaluation of current outdoor exercise equipment to establish the suitability of those designs and to identify appropriate design parameters for the development of future outdoor interactive spaces that are adequately equipped to manage this susceptible ageing community.

Findings

Many systematic reviews were uncovered which outlined the different physiological needs of older persons, for the prevention of age-related morbidity. It was found that globally there was much agreement on the required levels of physical activity for older persons for maintaining health and wellbeing. Studies highlighted the significance of outdoor spaces for the promotion of physical activity in older adults through methods such as recreation in parks, group fitness, interactive exercise equipment or elderly playgrounds. In particular, there was substantial support for developing interactive outdoor spaces for managing the ageing populations.

Suitability of Exercise for Elderly Persons

A large majority of independent unimpaired older persons have the capacity for participating in moderate to high intensity exercise (Brown, et al., 2011). Thus, recommendations for cardiovascular, strength and balance training is relatively comprehensive in order for people over 60 to maintain independence, prevent non-communicable diseases, and build resilience to falls and frailty (World Health Organisation, 2010). The New Zealand Ministry of Health recommends older adults engage in a minimum of 30 minutes of moderate aerobic activity, 5 days per week. This could include brisk walking, cycling, kapa haka (a Maori performing art), kilikiti (a Pacific Island version of cricket) or playing with grandchildren (Ministry of Health, 2013). There are also the options of vigorous aerobic exercise, such as running, tennis, hiking, energetic dancing or martial arts, to a total of 75 minutes per week (Ministry of Health, 2013). Additional resistance training on major muscle groups such as legs, hips, back, abdomen, chest, shoulders and arms should be undertaken at least 2 days per week to receive muscle and bone strength benefits (Hurley, et al., 2000; Seguin, 2003; Ministry of Health, 2013). Sessions of flexibility and balance exercises are also extremely beneficial for elderly persons' to improve mobility and increase resilience to falls and injury. This could include modified tai chi, stretching, yoga, pilates (Ministry of Health, 2013; Chen, et al., 2007; Mason, et al., 2013; Pata et al., 2014). For impaired elderly, the range of ability is still quite varied and recommendations suggest participation as capability allows (Ministry of Health, 2013). Consequently, progressive rehabilitation and preventative strategies for improving independence and well-being would seem essential for outdoor interactive spaces.

Suitability of Interactive Outdoor Spaces

While there is numerous research on the effectiveness and adherence of traditional outdoor exercise strategies (Ishee, 2004; Laurant et al., 2002; McPhate et al., 2013), very little research has been published on the application of modern outdoor fitness equipment for elderly participation (Chow, 2013; Cohen, et al., 2012; Betterncourt, et al., 2012; Cranney, et al., 2016; Mitchell, et al., 2007; Scott et al., 2014). Additionally, studies which test the health implications of outdoor exercise equipment on elderly persons were limited to: a study of balance training in elderly women using public parks, Leiros-Rodriguez, et al., 2014) another study on the physiological effects of outdoor exercise equipment in elderly people, (Kim, et al., 2013) and two studies which assessed the effects of an outdoor recreational exercise program on sedentary seniors (Mitsouka, et al., 2008; 2008b).

Recreation in Parks / Group Outdoor Fitness

Studies showed that group outdoor fitness was very beneficial in providing the social interaction and leisure which helped for exercise adherence (Young, et al., 2016). The adaptable nature of group classes meant that changes could be made to suit preferences and interest to increase uptake. A limitation of this method of exercise is its exclusivity, as it is often targeted towards specific demographics and may be inaccessible to certain cultural groups or people with low esteem (Francis, 2014). Additionally, the reliance on other people for direction or motivation, the lack of equipment and low self-efficacy were deemed to be detrimental to long-term adherence (Grant, 2008). Furthermore, in instances without feedback it is difficult for elderly persons to undertake appropriate levels or types of exercise, or to monitor their progress. A systematic review conducted in 2002 found that common participation barriers for exercise in public green spaces were that; the provided spaces were not appropriately designed for elderly physical activity; environmental factors such as lack of scenery and vegetation resulted in undesirable settings; exercise surfaces were often of poor quality, a lack of equipment limited opportunities for exercise (Francis, 2014; Humpel, et al., 2002). Without adaptation currently existing public parks may not have appropriate or maintained facilities for effective physical activity, reducing enjoyment and safety (Grant, et al., 2007).

Outdoor Exercise Equipment

Research found there is a strong demand for age-friendly exercise equipment within the outdoor public sector, as elderly people have a stronger tendency for participating in exercise in an outdoor environment, if it is well-designed (Kim, et al., 2013). Additionally, there are many economic barriers, which prevent people from engaging with beneficial exercise which must be addressed when designing within public space (Loukaitou-Sideris, et al., 2016). This can be seen in the numerous case studies of free outdoor fitness zones which are increasing in popularity globally and are becoming increasingly implemented in public parks (Chow, 2013; Volkanovski, et al., 2015; Cranney, et al., 2016; Elwell, et al., 2016). These interventions are of specific significance for people of low socio-economic status, whom are more likely to face health problems and may have scarce access to health care and exercise equipment (Elwell, et al., 2016).

Based on an assessment of exercise equipment currently available of the market, it was found that many of the elements do target muscular strength, balance and cardiovascular fitness in older adults (Caldwell, 2010; Martin, et al., 2007). However, the resemblance to indoor gym equipment is uncanny, with only equipment materiality altered to be more durable in outdoor conditions (Caldwell, 2010). Thus, the only key difference between outdoor and indoor equipment is that comfort is often stripped when adapting it for outdoor use (Chow, 2013). Therefore, there is a requirement for better-fit, ergonomic designs to make outdoor gym equipment more comfortable for older persons, while ensuring and outdoor maintenance is still a significant design parameter.

While there is an essential need for the equipment to be designed to effectively target specific muscles and bodily systems, which the equipment seems to do, the existing capabilities of older persons need to be considered for equipment to be utilised for strength maintenance and rehabilitation in a safe manner (Aparicio et al., 2010). This is a main concern for many older persons, who find equipment intimidating and have health and safety concerns such as physical disabilities (Fredriksson, et al., 2011). We suggest there a need for progressive adaptable elements to allow for a diverse range of capabilities as well as systems that provide meaningful feedback.

Adherence rates for the utilisation of outdoor interactive spaces also need to be addressed. One study showed that within 6 months of engaging in physical activity, 50% of participants dropped out before they were exposed to any long-term health benefits (Schutzer, et al., 2004). This is a significant problem as once exercise participation ceases, the health benefits are quickly lost (Schutzer, et al., 2004). Other issues identified include a lack of encouragement, energy and time, or perceptions of incapability due to old age (Kolt et al., 2007; Grant, et al., 2007). In addition, lack of company or interactivity was another common theme (Grant, et al., 2007). This suggests that while the equipment may be appropriate for the required training of balance, muscle strength and cardiovascular fitness, the equipment may be ill-suited for the physical, mental and social disparities within ageing population. Furthermore, the equipment may not inspire the social behaviour and confidence that are deemed essential for adherence. In summary, while it is important to establish stimulating exercise strategies for elderly persons to maintain long-term engagement, there are significant participation barriers, which need to be adequately addressed to successfully engage older persons in physical exercise. We conclude that while there is now a wide range of equipment available on the market, it is not mentally stimulating enough to encourage long-term participation (Lim, et al., 2007) and there may be a need to provide a form of interactivity or feedback system into the outdoor exercise equipment to develop physical activity motivational strategies (Kelders, et al., 2016).

Elderly Playgrounds

One attempt to address needs for increased social interaction and feedback and introduce some enjoyment is the clustering of fitness equipment into playgrounds for the elderly. The design challenges for these senior playgrounds have been to either adapt previous equipment to be more enjoyment and sociable, or to develop an entirely new concept which is enjoyable, yet efficient at training balance, muscular and cardiovascular fitness. Manufacturing companies developing equipment for these outdoor spaces include Kotobuki and GameTime who often modify existing exercise equipment for elderly play such as new interactive bars adapted from lateral pulldowns. Other companies, such as Xccent and Lappset have focussed designs around improving daily functioning and improving balance and proprioception for fall prevention in older adults (Lim, et al., 2007). A Lappset study showed that interactive equipment such as the high horizontal bar was useful for exercising the upper body for flexibility and strength, which could aid individuals in reaching high shelves, putting on shoes, or hanging laundry (Lappset, 2014) Another designed element involved walking on varying surfaces to develop lower body strength and joint flexibility for improving mobility up and down stairs and for moving in and out of a chair (Lappset, 2014). While marketed as play equipment, these elements were perhaps the least interactive pieces in the playground compared with the swing, or tai chi wheel so there may still be a disconnect between physiological needs and the requirement for psychological stimulation.

Recent studies show that currently elderly playgrounds are effective at enticing seniors to engage which is stimulating a cultural shift towards an acceptability for exercise and exercising with equipment among older adults (Cranney, et al., 2016; Scott, et al., 2014; Scott, 2006; Neville, et al., 2013). It appears many hesitant older persons were sufficiently intrigued by the new playgrounds that they let go of the notion that they were either too old to exercise, or their fears of appearing silly (Scott, 2006). Research found that participation in exercises in this form promoted social interaction among elders' as it provided a platform for them to meet for group exercise. Consequently, these interactions allowed increased encouragement towards participation and adherence (Loukaitou-Sideris, et al., 2014). This is particularly beneficial as studies found that female seniors preferred to exercise in groups, as it gave them more motivation, confidence and enjoyment (Chow, 2013; Leiros-Rodriguez et al., 2014). Through this social interaction, important relationships may be developed for overall wellbeing and improved quality of life. Furthermore, a study found that the inclusion of a trainer or supervisor, for introducing elderly to the equipment increased confidence within participating seniors, thereby increasing the efficacy of these therapeutic landscapes (Mitchell, et al., 2007; Scott, et al., 2014; Leiros-Rodriguez et al., 2014).

As senior playgrounds have only recently gained international popularity, there is the risk that the equipment may not be entirely fit-for-purpose despite the increasing inclusion of interactive elements. Furthermore, there are limited studies on the effectiveness of this play equipment for improving balance, muscular strength and cardiovascular fitness, or the long-term usage. In addition, very little research was found regarding the ethnic, cultural, and gender barriers. These knowledge gaps must be addressed in future research to ensure appropriate development of interactive outdoor spaces that are inclusive for all elderly populations

Conclusion

This paper explores the potential of exercise strategies in interactive outdoor landscapes, by integrating cross-disciplinary knowledge to identify appropriate design parameters of these spaces. It argues that the interactive outdoor landscapes can be beneficial to elderly lifestyles for maintaining their independence and well-being. Findings suggest that there is demand for public open space interventions that can safely train balance, muscular strength, and cardiovascular fitness. However, there is a lack of research with respect to both the usefulness and the appropriateness of currently trending senior exercise equipment, which may not be fit for purpose for this older age group. Additionally, while there is promising enthusiasm around contemporary outdoor senior fitness equipment there are still physical activity participation and motivational barriers for the older person. In addressing adherence barriers findings suggests that more interactive and engaging exercise equipment, improved feedback systems and better integration with outdoor landscapes, could promote long-term effectiveness of physical activity for the elderly. Furthermore, to overcome additional participation problems, further research is required on specific ethnic, cultural, gender and age barriers.

Models of care and physical environments of current housing for the elderly: the possibilities of the rental housing for the dependent elderly in New Zealand

Yukiko Kuboshima[1], Jacqueline McIntosh[1], Geoff Thomas[1]

[1]School of Architecture, Faculty of Architecture and Design, Victoria University of Wellington, Wellington, New Zealand. email: jacqueline.mcintosh@vuw.ac.nz

Abstract: There is a scarcity of suitable housing options for the elderly who need assistance to live independently in New Zealand. Currently, there are three main types of housing; retirement villages, public-sector housing (central government and local council), and private-sector rental housing for the elderly. However, the rapid growth of the ageing population means that demand far outweighs supply. In particular, there is an increasing need for rental housing. The objectives of this study are; to identify the features of each type of housing, and to explore the models of rental housing for the elderly who need assistance. Data has been collected through archival research and a questionnaire survey for housing operators on the models of care and the physical environments of these three types of housing in the Wellington Region. Rental housing is most typically provided by the public and private sectors, however, they are less likely to provide high levels of services for the elderly, with some exceptions in the private-sector housing. The government policy objectives associated with 'ageing in place' are unlikely to be achieved if this imbalance of suitable housing supply for dependent older people and the demands for such housing which allows them to remain independent cannot be addressed.

Keywords: Housing for the elderly, dependent elderly, models of care, physical environment, rental housing

Introduction

Globally, the ageing population is projected to increase rapidly. As people age, they experience greater difficulty performing everyday tasks such as those involved with maintaining their own home. In addition, the elderly typically have a higher prevalence of psychological concerns such as insecurity, loneliness and isolation (Davey et al., 2004, Jaye et al., 2015). At some point, typically in their 70s or later, these experiences induce them to seek a more suitable dwelling (Statistics New Zealand, 2002). Unfortunately in New Zealand, the supply of suitable housing is in short supply and the government policy has been to encourage ageing in place. To successfully achieve ageing in place, which puts the focus on avoiding entering institutional residential care (Davey, 2006a, Ministry of Social Development, 2001), the housing for the elderly needs to provide an adequate environment for the provision of support and care.

When older people need more assistance, some consider moving closer to their children; but most do not want to live with family in order to avoid being a burden (Davey, 2006a). However, there is a scarcity of suitable independent housing options for the elderly who need assistance to live on their own in New Zealand (Davey, 2006b). Currently, there are three main types of housing which provide some level of care and assistance; retirement villages, public-sector housing (central government housing and local council housing), and private-sector rental housing, which includes community providers and various other groups who provide for older people. While often retirement villages require the execution of 'Occupation Right Agreements' which state that a resident who cannot live independently may lose their right of residence, many retirement villages in New Zealand provide a continuum of care by physically attaching residential care facilities to independent and/or assisted living units. Retirement villages offer company and security, reduce concerns about home maintenance and are viable options for current homeowners and the relatively well-off. However, they are not viable options for those without substantive savings because the majority require some form of capital contribution, such as the purchase of a Licence to Occupy (Greenbrook, 2005).

Local authorities provide affordable housing and some of them provide social support for older people to live independently (Davey et al., 2004). Central government (Housing New Zealand) also provides affordable housing but does not with support especially for older people to live independently. Of the private-sector rental agencies, religious and charitable groups, which have been the providers of choice for the government, have been withdrawing from the older persons' residential accommodation sector. This is largely due to their inability to afford to upgrade facilities to make them suitable (Povey and Harris, 2006). Recent government initiatives are seeking to address this situation, encouraging community housing sectors to grow (New Zealand Government, 2015).

The number of units in retirement villages in New Zealand was 32,854 in 2014, with the penetration rate of 12% among those aged 75 and over (JLL, 2015). The demand for retirement villages has been projected at an increase of more than 50,000 units between 2014 and 2038 with the scenario of the same penetration rate, which equates more than 1.5-time increase (JLL, 2015). Shortages are currently reported in private-sector rental housing for the elderly in Auckland (Seniorline, 2016).

New Zealand is a bicultural country, predominantly populated by people of European descent. Of older people, non-European groups are more likely to be renting than those of European descent (Davey et al., 2004). This has implications for rental housing as the proportion of non-European people is expected to grow significantly (Statistics New Zealand, 2013). In addition, the levels of homeownership among people in mid-life are falling (Davey et al., 2004). The combination of these two factors will increase the demand for rental housing in the future. The retirement villages, which mainly accommodate homeowners, provide high levels of care as part of the continuum of care; however, the possibility of rental housing accommodating the highly dependent elderly is unknown.

Objectives and methods

The objectives of this research are to identify the features of each type of supported housing in terms of their models of care and their physical environments to better understand the options available for the elderly who need assistance in rental housing. While information on retirement villages is publically available, there is a scarcity of information on the other two forms of housing, especially private sector rental housing for the elderly. The focus of this study is to obtain equivalent information for all three types of housing, so as to enable a clearer, more direct comparison and better understand the rental options for the elderly.

Data was collected through archival research followed by a questionnaire survey for housing operators of retirement villages, public-sector housing, and private-sector rental housing for the elderly in the Wellington Region in New Zealand. First, information on the housing was obtained through the websites such as housing operators' homepages and/or the websites that provide comprehensive information on services for the elderly (Eldernet

Ltd, 2017). Next, data on the models of care and the physical environments of the housing was collected from housing operators. The sample was limited to housing sites with eight units or more. Data was collected using online questionnaire software or questionnaire forms attached to emails, and complemented by additional emails and/or interviews.

Physical environments and models of care

To gain an initial basis for comparison, the total number of units per site were compared by housing type in the Wellington region (Table 1). The average number of units was the largest for retirement villages, which included a wide range in the size of complexes, from 20 units and less to over 200 units. The size of public sector housing varies, and the majority were complexes of 20 units or less. The size of complex was the smallest for private-sector rental housing, with over 80% of the sites containing 20 units or less (Table 2).

Table 1. Total number of units and the size of the housing complexes

Type of Housing	Unit number (percentage)
Retirement villages	2862 units*
Public-sector housing for the elderly	2622 units**
Private-sector rental housing for the elderly	276 units

*The total unit number of retirement villages doesn't include those of two villages which are unknown.
**Of the public-sector housing only the number of units which are occupied by people 65 years are included in this table.

Table 2. Number of units per housing site (among the housing sites with 8 units and more)

Type of Housing	Average number of units per site	Number of units per site							
		8-20	21-40	41-60	61-80	81-100	101-200	201-300	Unknown
Retirement villages	95	25%	9%	13%	0%	9%	19%	19%	6%
Public-sector housing (excluding HNZ)	40	54%	22%	3%	5%	3%	10%	3%	0%
Private-sector rental housing for the elderly	15	82%	12%	6%	0%	0%	0%	0%	0%

The data on communal spaces and the services provided for residents in three types of housing were collected by questionnaire survey. For the analysis, retirement villages were divided into two types; independent living units and assisted living units (Figure 1, 2). Retirement villages provide a wide range of communal facilities such as lounge and community rooms; dining rooms and restaurants. All assisted living units in the retirement villages were attached by the lounge/community room and the dining room. In contrast, most public-sector housing sites had either no communal space or only the lounge/community room for shared use. The communal spaces provided by the private-sector rental housing providers were also relatively small and the spaces varied in type (Figure 1).

With respect to services for residents, retirement villages provide the widest range of services. For example; all villages that participated in the survey provided emergency on-call 24 hours a day, most arranged to visit residents regularly and organised activities and outings the costs for which were included as part of the 'Licence to Occupy', or in the 'Weekly Fees'. Assistance with transportation, meals, laundry and other assistance with household tasks were provided either inclusively or with extra cost. The services for residents in assisted living units are greater than for those in independent living units. Public-sector housing provides emergency-on-call service and social support such as regular staff visits, organised activities and outings at over half of the sites. Most private-sector rental housing provides regular staff visits, which may be accompanied by other services but services vary by the site.

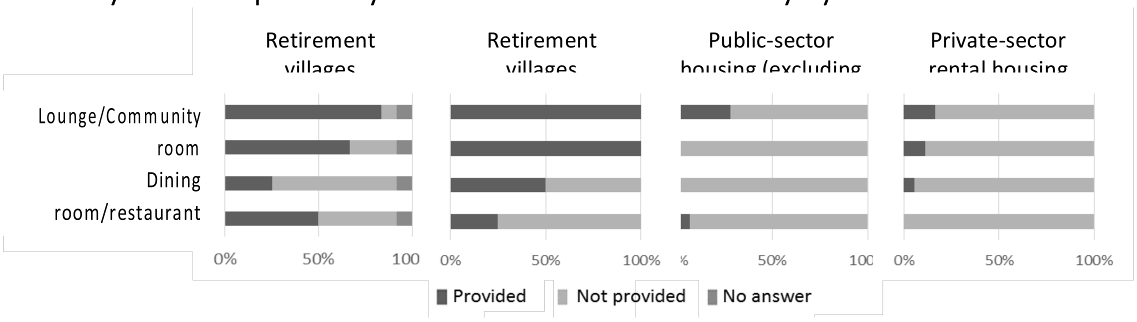

Figure 1. Communal space for residents

Figure 2. Services provided for residents

Levels of services

To compare the levels of service, the services provided for residents were given scores as; 'provided without extra cost'=2, 'provided with extra cost'=1, 'not provided'=0. Then the housing sites were classified by the total scores for 10 kinds of services; 0-3: low levels of services, 4-9: medium levels of service and 10 and over: high levels of services. The retirement villages were divided into independent living units and assisted living units. The table 3 shows the number and the proportion of housing sites by the housing type and the levels of services. The residents in most independent living units, and all of those in assisted living units in retirement villages are provided with high levels of services. The public sector provides either low or medium levels of services. The levels of services provided by private-sector rental housing are relatively low overall but have a wide range.

Table 3. Levels of services by the housing type

Housing sites		Low levels of services	Medium levels of services	High levels of services
Retirement villages	Independent living	0%	20%	80%
	Assisted living	0%	0%	100%
Public-sector housing (except for HNZ)		35%	65%	0%
Private-sector rental housing for the elderly		78%	17%	6%

Characteristics of each type of housing

Retirement villages

Of three housing types surveyed, the overall size of the housing complex was the largest for retirement villages. They provide the widest range of communal facilities, services for security, facilitating activities and assisting with household tasks than other two types of housing. 'Independent living units' and 'Assisted-living units' are the well-known classifications of the units by the level of care provided in retirement villages.

a. Independent living model
Independent living units are self-contained villas, flats, townhouses and apartments that are physically separated from residential care facilities, if they are provided on the site. Residents can make use of internal and/or external service and care providers for support with household tasks and personal care, as well as other services. The inclusion of services are variable by complex, some provide these services for no additional charge and some charge by use.

b. Assisted living model
Assisted living units are designed to bridge between independent living units and full residential care in the continuum of care. They are often called 'serviced apartments.' The units are all self-contained apartments with the lounge and the dining spaces. They are often connected internally to the residential care facilities, so that flexible and efficient services and care can be provided to residents. Services for items such as social activities, household tasks and meals are typically financially combined with the housing unit in this type of housing.

Public-sector housing

There is a wide range in terms of unit size in the public sector, but over half of the housing sites were small containing 20 units or less. The units were self-contained villas, flats and apartments with limited communal space. Some housing complexes with relatively large numbers of units had communal spaces such as community rooms. The services for the residents varied, but residents who need assistance in household tasks and/or personal care receive services from external service/care providers, which include those allied with District Health Boards. The types of the housing are classified by the levels of services as below;

c. Housing with low levels of services
This type has no communal space. The only service provided is regular staff visits.

d. Housing with medium levels of services
The residents of this type of housing are provided with organised activities, outings and/or transportation as well as regular staff visits. Some of the complexes had one or more communal spaces, which were used for organised activities. Residents in complexes with no communal spaces were encouraged to use external facilities, such as community spaces in other complexes; community halls; the church, or public libraries for social activities.

Private-sector rental housing for the elderly

Both the total number of units and the size of the housing complex is considerably smaller in private-sector rental housing. Some rental housing complexes are located adjacent to residential care facilities. The number of communal spaces for the use of residents in rental housing, which may include those in residential care facilities, are relatively few, and might include dining/restaurant spaces, lounge or community rooms, or a shared kitchen. Residents in most sites receive regular staff visits. The private-sector rental housing has a variety of models in terms of the levels of services provided and the unit types which can be classified into four types as shown below.

e. Housing with self-contained units and low levels of services

The majority of private-sector rental housing sites are of this type, which is similar to the housing with low levels of services in public-sector housing. The units are self-contained villas and flats and most sites have no communal space for residents. In most sites, the only service provided is regular staff visits. This type of housing includes some units which were formerly owned by the public-sector but were sold off to private-sector rental agencies.

f. Housing with self-contained units and medium levels of services

In most sites of this housing type, residents are provided with organised activities as well as regular staff visits. Some sites which are located adjacent to residential care facilities provide organised activities for the residents using the spaces in the adjacent residential care facilities but provide no dedicated communal space.

g. Housing with semi-self-contained units with medium levels of services

The combination of services provided in this type of housing are all inclusive; regular staff visits, meals and other services which are provided by a housekeeper without extra cost (included in the rent). Each unit is semi-self-contained with a kitchenette containing a sink and space for a fridge. The residents share spaces such as a full kitchen and dining room as well as the lounge. To be eligible for this type of housing, residents must be independent, but they can obtain external assistance for additional household tasks and/or personal care.

h. Housing with semi-self-contained units with high levels of services

This housing type is similar to assisted living units in retirement villages in terms of the high levels of service and care provided and the indoor connection to the residential care facility; however, the units are semi-self-contained with a kitchenette containing a sink and a fridge, rather than the full kitchen provided in the assisted living units in retirement villages. These rental units contain a lounge and a dining area, and the residents are provided with a wide range of services such as; regular staff visits, organised activities and outings; transportation, meals, as well as assistance in household tasks and personal care with extra cost.

Discussion

Ageing in place, which is preferred by the elderly themselves as well as by the New Zealand government, implies that 'older people remain in the community, rather than moving into residential care' (Davey et al., 2004). However, the realisation of ageing in place cannot be achieved without suitable housing and the provision of service and care which supports the elderly person's independent life. Retirement villages, which are the most viable option for those with sufficient capital (often former home owners), can accommodate high-dependency elderly. However, for those who require rental housing, which is provided mainly by the public and private rental sectors, the options for those elderly who need high levels of care are scarce. To cater to this ever-growing sector of the elderly population, strategies to provide the services they need with the limited resources and space are urgently required.

The combination of service provision with housing creates difficulty for all housing providers; however, some are more challenged than others. With respect to the more expensive end of the housing spectrum, a recent study reported that the residents in assisted living units in retirement villages reported experiencing a lower quality of life, because of size and inadequate spaces as well as the loss of privacy with regard to personal care (Hayward, 2012). At the other end of the housing spectrum, the experience of rental housing shared all of the same issues, in addition to the added challenges associated with limited resources.

Housing available for those seeking to rent rather than own is problematic. The public and private-sector rental housing providers are limited in what they can afford with the limited resources made available from low income rentals. Their numbers are limited simply due to availability. Both public and private-sector rental housing providers operate with smaller numbers of units which makes provision of additional services uneconomic for in-house service. Both typically operate with an older housing stock which has not been designed for those elderly who have mobility issues or are not fully independent. Both operate with limited resources and serve those in most need, both in terms of health and mobility, but also in terms of income.

Strategies which could improve the quality of space for the high dependency older population include, more flexible design of communal spaces; organising external transportation options with housing; modified meal service options for use in a minimal kitchen space; and increased efficiency of adjacent facilities. More specifically:

a. In public and private-sector rental housing with medium levels of care, the communal space, often called the 'community room' could be easily adapted for multiple-purposes for various organised activities and other services.

b. In public-sector rental housing with medium levels of care, activities could be organised using other public facilities in the community, such as public transportation services for those who have difficulties in mobility.

c. The private-sector rental housing includes semi-self-contained units, which have a kitchenette, not a full kitchen. This is provided on the premise that the main meals will be provided communally. With the increased availability of commercially-available prepared meals, a well-designed kitchenette might be suitable for some who cannot or does not wish to prepare complete meals or does not want to eat communally. This could reduce the cost of providing a full kitchen.

d. Physically locating the housing units adjacent to residential care facility is a strategy for the provision of high levels of care, as seen in the assisted living units in retirement villages. Some private-sector rental housing provide high levels of care (and have specialised residential care units), however those that provide medium levels of care have no communal spaces for rental tenants. By attaching to a main residential care unit services such as organised activities and meals could be provided using the spaces and the staff of the residential care facilities.

Combining the service and care should also be accompanied by the appropriate physical environments and vice versa. Even new housing designs are rarely designed with an understanding of the special needs of the highly dependent elderly. For example; the space for the service staff should be considered in all such housing; rarely do showers have sufficient room for two and in the designing a communal room, it should be flexible enough to accommodate multiple uses. Similarly, semi-self-contained units should not be without the consideration of meal service. Further exploration is necessary for models of housing which provide greater quality of life along with accommodating higher levels of services and care for dependent people in order to live independently. This should be of equal consideration in the setting for rental housing as well as that for the more exclusive retirement villages.

With limited resources, comes the need for expanded ways of thinking and greater creativity. Questions of how rental housing can provide services and care for its residents through careful placement of adjacent services; or how tenants can work more effectively with the landlords in service provision are rarely addressed. Many rental housing tenants have access to external services for assistance in household tasks and personal care. Partnerships between housing providers and service/care providers could provide a more supportive service system for the elderly to live independently. It has been reported that there are some public sector housing providers that facilitate high levels of care for the elderly through the partnerships between housing and/or services providers, such as those between local authorities and District Health Boards; private-sector rental housing providers or local community trusts (Davey et al., 2004, Reid, 2008). However, this study could identify no such example in the public-sector housing in the Wellington Region. Increasingly providers of social housing for the elderly are expected to exhibit greater innovation and develop better combinations of housing and services to meet people's needs (New Zealand Government, 2015). This is indeed necessary but there also needs for greater consideration of those aspects that contribute to an improved quality of life for residents in the design of their individual spaces.

Conclusion

Agencies that provide both housing and care are most commonly found in retirement villages where home ownership is essential. These facilities can offer high levels of service due to the high number of units, the security of income and housing tenure.

In retirement villages, the elderly who need assistance are aided to live independently with a wide range of services and care; however, this option is mainly for homeowners. The demand for rental housing is projected to increase. Rental housing is provided both by the public and private sectors; however, they are less likely to provide high levels of services for the elderly, with some exceptions in the private-sector rental housing.

The objectives associated with 'ageing in place' are unlikely to be achieved if this imbalance of suitable housing supply for dependent older people and demands for housing which allows them to remain independent cannot be addressed. The research finds some strategies to provide the services with the limited resources and space; however, more solutions are required to combine high levels of services/care with housing. There are possibilities for providing innovative models of care, potentially facilitated by social-housing providers or through partnerships between public sector housing and service providers. Further research is needed for the specific housing models that could provide greater quality of life along with higher levels of services to accommodate the dependent elderly, in rental housing as well as other types of housing.

Abstract: Background: The number of people with dementia will increase tremendously within the next decades. Aim: The aim of the project was to develop an analysis tool that matches home environmental interventions to dementia-related needs. Methods: A systematic literature review was conducted to evaluate possible home environmental interventions for community-dwelling people. The analysis tool was developed taking into account current German health care regulations and dementia-specific needs that might be influenced by interventions in the built environment, in particular the domestic environment. Results: The analysis tool is an aid to help with better decision making when planning home improvement measures for people with dementia and shows the spectrum of possible interventions to meet individual needs. Conclusion: The main precondition for the use of this analysis tool is the need to assess the specific situation and the individual abilities of people with dementia. The complexity of the domestic environment can only be illustrated if personal and environmental requirements for the respective intervention are determined. The detailing of these factors will follow in a further study.

Keywords: dementia, home environmental modification, fit, dementia-related needs, instrument/analysis tool

Introduction

Advances in medicine, a decline in birth rates and increased longevity all contribute towards demographic changes and an ageing population in Germany. According to current population projections by the German Federal Statistical Office the percentage of the population aged 65 and above will increase from 21% (2013) to 28% (2030) and 33% (2060). In particular, the number of people aged over 80 will go up from the current 5% to 8% (2030) and about 13% (2060) (Pötzsch et al., 2015).

With increasing age, the probability of a progression of age-associated diseases such as dementia rises, too. Dementia is a syndrome associated with progressive memory loss and impaired cognitive and physical ability. The progression and reduction of abilities vary greatly from person to person. After 60, the probability of developing dementia doubles every 5 – 6 years (Ziegler et al., 2009). According to projections by the German Alzheimer Society the number of people with dementia will increase from the current 1.5 million up to 3 million in the year 2050 (Bickel, 2014).

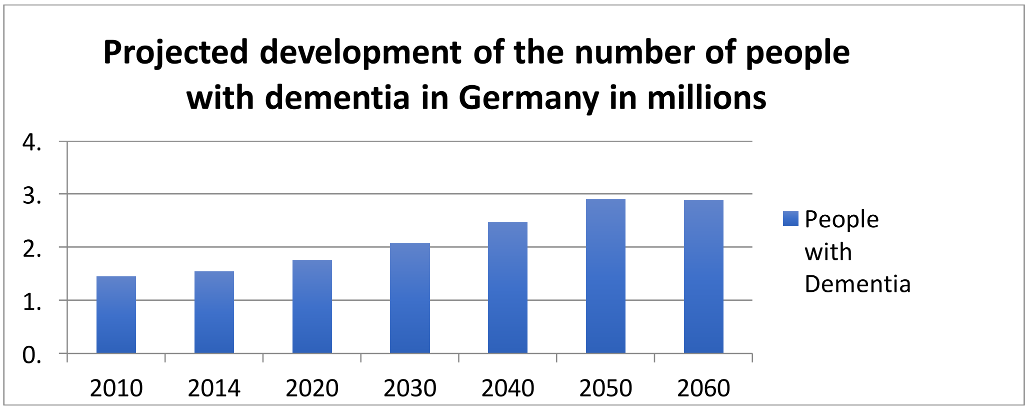

Fig. 1 Dementia in the age group 65 and older in Germany, 2010 – 2060 (German Alzheimer Society, 2014)

The majority of people with dementia live in in their home environment. Restrictions that may occur due to dementia – such as a decreasing ability to make logical decisions or impaired perception and orientation – can jeopardize the ability to lead an independent life. With progressing dementia, the dependence on personal support increases and with lower ability to cope with everyday challenges, caring relatives often feel burdened by more care dependency and incidences of challenging behaviors. These reasons are often reported when care in the familiar environment can no longer be maintained (Schäufele et al., 2005).

Measures to improve the domestic environment for people with dementia

Home adaptions include a number of building- and structural measures in the familiar environment, usually for people requiring care or for disabled people. The guidelines for living space interventions eligible for aid are defined in the German Social Code (SGB XI) which states that nursing care funds can subsidize improvement measures in the home if these substantially facilitate care or allow a person to mainly live independently again (sect. 40 SGB XI, 2017).

Due to the loss of competences associated with dementia, the demands on the environment go up as the symptoms progress and it gets continuously harder for the afflicted to adjust to their surroundings. Studies with people with dementia have shown that adjustments to the built environment can compensate for individual losses by making the right adjustments for the needs of people with dementia (van Hoof et al., 2010).

The adjustments to the environment should compensate for building defects or restrictions on the one hand (Soilemezi et al., 2017), but also make up for the individual restrictions of the residents and thereby improve the home situation in view of the special requirements caused by specific physical and cognitive impairments (BMFSFJ, 2002). The corrections to defects in the homes are made to allow people with dementia to lead a safe and independent life (Struckmeyer et al., 2016), to make life easier for those providing care and to allow them to remain longer and better in the own home. Achieving these objectives means interventions that are directed at the individual needs of people with dementia (van der Roest et al., 2007).

Development and objective of an analysis tool

There are a great number of different improvement measures for homes but most focus on the spatial problems rather than on the needs of the persons concerned and least on the special needs related to dementia. The lack of linking interventions with the requirements of the afflicted persons makes it difficult to assess if the measure is appropriate or not. Against this backdrop the following questions directed the development of the analysis tool:

a. Which dementia-specific needs can be met by special improvements to the home?
b. How can a building intervention be matched to individual problems?

The analysis tool systematically links dementia-specific problem areas with structural interventions that are as much as possible evidence-based. Residential consulting offices, which can be found in many German communities, are envisaged as the users of the tool as they can implement the tool in the course of their advising activities; they can point out or recommend possible building adjustments. It is also conceivable that the Health Insurance Medical Service (MDK) uses the tool in the course of assessing a person's nursing care needs.

Background on the legal and domestic situation

The starting point for the development of the analysis tool is the reorientation of the term *"in need of care"*. In January 2017, the Second Nursing Care Act [Pflegestärkungsgesetz] came into force. With the passing of this law, the understanding of what constitutes *"requiring nursing care"* changed in as much that now for the assessment of the degree of required nursing care no longer the amount of time needed for the support due to physical impairment was considered but instead the ability to lead an independent everyday life is reviewed. This competence-based view is of particular relevance for people with dementia since they might often still be physically able to perform certain tasks but are hindered due to cognitive and motivational restrictions to cope independently with complex situations of daily life. This new approach allows to assess the individual needs of a person and to gain a holistic view of a person in everyday life.

Most older people prefer to stay as long as possible independently in their familial environment even if there are impairments. Moreover, it is the national and international objective of policy discourse in this field to rather provide ambulatory than stationary care. However, 95% of existing homes of elderly people lack appropriate facilities for nursing care needs (BMFSFJ & BMGSS, 2005). This assessment is further supported by regional surveys, which show that 26% of owners and 46% of renters mention the need of improvements in their home environment (Balderhaar et al., 2006). For people with dementia it is difficult to compensate for inadequate facilities due to their cognitive and physical restrictions. Therefore they are especially dependent on a suitable built environment, which is appropriate to their individual needs.

Lawton and Nahemow established the relationship between the level of individual competence and the environment in 1973 in their "competence-press-framework". This model describes an individual's ability to cope with the environment as depending on the individuals' degree of competence and the demands of the physical and social environment (Lawton et al., 1973). When the environment exerts significant pressure then the individual is forced to adapt. Failure here leads to discomfort and unease. In particular, in old age and with impairments due to chronical illnesses such as dementia, the dependence increases on an environment that is suitable the individual competences in particular regarding the physical, social and infrastructural features of the environment (Gitlin et al., 2003). Thus it is necessary to adjust the environmental aspects to the (remaining) abilities of the individual in the best possible way (Schneekloth et al., 2005).

Methodological assessment of areas of life, dementia-specific needs and home environmental interventions

In the eleventh German Social Code (SGB XI) the following six criteria are considered authoritative for the presence of health-related impairments (i.e. in need of nursing care):

mobility, cognitive and communicative skills, behavioral and psychological problems, self-sufficiency, coping with and dealing independently with illness- and therapy-related requirements and burdens, structuring every-day life and maintaining social contacts (*§ 14 SGB XI*, 2017). In addition, the assessment should also include the abilities concerning activities outside the home and housekeeping, to enable planning of care and services (*§ 18 SGB XI*, 2017). For the assessment of the extent of care required, the newly defined German assessment (NBA) includes these areas and defines individual modules as illustrated below:

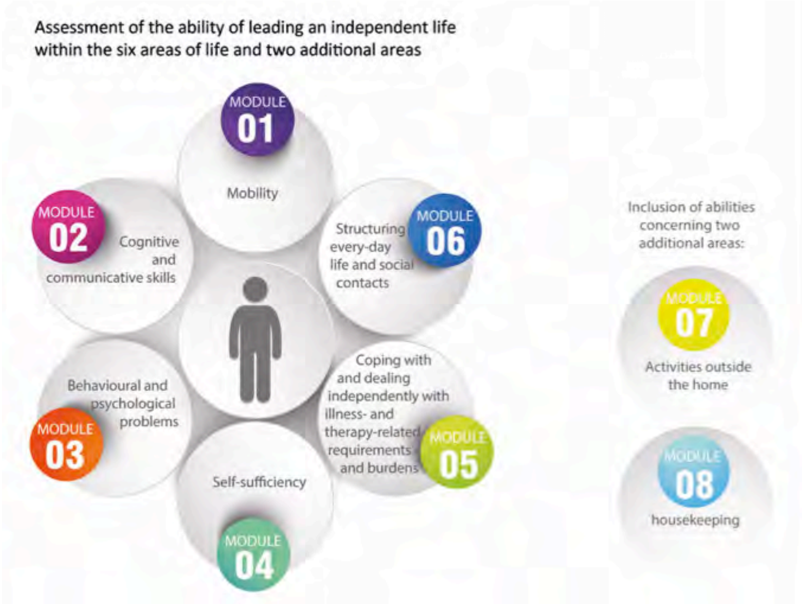

Fig. 2 The six areas of life and two additional areas for the determination of independence. Own diagram based on (NBA, 2015)

In a systematic review of literature interventions were identified which would support people with dementia by independently carrying out the activities of daily living in their domestic environment. The analysis tool included 84 – mainly structural and technical interventions – to support an independent, self-sufficient life of people with dementia.

Typically, the needs of people with dementia differ considerably in scope (Riesner, 2010). Many investigations on the appropriateness and fairness of interventions focus on the care-providing relatives. Only rarely the needs of people with dementia are focused in the context of interventions to improve their home environment. In order to plan and implement interventions with a view on maintaining and supporting resources, need-based and justice measures are of major relevance (van Hoof et al., 2010).

People with dementia often do not only suffer from restricted mobility and physical restriction but they also show signs of cognitive impairment such as problems of perception and orientation. To categorize situations and conditions that trigger the need for support, we used the *"signs and symptoms"* theory coined by MacBryde and Blacklow (1970) for the analysis tool. Signs are objective, physical manifestations and can as such be measured and observed. Symptoms, however, are subjective experiences (such as pain or hunger) and can only be experienced by the person concerned (Cacioppo et al., 1989).

Vague descriptions of symptoms or the limited ability of expression by those concerned can lead to wrong interpretations of needs. There is also the fact that self- and outside assessments by people with dementia and their relatives often differ in regard to the remaining abilities and self-sufficiency (Riesner, 2010). In spite of the challenges of detecting and interpreting symptoms, as mentioned above, the analysis tool integrates the experience of symptoms of the people with dementia and allows a better understanding of the individual situation so that interventions can be targeted directly to the individual needs of the person and the respective stage of dementia (Pynoos et al., n.d.). Fig. 3 shows the categories of typical signs and symptoms of dementia that the analysis tool addresses, on a higher level. The systematic assignment to the dementia-specific needs was made by taking into account the objective of an intervention and the potential effect.

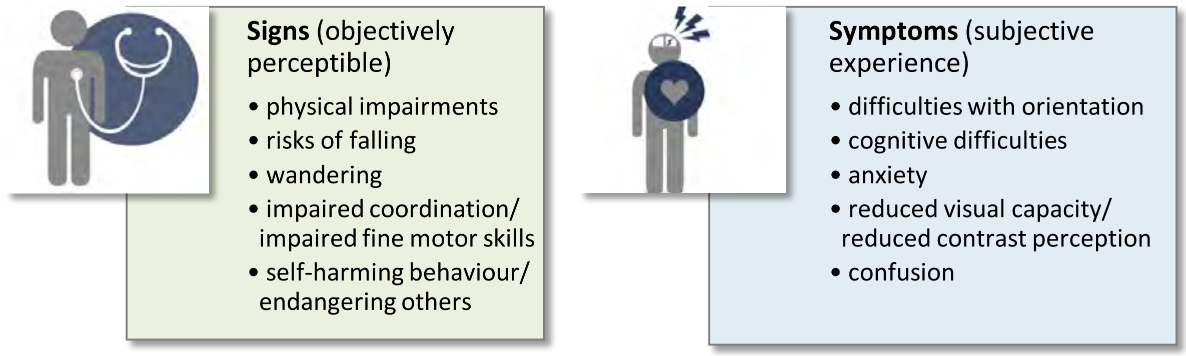

Fig. 3 Relevant signs and symptoms of people with dementia calling for structural interventions

Results and structure of the analysis tool

Therefore the analysis tool is organized hierarchically (Fig. 4). The top level is made up of six **target categories**, according to the six previously identified areas of life and NBA-modules (1,2,3,4,6,8). On the second level, those **items** from the sub-categories of the NBA-module are collected which are relevant for structural interventions (e.g. movement inside the home). Below, on the third level are the **needs** arising from the signs and symptoms of dementia which are linked, on the fourth level, with **measures to improve the domestic environment.** In order to give consideration to the contextual conditions, the interventions are linked to the **individual and environmental resources**. On the lowest level of abstraction there are tables which assign all the interventions included to the respective needs and categories (see Fig. 5).

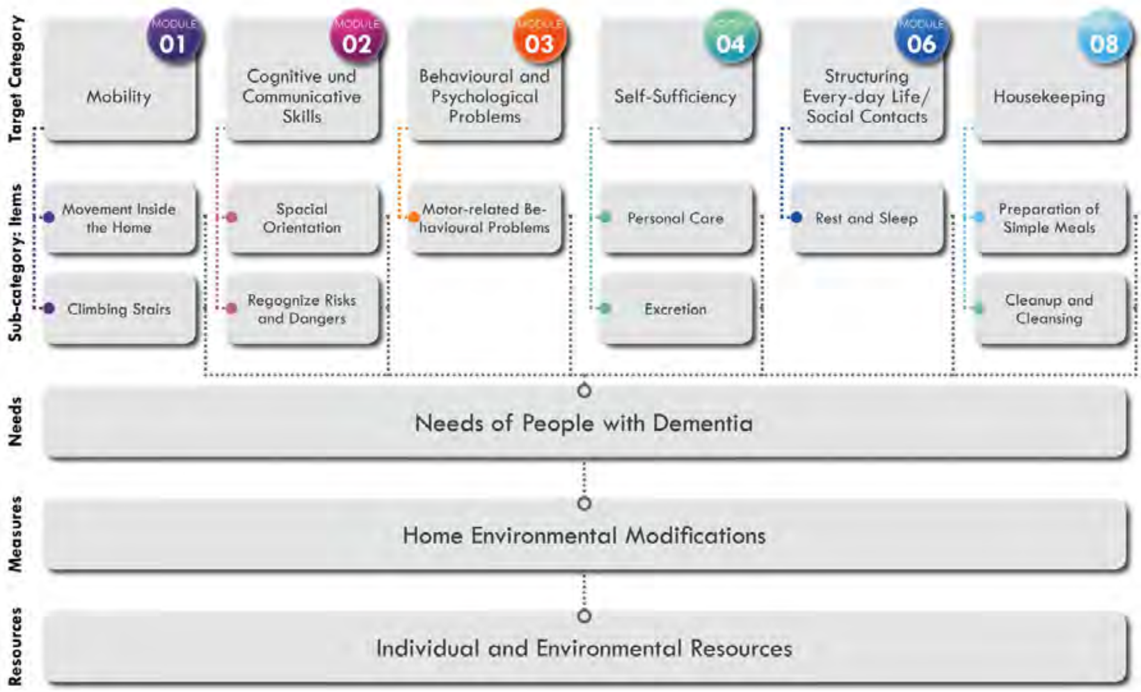

Fig. 4 Base structure of the analysis tool for the assessment of the suitability of measures to improve the domestic environment.

Each intervention for the improvement of the domestic environment aims to meet one – or possible several – specific needs and issues. Therefore, explanatory notes have been prepared for all home improvement interventions that are included. The following figure shows an example of the structure of these overviews. For each **sub-category** of the analysis tool, the specific **needs** of people with dementia, possible **measures** to meet the specific needs resulting from the issue and relevant **explanations** are included.

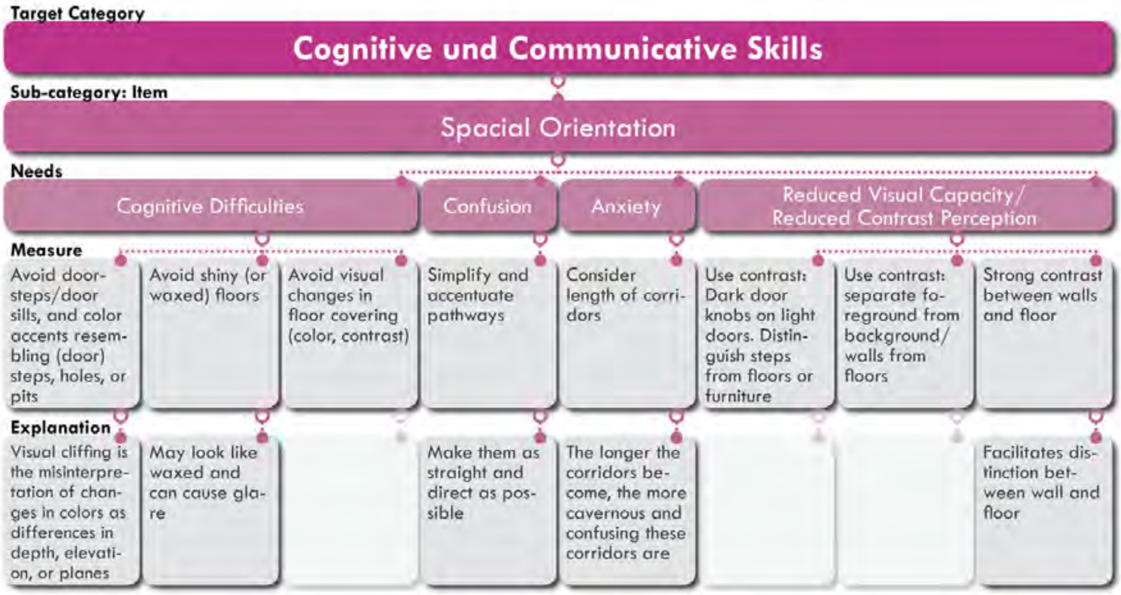

Fig. 5 Home improvement measures to help with spatial orientation

Discussion

The analysis tool is an aid to help with better decision making when planning home environmental interventions for people with dementia and shows the spectrum of opportunities to meet individual needs. Together with the consideration of personal and the environmental circumstances the tool can serve as a decision-making guideline for user-centred needs-based justice and appropriateness of building interventions.

The selection of building interventions is made by matching needs with interventions. The main precondition for the use of this analysis tool is to assess the specific situation and the individual abilities of people with dementia. The determination of individual needs – including both self-assessment and external assessment – will have to be made in future, too, by those concerned, people with dementia, their relatives and professionals. For people with dementia it is difficult to precisely communicate symptoms so that they are constantly on the risk of misinterpretation (Cacioppo et al., 1989). As a result interpretative skills are more important in the determination of the needs of people with dementia than those of people without cognitive and communicative impairments (Riesner, 2010). It is therefore a central condition that those interpretative skills are systematically acquired for the successful application of the tools and they will have to be further developed in future.

Due to the various influences that domestic interventions are subject to, it is difficult to narrow down cause-and-effect relationships, a problem that still exists when the analysis tool is applied. Whatever effects that occur after a home adjustment, cannot be attributed solely to the interventions. There is also the individual disease progression or social changes due to the interventions that can have an influence on the results. The analysis tool does, however, offer a frame for comparison of the effects of interventions in the home environment and a generalization of results might be possible.

Outlook

The complexity of the domestic environment can only be illustrated if personal and environmental requirements for the respective intervention are determined. By adding the environmental resources, the various influencing factors of the built environment can be narrowed down and examined. Linking the measures with the relevant necessary personal requirements is of relevance in terms of improving needs-based justice.

Moreover, the targeted observation of the correlation of dementia-specific needs and requirements for possible interventions allows an exact assessment of potential effects of home environmental interventions on the independence of people with dementia. In a further study the detailing of these requirements will follow.

Smart environment for the self-sufficient elder users

Gabriella Peretti[1], Francesca Thiebat[1] and Grazia Cocina[1]

[1] Dipartimento di Architettura e Design, Politecnico di Torino, Turin, Italy. Corrispondence email francesca.thiebat@polito.it;

Abstract: In an increasingly demographic and technological transition that is set to radically transform lifestyles and the way living environments are structured, it is necessary that all actors work together and interact with each other, migrating from the concept of a single person to the concept of community. Our proposal, intended to make people's elderly lives easier, aims to bridge the gap between self-sufficient older adults, that do not need constant medical help, and those that need continuous support. Through appropriate technology use, the project aims to integrate and manage the information related to the user, his environment and his health devices. A kind of invisible "smart care network", supported by ICT, unites the places of their everyday lives enabling independent elders to simplify their way of life and avoid being a burden to their relatives. The technological care network must cover three different environments used by the elderly: home, community and the city. The main goal of the research proposed is to redefine the home environment by designing it on the basis of lifestyles habits, the degree of autonomy of the individual and personal needs. The home is connected both to the neighbourhood and to the city providing a link with a community of other users with similar problems and needs, with health and social care infrastructures, local medical clinical centres, recreational activities and various other services.

Keywords: Care network, self-sufficient elderly, smart house, smart city, senior living

Introduction

The ageing population is one of the most important social and economic phenomena both at a national, European and worldwide level. The latest statistical estimations reveal that the population over 60 will represent 1/5 of the world population in 2050, against the current ninth. In Europe, the demographic old-age dependency ratio (people aged 65 or above, compared to those aged 15-64) is estimated to increase from 27.8% to 50.1% in the EU in 2060 (European Commission, 2015).

The ageing phenomenon, regarding the general improvement of the health and independence of older people, brings out the specific requirements, which are different from those of the young and working population. The older adults at this stage of their life have to adapt to living alone in a process of transition that can be painful for those who were used to living with their family or other people.

It is necessary, however, to distinguish between two types of ageing people, those self-sufficient, for whom it is important to provide for integration policies at various levels (city, home, neighbourhood) and those not self-sufficient for whom continuous assistance from caregivers is required. In this paper, we will consider the needs of the self-sufficient elders falling within the state of "active ageing", defined by the World Health Organization "*a process to optimize opportunities related to health, participation and security in order to* *improve the quality of life of older people*" (WHO, 2002). With this intention, WHO has outlined a strategy with the aim of creating and strengthening the conditions for an "active ageing", which is based on three fundamental pillars: Health, Participation and Security. The goal is to foster the transition from policies, based on the needs of older people considered as passive subjects, to policies that recognize every person his right and responsibility to take an active role and participate in community life in every stage of life, including old age. This strategy requires major changes in health, social and environmental systems, in order to improve their effectiveness and efficiency.

The proposal presented in this paper, therefore, is to provide "smart care networks" that simplify and improve the lives of this category of users starting from the redefinition of the home environment and connecting it with the neighbourhood and the rest of the city through the use of ICT technologies.

State of the art: environment for self-sufficient elders

In order to respond to the older people’s needs in a more extensive manner and to improve their autonomy and quality of life, it is increasingly important to find solutions through both “passive and active technologies” (Zallio and Casiddu, 2016). The “passive technologies” collect all the architectural characteristics that an environment must have, to meet the needs of a constantly growing population; the “actives” refer to the technological devices that can help the ageing population to live a safer and more connected life.

The following are examples for both cases: the most common housing typologies currently in use for the self-sufficient elderly and some international examples of smart technologies, tested in pilot projects, able to connect the house with the city.

Current housing typologies for the self-sufficient elderly

The residential options for self-sufficient people are currently the following:

- Collective housing managed by companies.
  They are exclusively residential complexes for the elderly in which the services are centralized and managed by the responsible company. Often in these contexts, both due to the high concentration of marginal situations in which the elderly find themselves, and for the lack of active life, problems of loneliness and physical and mental decay are accentuated.
- Houses in residential complex integrated with services (cohousing).
  These typologies represent an independent and voluntary choice of a way of life within a small community, preserving autonomy and remaining inside a partially protected environment. The integrated residential complexes have already been designed to offer mixed housing, suitable for both the elderly and other users (young people, students, etc.).
  Essential conditions for a co-housing are:

- it must be designed and built on the basis of a project shared with the future users in order to meet their needs (participatory design);
- it must have collective spaces for functional activities to develop a sense of community and stimulate relationships among residents;
- it must be organized and managed according to a set program of activities shared by the residents themselves.

Co-housing then allows to have an individual life in private accommodation enjoying the same advantages of community life, thanks to equipment enabling collective life and a fully shared daily management system.

This typology is very common in the USA and the North of Europe, however it is not traditionally recognised in other countries, such as Italy.

- Living alone or with a family

The elderly who are still in good health can live alone. However, reduced abilities often require older people to make changes in their living environments moving to a more supportive location, or to their family.

Smart applications for the elderly: some examples

Many studies reported that the use of information and communication technologies (ICT), such as computerized health device, home computers, Internet and other communication devices could help elderly people to improve their quality of life, as well as facilitate cost-effective care by both formal and informal caregivers (Heart and Kalderon, 2013). The ICT – based solutions can help old people to participate actively in community activities and to reduce social isolation. Therefore, ICT can be useful to improve the existing housing models, based exclusively on the passive technologies, converting them into smart housing.

Some examples of new applications for smart devices planned for the elderly are:

VINCLES Barcelona Care Net[1]: the project of the Barcelona City Council that won the first European edition of Mayors Challenge. The project is an application for mobile devices that will help elderly people to keep in touch with their circle of relations and with social or health care services. Family, friends, public sector employees and volunteers will be connected with each other and with the user, who will be able to select who they want in their network. The system will be available to elderly people who live alone, and to people who have some physical or mental limitations. Given the user profile, a very simple design has been selected that is easy to understand. *Vincles BCN* will extend the network of municipal support for the elderly. The programme's main innovation is that it combines public and personal care.

SOCIALIZE[2]: a hardware/software platform able to put the elder users in close contact with the community they live in through the use of new technology implemented in the elderly day by day context. The platform offers information and entertainment content geared to the needs and interests of elderly people. This contents will be provided in a barrier-free and user friendly way tailored to the age group and to different SOCIALIZE devices.

STIMULATE[3]: a platform which enables seniors to specify their assistance needs, to plan a trip, to optimise transport means and itineraries, to be provided with personal assistance while on the move, as well as to obtain local shopping recommendations and assistance. Advanced knowledge based on GIS technologies will be used for processing and personalising seniors' travel and shopping requests, optimising transport itineraries, providing travel assistance and securing health care support.

Smart houses for the elderly: some examples

The term "smart house" is generally used to refer to a modern house that combine innovative housing typologies with smart devices. A number of researchers have stated that the main

[1] http://www.ub.edu/senesciencia/noticia/1503/

[2] http://www.aal-europe.eu/projects/socialize/

[3] http://www.aal-europe.eu/projects/stimulate/

focus of smart housing design should be the development and the application of embedded advanced technologies in order to improve the quality of life, autonomy and a sense of security for the elderly and the disabled (Chan et al., 2009). Many examples of worldwide case studies, mostly experimental laboratories, take on the challenge of integrating ICT systems with the design of the house in a very high-tech approach (GhaffarianHoseini AH., 2013). In most cases, experimental and monitoring projects improve the comfort, communication, safety and health control of occupants through the analysis of their needs. Furthermore, some examples also focus on the social aspect, using ICT to connect the house with the community as shown below.

The Aware House (USA) is a living lab created by The Georgia Tech Broadband Institute Residential Laboratory based on the human-centered design approach. The promoters believe that "*the development and careful placement of appropriate technological support that can empower older adults to continue living in their own homes longer. They specifically focus on the effects of declining cognitive abilities on independent living, and the role information technology can play in augmenting those capabilities*"[4]. The principle of the house starts from the idea that living environments must be 'aware' of their inhabitant's needs and activities. It is based on ubiquitous computing that senses and recognizes potential crisis of users. Likewise, the University of Florida develops an intelligent lab-house, The Gator Tech House[5], to assist users with special needs and the elderly to enhance their quality of life. Many smart furniture and devices designed for comfort and energy efficiency, safety and security, activity monitoring, reminder/prompting technologies, fall detection systems, communication devices and biometric technologies (weight, temperature), create an environment that can assist and support the users. Several projects aim to maximize the use of active technology for assisting and monitoring the elderly at home. Infrared sensors can be associated with one or more activities: working in an area, having a meal, etc.

Some most recent examples based in the USA and the North of Europe have expanded the smart concept to the whole building and even to the outdoor environment enhancing the social aspect of life. For instance, in several UK, Dutch and Sweden residential housing settlements, the relationship between private and common spaces is one of the main goals of the project enhancing the quality of life of old adults.

From the state of the art analysis, the use of smart houses involves different benefits reducing the number of adverse incidents, providing support for conditions such as chronical illness and compensating individual's functional limitations. The main advantage of the smart house is that it allows the elderly to stay in a familiar and comfortable environment, realizing the goal of aging in place. However, if by one hand smart home technology can reduce social isolation due to the sense of security from having someone monitoring one's status, by the other hand can contribute to disconnect people from society. "*In trying to promote autonomy, we may end up promoting isolation. In keeping people in their homes past the point where they can interact with the community, we've essentially put them under house arrest*".[6]

From these considerations, our research question arises: how can smart homes solve the problems of elderly disconnection from society? We tried to answer the question through the proposal of a "smart care network".

The “smart care network”: a proposal for the elderly of 2030

A kind of invisible “smart care network”, supported by ICT, unites the places of their everyday lives in a physical and virtual manner, enabling independent elders to simplify their way of life and avoid being a burden to their relatives. It would ensure services of autonomy and personal safety, as well as the physical and psycho-emotional wellness in a Smart Living Environment. The “smart care network” covers the two different dimensions of house/building and neighbourhood/city, and should permit the elderly modern technologies and services to enable them to lead an independent, up to date, but simple lifestyle.

In the last two decades, ICT has revolutionized our lives in term of access to information. However for elderly people the “digital barrier” still remain. Many researches has demonstrated that nowadays most of the “over 65” are not yet ready to take advantage of what the digital world offers (Warschauer, 2004). This “digital divide” will be solved in the next decades as the future older people will be grown in the digital era. Our “smart care network” is thought for this category of users.

The aim of the proposal is to design, implement and validate an innovative way of considering the elderly of the future (people born from the 1960s) and their needs.

The idea is to redefine the living environment by designing it on the basis of lifestyle habits, the degree of autonomy of the individual and personal needs. The home is connected both to the neighbourhood and to the city providing a link with: the community of other users with similar problems and needs, the health and social care infrastructures, local medical clinical centres, recreational activities and various other services. Fig. 1 shows how the innovative elderly living model can work. The elderly’s space is not only limited to the ‘home’ which, even if highly smart, can cause isolation. However, the interaction between “passive” and “active” technologies helps to break physical boundaries extending the ‘home’ to the whole city. Thus, physical distance is reduced by active technologies, prolonging ageing in place, where the ‘place’ includes the whole community.

The main needs of the elderly, as the literature shows, can be divided into three categories:

- psychological and physical well-being
- social interaction and self-sufficiency
- safety, security and accessibility.

Psychological and physical well-being are closely related, and the link becomes more important at the older ages with the increasing of chronic illness. As life expectancy increases and treatments for life-threatening diseases become more effective, the issue of maintaining well-being at advanced ages is growing in importance. There is an increasing research literature which suggest that psychological well-being may even be a protective factor in health, reducing the risk of chronic physical illness and promoting longevity. It has also been argued that psychological well-being should be addressed in measures of health valuation, and be considered in health care resource allocation.

Social interaction plays an important role in elderly people's life and new technology can help older people to maintain social contact, interact in new ways with family and friends, engage actively in their communities and share learning, skills and experience with others. The integration of ICT in the home and the urban environment can improve the social inclusion which helps older adults to maintain good physical and emotional health and cognitive function.

With regards to the safety and security needs, it is recognized that older adults are more susceptible to accidents and injuries than younger adults because of internal and external factors. Internal factors include the normal physiologic changes with ageing, increased incidence of chronic disease, increased use of medications, and cognitive or emotional changes. External factors include a variety of environmental aspects that present hazards to older adults. For these reasons, it is important to make homes and cities safer, through customized services and the use of new technologies.

Our "smart care network" try to satisfy those needs through the use of the active technology (upper part of the diagram of fig. 1), the passive one (lower part of the diagram of fig. 1) or by combining the two. For instance, a smart application can be used to do activities outside the house or to connect the user with other places/people whilst staying home.

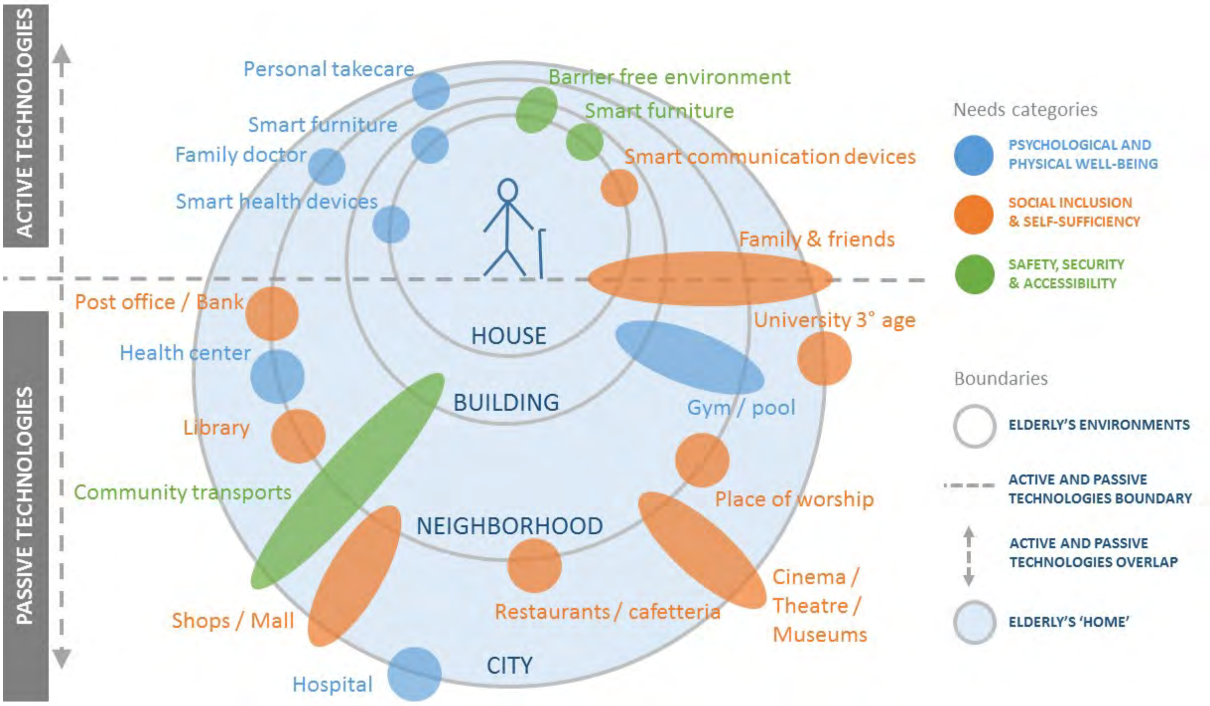

Figure 1. "Smart Care Network": an innovative senior residential model based on the integration of active and passive technology to fulfil the elderly needs and requirements.

The "smart care network" at the house/building level

A residential model for the ageing society based on the "smart care network" represents an alternative model to the elderly independent living often subordinate to the family's structure and needs and very common in countries like Italy and Asia. The experimental task of the proposal consists of an apartment for 5-10 older people aimed to improve their self-sufficiency. Users can make use of private spaces (room, toilet, kitchenette), semi-private spaces (living room, kitchen, dining room, laundry room, sickroom, outdoor green space) and semi-public spaces open to non-residents too (gym, coffee shop, playroom, place of worship, garden, terrace, etc.). Table 1 shows how the residential model aims to fulfil the three main elderly needs at the house/building level.

Table 1. Needs and strategies of the residential model based on the "smart care network" (house/building level)

NEEDS CATEGORIES	STRATEGIES AT HOUSE/BUILDING LEVEL
psychological and physical well-being	• smart furniture connected with the family doctor to monitor and support the elderly (ex. activity monitoring floor or mirror, infrared sensors); • smart devices such as a personal trainer board or wearable ICT objects for fitness and games which can stimulate mind and body; • specific applications for smart phones which help people monitor individual health problems;

	• the presence of a fitted outdoor space enhancing the quality of life and health benefits.
social interaction and self-sufficiency	• smart devices such as a personal trainer board or wearable ICT objects can help daily planning to encourage the elderly independency; • specific applications for smart phones allow the elderly to share special information, activities and events present in the apartment/building with a small group of friends and relatives;
safety, security and accessibility	• conventional house furniture is designed to satisfy elderly needs in ergonomic, flexibility, simplicity and safety terms from a shape, colour and material point of view; • the addition of smart furniture can optimize the home safety and accessibility (ex. activity assisting floor or mirror, infrared sensors).

The "smart care network" at the neighbourhood/city level

Users can join activities offered in the neighbourhood and the city from their home with the support of cooperatives, the municipality or other social agencies. In the same way, the three main elderly needs are taken into account at the neighbourhood/city level as shown in Table 2.

Table 2. Needs and strategies of the residential model based on the "smart care network" (neighbourhood/city level)

NEEDS CATEGORIES	STRATEGIES AT NEIGHBOURHOOD/CITY LEVEL
psychological and physical well-being	• smart street furniture for fitness and games can stimulate mind and body; • the proximity of a garden enhances quality of life and health benefit;
social interaction and self-sufficiency	• specific applications for smart phones allow the elderly to share special information, activities and events present in the neighbourhood/city with a small group of friends and relatives; • a small group of users can share useful collective services such as minibuses, concierge services, food delivery, private laundry, dog sitters, etc.
safety, security and accessibility	• the amount of economic intervention required by the city and social associations is less than in conventional assisted living situation.

Outlook and discussion

Our proposal aims to create a connection between smart homes, neighbourhoods and cities through ICT use, in order to answer to the specific needs of the ageing population to support independent elderly living. Understanding the needs of users is therefore crucial in order to offer the most appropriate service. However, elderly users are not a homogenous group and their needs vary significantly according to socio-demographic characteristics, gender, socio-economic differences or cultural area. In order to fill these gaps, one of our next objectives will be to make a more complete and detailed study of the user's profile which could help to create a needs-oriented approach for service development.

Further developments of the project require the collaboration between the property owners, the associations dedicated to helping the elderly, the older adults' communities and the industrial/research partners in order to define a complete framework of requirements and recommendations. The humanization principles as well as testing the functional, technological and economic adequacy of spaces are top priorities.

Conclusions

The new elderly living model aims to identify opportunities for experimentation in housing models as a valid alternative to health care residences and cohousing. The new objective becomes defining a new lifestyle model for senior people in a non-intrusive, customizable, adaptive and sustainable way. The proposal, mainly addressed to the elderly grown in the

digital era, should start from pilot case studies to develop, as ultimate aim, a widespread model for the next future (i.e. from 2030).
The proposal could also be an excellent solution for many older adults who do not wish to leave their accommodation, which could therefore be shared with friends, relatives or other people interested looking for a place to live. It can also be a dwelling situated in a traditional building, which would be renovated in order to be fully accessible and equipped with home automation systems and special assistive technologies.

Users lead an independent life, which can be supported at distance, through technological monitoring, or directly, through periodic visits, by private operators or active volunteers participating in the personalized care plan. These solutions can also have a great impact on reducing health care costs in the medium to long term, as they reduce the institutionalized hospitalization.

Hence, the aim of the proposal is to ease and improve the elderly's quality of life, giving solutions by connecting different environmental dimensions (house/building and neighbourhood/city) and combining active and passive technologies, in order to promote aging in place and avoid social isolation.

PLEA 2017 EDINBURGH
Design to Thrive

The Almshouse Reimagined: challenging students in creating community

Alison Pooley[1] and Annabel Brown[2]

[1] Department of Engineering and the Built Environment, Faculty of Science and Technology, Anglia Ruskin University, Chelmsford, United Kingdom, alison.pooley@anglia.ac.uk;

Abstract: For the past three years the authors of this paper have run a design project for second year architecture students entitled the Almshouse Reimagined. This collaborative project was proposed to studio tutors by a local almshouse charity to engage the next generation of architects in the social, political, and economic landscape of housing. The Almshouse Reimagined brief challenged students to rethink housing by designing a prototype Almshouse for Essex, questioning the housing needs of the local and wider community, and considering the opportunities presented by an ageing population. The challenge of the brief for second year architecture students should not be underestimated. The project constraints varied over the three years as did the site, a key constant being how do we create opportunities to build community. This paper explores how, through examining the almshouse typology in the early stage of their education, students are engaged in the pressing issues of our time, housing and the ageing population, whilst designing affordable homes that are protected from the ravages of the free market rented sector.

Keywords: Almshouse, community, housing

Introduction

On a cold day in early February 2015 second year architecture students studying in Essex were introduced to their design project brief for the forthcoming semester –The Almshouse Reimagined, a collaboration between the local school of architecture undergraduate course and the newly established almshouse charity, the Legacy East Almshouse Partnership (LEAP, n.d.). LEAP were keen to engage local architecture students in a design exercise that explored a prototype almshouse for Essex. Having a prototype almshouse presented the charity with an opportunity to use the proposals to test new sites with new communities and local planning authorities. For the studio tutors is represented an opportunity to get students thinking and designing for a client with constraints that were tangible, whilst engaging in wider societal debates focused on an ageing population and the housing crisis. The latter being more pertinent and immediate for students.

During the three years of running the project, during 2015, 2016 and 2017, the students and staff worked closely with the chair, vice-chair, and trustees of LEAP but also with almshouse residents, wardens, and the local community. Creating community is one of the challenges of a brief such as this, and the students responded by creating opportunities for sitting with views out across landscaped areas, quiet pedestrian routes, places to meet neighbours or talk over the garden fence in communal gardens, allotments, and outdoor rooms for afternoon tea. Before expanding further on the project outcomes it is worth placing the almshouse in context, and outlining how it differs from other housing types.

A potted history of the almshouse

In his 1955 text, Godfrey (1955) sets out the history and development of the almshouse from the medieval hospital. He draws attention to their architectural merit as well as their social history describing almshouses as “remarkable buildings, provided from a remote period for housing the needy and the aged” (Godfrey, 1955: 7) and that they “seldom lacked architectural merit and some of them were magnificent monuments of design and craftsmanship” (Godfrey, 1955: 15). This is where most people place the almshouse, a small, often elaborately crafted dwelling forming courtyards or quadrangles or a neat row of two or three in a quiet country village.

The almshouse is not unique to the UK and shares its history with the hofje (small courtyard house) of the Netherlands (Wilms Floet, 2016), and with the beguinage of the Low Countries. The roots of all these sit in philanthropy. The medieval response to those in need manifested in cloistered hospitals with refectories, chapels and modest dormitories. This continued throughout the centuries, as the need changed the typology largely did not, almshouses retaining many similar patterns of development as the early medieval plan. By the turn of the nineteenth century provision of housing for those in 'need' had developed, and continued to do so through philanthropic acts and utopian ambitions such as those of Octavia Hill and Joseph Rowntree. This provision developed from philanthropy to local authority, and led to what we now know as 'affordable housing', which used to be called social housing, and prior to that was just good old council housing. Worpole (2015) provides a concise history of the utopian dream of a planned society and its housing in his essay for the Swedenborg society, this is given as a key text to each student at the start of the project.

The merit of social housing and the concept of 'need', or the idea of the 'deserving poor' is not to be debated here other than to acknowledge that almshouses did exert control over their beneficiaries, with praise to the benefactor at worship on a Sunday often being compulsory. Many of the almshouses had additional restrictions on lifestyle – no drinking, no men, no women – and often required the residents to wear a uniform. The Royal Hospital Chelsea (left in legacy by Charles II) still does, and retains 'hospital' in its title, connecting it to its medieval roots. Chelsea, as with nearly all almshouses, has a restrictive admissions policy. Restrictions on who is eligible to become a resident of an almshouse range from; age - over 50 (or over 65 in the case of Chelsea), geography – having to be resident in an area for a certain period of time, or occupation – housing for retired teachers, carpenters, seamen. These restrictions on allocation of the houses are often borne out of the legacy of the benefactor. The distinction between being a resident as opposed to a tenant is crucial in almshouses, where residents pay a contribution to weekly maintenance rather than rent, and the charity is a registered provider rather than the landlord. The significance of this is discussed later in terms of contemporary issues.

A commonality among almshouses is that they provide housing for those in need in perpetuity, providing security and an ongoing potential to build community connections. This need for security and community remains evident today, and not just in terms of housing. As Godfrey (1955) highlights, with a population of only four million the medieval built response to 'need' was astonishing when compared with government responses to the current housing crisis housing and a population at just over sixty-five million.

Three projects and three years

Given such a rich and long history, the opportunity to work with a local charity to explore the almshouse typology further through a student project was exciting, especially when cast against the backdrop of the current housing crisis in the rented sector, the ageing population, and increase in single person households. In 2016, around 7.7 million people lived alone in the UK, the majority were women (ONS, 2016). The students, in the second year of their undergraduate degree, were faced by social and community aspects of the projects, this embedded them in current issues whilst simultaneously calling on a 1000 year old history. This section outlines the three projects undertaken over the past three years, and provides a brief exploration of the main issues and outcomes.

Chelmsford 2015

The first year the project was based in Chelmsford, where a notional site was chosen to test the development of the prototypes. The site, just over half a hectare and used as a car park, was located due south of existing almshouses built in 1933. This site offered an opportunity to explore the reuse of a car park for housing whilst linking the new almshouses into the existing infrastructure and almshouse community. The students were able to determine the density of the development, what type of housing to explore and imagine their own scenario for the client, all within a guiding principle that each unit was to be approximately $55m^2$ in floor area to attract funding from the Homes and Communities Agency (HCA). Some students chose to look at intergenerational housing, addressing their own housing needs and those of the local student population. Other issues raised through this project concerned views out over a busy road, material use, energy efficiency, existing community, rebuilding the street, access and transport to the city centre, water reuse, gardening, food growing and the inevitable three Bs – bins, bikes and buggies – although in many cases the buggy was replaced by the mobility scooter. As this was the first time running the project with the client (LEAP) their budget restrictions were absorbed into the brief for the students, a tight budget of £70,000 per dwelling delivered. Projected costs were kept in check by final year quantity surveying students who met three times during the twelve week semester with the architecture students to discuss the budget and exchange design ideas. The outcomes of that collaboration were mixed in terms of success, with the design process curtailed for some architecture students as costs appeared to take priority over design for the quantity surveying students (Pooley et al., 2016).

One and two-story buildings were designed to make use of the site and to address neighbouring housing developments. Proposals had community at their heart, reinterpreting the traditional ideas of central shared space. The traditional courtyard arrangement remained a feature in many of the projects where units were situated around landscaped areas and captured the ambition to provide a safer site with no public right of way, another feature of courtyard housing (Wilms Floet, 2016). Safety was one of the key issues that arose out of the ongoing consultation with LEAP and the residents and wardens at the neighbouring almshouses. Students were conscious of the need to address this without compromising access and views.

The students' proposals for the first iteration of the project, run in 2015, were presented to the National Almshouse Association (NAA) at a meeting of design consultants, the students went on to present again at the Housing LIN Eastern Region meeting later that year. On both occasions the projects were well received and the students commended for tackling such complex issues early in their architectural careers.

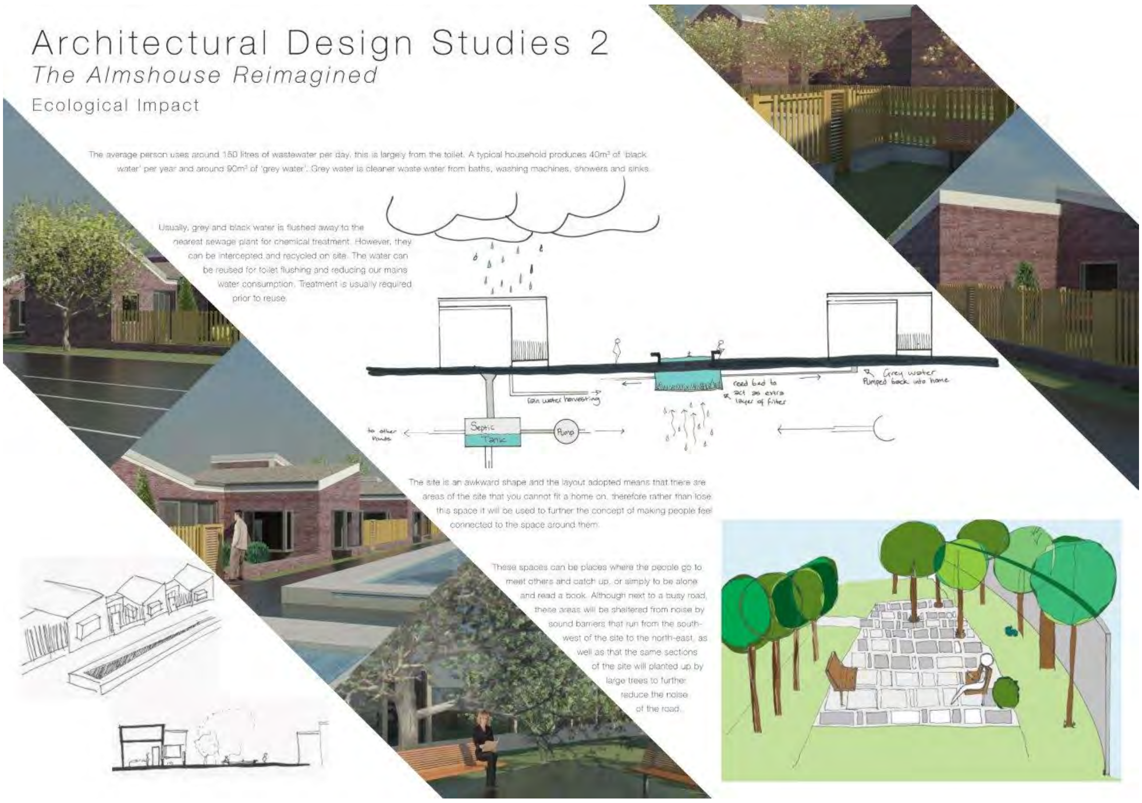

Figure 1. Student project for Chelmsford. Image: Jack Moloney

Colchester 2016

In the second year running the project the brief looked again at expanding an existing almshouse community. This time the issues were more complex. The site was a former bus depot, with a meter drop in level from the existing historic almshouses, with dwellings dating from 1791 and 1803 (and even older dwellings dating to 1678 across the road), to the new site. The bus depot had an existing planning application for student accommodation, and faced a reasonably busy road leading into the centre of Colchester. Once again LEAP acted as client, with the potential that this could possibly become a site for future almshouse development, rather than the fictional site used in 2015.

The restrictive nature of the budget in 2015 placed too much emphasis on keeping costs down, and curtailed creative exploration of housing types. In the 2016 iteration of the brief students were freed from budget constraints but given reasonable guidance from the client. The Colchester project also diverged from the original ambition in that this was a site specific project – not a prototype that could be located anywhere for the right price, inviting students to respond to the site and to knit the new almshouses into the existing fabric of Colchester, as well as the historic almshouses to the south. Issues that had arisen in the previous project – particularly those focused on mixed use and inter-generational living – came much more to the fore. One of the interesting questions that arose more through this project compared to the first year, was the nature of an ageing population. For students who were predominantly in their late teens/early twenties being over 60 or 65 seemed old enough, however if you were 65 in 2016 you were part of a generation that grew up on punk, and were probably still listening to it, you wanted to cycle, garden, go out, and have parties, have friends to stay as well as children and grandchildren. The project had to be about being active in an almshouse, as well as cater for the mobility scooter, or the potential of a mobility scooter in the future.

The response to this challenge, meshing old and new homes, old and new residents, old and new ideas about housing, onto a tight urban site whilst creating an oasis in the middle of a busy town, another feature of the Dutch hofje as well as the almshouse, demanded that students address issues of environment and sustainability beyond energy and materials, to consider what makes society, not only now but in twenty or fifty years. This is where the almshouse typology is useful, as it creates new visions for living in reasonably dense developments whilst looking towards exemplar models of community living that can be hundreds of years old, as with the almshouses adjacent to the Colchester site used in 2016.

Jaywick Sands 2017

The final project, and this year's iteration of the brief, was based in Jaywick Sands, Essex. Jaywick Sands has its own quite unique history, drawing on the utopian living experiments of other nearby communities of Essex (Worpole, 2015) as well as the arcadian vision of the plotlands movement and idealised rural living (Hardy et al., 1984). Jaywick has been heralded as one of the most deprived areas of the UK, and recent television programmes have focused on the less salubrious aspects of the seaside town. This project offered the most potential to actually get built as LEAP, once again acting as the client for the project, successfully secured a development site through the local authority.

Figure 2. Students and community discuss housing issues over lunch.

As in the previous two years, the students met with the local community, spent time with them at the lunch club in the community centre, and broke down some barriers (on both sides). As well as the social and economic pressures in Jaywick Sands there are the additional constraints of marshy land and developing below sea level with a risk of flooding. The site varies from the previous two projects in that it is a green field site but still has complex constraints. As the Jaywick Sands project matured so did the collaboration between our academic pursuits and the potential for the project to become a live project, for the student work to feed into the community and for all involved to realise the original ambition. Jaywick Sands raised the most controversial questions in terms of creating community, the view that we can design out certain behaviours or design in others harks back to the control and patronage of historic almshouse benefactors. Raising critical issues of how we design, who with and who for, and what potential environmental, social and economic futures can we address.

Implications for pedagogy and practice

> We spend our lives in what were once the thoughts of architects. Today's thoughts make the world of tomorrow – an awesome responsibility (Day, 2004: 283).

As Day states above, there is an awesome responsibility in creating tomorrow's world, and one second year architecture students faced. Understanding the history and development of housing places that responsibility in its historic context, one that threads from the monastic communities of the middle ages, through the therapeutic communities of the twentieth century, to the present day via Victorian philanthropy and the Thatcherite commodification of home through the right-to-buy (Worpole, 2015).

One of the issues returned to again and again through all three projects is the importance of proximity to neighbours, knowing your neighbours and allowing those happenstance moments, the face-to-face interactions that build and maintain community. The almshouse has a human scale, and even though they are often small compared to other types of housing, residents are forgiving of them, they like to live there (Pannell et al., 1999), they also have potential for releasing development land, exploring new ways of funding and providing 'social' housing in perpetuity. Almshouses are not subject to the right-to-buy and it is hoped that they never will be. As Godfrey wrote over sixty years ago:

> it must be generally recognised that almshouses are performing a really useful function in the community, and all who value our art and history will agree that their preservation is a matter of real moment (Godfrey, 1955: 87)

Themes reoccurred over the three projects, through different sites and different constraints and challenges. One of the issues for us as educators with a keen eye on the future of the built environment, is how these projects feed into the development of the future professional. This is almost impossible to capture, but what is possible to identity is the reflective process students went through during the project. As they explored the needs of almshouse residents so they also explored their own needs, their family relationships, questioning what their grandparents would want, as well as what they might want when they are older. In this way the project has additionally become a personal reflection on the meaning of family and home, of social and emotional space as well as physical space.

There is a diversity amongst the students, different backgrounds, experiences growing up in different countries, and this has created a richness in the debate in the studio – who are we being architects for, are we designing for or with the community, what is the nature of home? These questions push the original agenda for LEAP and for the students, and offer an opportunity for inter-generational learning. There is a propensity in learning and teaching for students to become product focused rather than process focused (Sterling, 2001), placing an importance of the qualification or grade over the experience. Engaging in community based projects, in this case housing focused, and encouraging reflection on the process, learning retains the possibility to be process focused, generating a social learning as well as an environmental and ecological one as students recognise the importance of community, space to meet, gardens, places to sit, proximity to nature, creating opportunity for happenstance (Jones et al., 2012).

Figure 4. Proposal for an elevated pausing place for Jaywick . Image: Chris Theobald

When the students presented to the NAA in 2015 it was the first time architecture students had presented at that meeting, or to the NAA generally. Presenting at the meeting developed the students confidence far more than presenting in the studio, under more normal review conditions, would have done. The challenge for almshouse charities and the NAA is to how to bring forward the model in a way that meets the current demand for high density and high-rise living (Pannell, 2013). The debate is currently all too often focused on smarter living in smarter cities. There is no argument here for a return (?) to a William Morris style utopian dream, where we live with almost no furniture and have to forgo servants due to our small houses.

Future housing needs to be adaptive and responsive to changing needs, allowing for those downsizing, but still providing space for visitors. There is an argument for a focus on the person within the city, and retaining that focus will enable issues of health and well-being to be more fully addressed in future planning. There have been good examples of the almshouse remodelled for the twenty-first century, as well as an increased number of community projects getting planning permission for co-housing projects. However these projects, as with shared ownership schemes, still rely on a capital investment, something that the almshouse will never require from a resident.

Conclusion

> In the end there is no escape from architecture, no matter how modest or improvised. Behind any social arrangement there is a physical structure, a location and a landscape as well (Worpole, 2015: 56).

This project requires longer than one semester to explore, the complexity lending itself to a postgraduate project rather than an undergraduate one. Students experiencing working with a client for the first time can be restrict and guided or misguided to producing what the client appears to want or is already familiar with, rather than questioning the client, the brief, and the ambition of the project. This too is a consequence of asking students early in their career to tackle complex issues, understand a different community, a different generation, and even a different culture. A criticism of the project is that students have to tackle too many of these previously un-encountered issues. However by facing these issues they in turn reflected on their own position now, as well as their future role as an architect.

The challenge of this brief for second year architecture students should not be underestimated. However the reward of engaging with a real client to tackle a growing area of concern for all those involved in the built environment should also not be underestimated.

Living with dementia condition in modern cities. Does urban renewal help vulnerable ageing population today?

Eleni Tracada[1]

[1] Department of Mechanical Engineering and the Built Environment, College of Engineering & Technology, University of Derby, Derby, United Kingdom, email E.Tracada@derby.ac.uk

Abstract: Current debate on ageing in urban environments focuses on how designers and planners develop age-friendly cities or communities. Since 2007, World Health Organisation has been supporting "active ageing by optimizing opportunities for health, participation and security in order to enhance quality of life as people age"; a global network of age-friendly cities has been launched and city councils are now engaging with local communities to transform urban areas into healthier and fully inclusive places. In 2014, the National Health Service (NHS), UK published their Five Year Forward View for three health, care and financial gaps to be closed. The NHS is currently running a new pilot long-term partnership with five cities' areas to develop healthier neighbourhoods by modernising services and integrating health and social care with welfare, education and affordable housing. The author of this paper and her colleagues formed a special cluster at their University to review recent national and international initiatives, such as the ones mentioned above. Their intention is to evaluate case studies and proposals related to ageing population with special needs and conditions, such as dementia, and apply innovative ideas of integration of arts not only in health places, but also in deprived neighbourhoods.

Keywords: Active ageing, urban renewal, dementia condition, health and social care, inclusive neighbourhood plan

Introduction

A year ago the author was invited by academics/colleagues from the College of Health and Social Care at her University to take part in initial discussions and presentations of ideas to be eventually developed as near future research projects. After two-three initial monthly two hour sessions, a cluster of researchers from a various disciplines was formed with interest in arts, architecture, social care and health (gerontology). Some participants were related to external organisations and/or attracted and brought in the cluster other people working or being involved with charity and arts' organisations, such as dementia carers' organisations or special theatrical groups often performing at the University dedicated theatre or other performance spaces run by local organisations, such as Déda (See further below). At the moment the cluster is known as an interdisciplinary group of people with the provisional title *Arts in Health: Arts in Dementia/Arts and Social Gerontology Research Cluster*. During the monthly sessions, the cluster coordinator and other members engaged in individual presentations of own research and experiences in previous years; these activities offered to all members of the cluster the opportunity to identify themselves in some particular research directions; a subdivision into four groups/work packs occurred with specific areas of interest. All four work packs are going to seek funding and develop project ideas related mainly to Arts and Health/ Dementia life condition. The four work packs have got provisional names:

Carers/Places and Spaces, Giving Voice, Intergenerational Aspects & Integrated Care and Participatory Arts as a Public Health Provision.

The author is co-Leader of the work pack called *Carers/Places and Spaces* with area of interest mostly on the following:

- Making the lives of carers better;
- Families for those cared for;
- What would self-help look like in relation to people with dementia;
- Performance & Spatiality (happening in space);
- Interactive/creative neighbourhoods.

Before starting writing specific bids, the cluster decided to spend more time and get involved in some initial activities and investigation on Dementia and Arts impact on people living with this condition. Last year, for example, the author and her colleagues had the opportunity to participate to a taster and consultation event on Arts and Dementia organised by Déda. They were invited by the Head of Dance Development & Learning of *Déda*, initially named as *Derby Dance* in 1991 and established as a local dance development agency based at Derby Playhouse. They became one of the first national lottery funded capital projects to move to new premises in 1997. The name of the organisation changed to *Déda* in 2008. This is the only dedicated dance house in the East Midlands region, acting as a local, regional and national resource for dance artists and the wider arts community. In their mission statement we find that:

> Déda's mission is to deliver an exceptional programme of dance, contemporary circus and outdoor work to as wide an audience as possible and be recognised for our outstanding contribution in the field of Dance Development and Learning.

(Déda, www.deda.uk.com, on 13/04/2017)

The author and her colleagues had participated in indoors and outdoors activities in which they tasted dance with people living with Dementia and their carers; they had the opportunity to get the feel of the project and understand the importance of participatory arts as public health provision for older people in the community and their carers, too. This particular experience led to decisions of integrating arts in the ordinary lives of both carers and people with Dementia condition in *Carers/Places and Spaces* work pack. The author's experience gained during this event also reinforced her belief that providing the conditions for free human flows in spatiality (happening in space) is more important than just designing spaces or places according to regulations only or being enclosed by rigid borders which are highly restrictive for people with special needs and conditions. Codes or signs of directions in urban spaces should be based mainly upon the principles established by the living conditions of the people rather than rigid grids and geometries. The author's experiences in urbanism and ongoing cooperation with experts in this discipline has affected her recent research projects and proposals enormously.

In December 2016 the Arts in Health: Arts in Dementia/Arts and Social Gerontology Research Cluster held a meeting during which a special workshop took place: a *Dementia Friends Information Session*. The session was delivered by one trained volunteer or Dementia Friends Champion and, at the end of it, all participating members of the cluster, including the author, became Dementia Friends (an Alzheimer's Society initiative) and created an account by registering at www.dementiafriends.org.uk; all members filled the *action mailer* and pledged an action. The author and her work group *Carers/Places and Spaces* pledged to campaign for change through teaching and research activities related to innovations not only in housing and services, but also in urban places; the aim is to improve the lives of people with dementia as well as the lives of the people caring and assisting them. This pledge was prompted by the Dementia Friends Information Session during which all cluster members learnt that *"dementia is not a natural part of ageing … it can affect thinking, communicating and doing everyday tasks; it is possible to live well with dementia; there is more to a person than the dementia"*(Leaflet: *Welcome to Dementia Friends*)

Case studies investigated to date - Discussion

The Carers/Places and Spaces group had also separate meetings to discuss details on research viewpoints and opportunities for funding. In August 2016 the author was asked by the cluster to present some inspiring case from the past; she created a presentation on *Historical past of hospices in Florence*; the presentation showed a historical route/path through the hospices/hospitals of Florence which is still working through the Santa Maria Nuova Hospital as urban connection and walk through. This particular communication path was once meandering unobstructed along piazza porticos, internal courtyards, through buildings and along corridors in order to connect ordinary people and their daily routine activities, such as markets and arts production, with healing places, such as the Santa Maria Nuova Hospital; the author revealed how art from the *Academia del Disegno* has been incorporated inside one of the oldest hospitals in Europe (founded by religious orders during 12th century) and how this integrations of arts has been contributing to carers and patients wellbeing.

Then, the author and her group carried out research on available literature and relevant publications and especially on latest developments on ideas and proposals for inclusive designs of entire neighbourhoods and inner-city or suburban areas as national and international projects. Thus, a first important document of great significance appeared; this is document published by the National Health Service (NHS) in England in July 2015: the *Forward View into Action*: Registering interest to join the healthy new towns programme. It is stated: *"The ambition of this programme is to go beyond existing good practice, developing new and creative approaches that offer the potential to make a substantial contribution to closing the three gaps* [health gap, care gap and financial gap]*"* (NHS, www.england.nhs.uk, on 14/04/2017, p2).

In this document mentioned above, we find that: *"Many areas already promote health and wellbeing through "place-shaping", including through better housing and urban design, and access to well-designed public spaces and facilities"* (NHS, www.england.nhs.uk, on 14/04/2017, p2). However, according to earlier discussions between local authorities and the NHS in 2014, these considerations were found not sufficient to tackle some important issues.

Thus, the *Forward View into Action* document in 2015 defines clearly the three core objectives as follows:

a. To develop **new and more effective ways** of **shaping new towns, neighbourhoods and strong communities** that promote health and wellbeing, prevent illness and **keep people independent**;

b. To show what is possible when we radically rethink how **health and care services** could be delivered, **freed from the legacy constraints** (i.e. existing services) that operate in other areas. This will support the **New Models of Care programme** by adding to the learning about how health and care services could be integrated to provide **better outcomes** at the same **or lower cost**;

c. **To accomplish the first two objectives in a way that can be replicated elsewhere**, making learning available to other national programmes as well as other local areas. (NHS, www.england.nhs.uk, on 14/04/2017, p2)

We have highlighted the most important points in the objectives above in bold fonts, because in our work pack we need to focus mainly on new radical models of care which will be integrated in new ways of designing and modelling not only new towns, but also renovating, or better, revitalising existing often rundown neighbourhoods in order to create strong communities of people of all ages and, especially keeping ageing population independent, without unnecessary constraints and barriers. All people should be cared to keep active whatever their conditions are, because, as Dementia Friends, we are fully aware that dementia is not a natural part of ageing; ageing population is mainly concerned about urban and housing designs that they may not offer them independence first and low costs of living.

In the 2015 *Forward View into Action*, NHS states that they cannot accomplish their three objectives above alone. Therefore they have invited areas with imminent population growth and housing needs to work with them to develop few *"radical new approaches to shaping the built environment"* (NHS, www.england.nhs.uk, on 14/04/2017, p3). We are citing here the first, third and fourth points on conceivable approaches, as stated in the same document, as we think that those should be also points of consideration to be encompassed into our own ideas and proposals:

- Building healthier homes and environments that support independence at all stages of life. We would like to explore new ways of integrating housing, care and communities to keep people independent and in their own homes. For those who do need support, more innovative residential care facilities may be combined with flexible housing options and step-up or respite care.
- Implementing a new 'operating system' for health and care that achieves "triple integration" between primary and secondary care, mental and physical health, and health and social care. This means developing a flexible health and care infrastructure that is linked to specialist care when needed, but provides many more services in the home, in primary care and alongside other public services. This infrastructure would also provide a strong platform for people to manage their own health and care, together with their peers and the voluntary sector, by making the most of mobile and digital channels.
- Creating connected neighbourhoods, strong communities and inclusive public spaces that enable people of all ages and abilities from all backgrounds to mix. Examples include 'dementia-friendly' design or ensuring that public spaces include features such as public toilets or benches that can make the difference between people being able to get out and about and being confined to their homes.

(NHS, www.england.nhs.uk, on 14/04/2017, p3)

At the time of this call in 2015, the NHS was seeking to establish some ambitious partnerships with local areas through which to develop healthier neighbourhoods and towns. Thus, they have invited expressions of interest from sites across England which are going to consider developments at different scales (from neighbourhood schemes as small as 250 homes to sites of 10,000 homes or more). The expression of interest had to be through a two pages long form; a lead partner had to be identified for the proposal, as well as other key stakeholders, including the Local Planning Authority. Where lead partners are not local authorities or statutory planning bodies, then, they may be housing associations, NHS Trusts and Foundation Trusts, private developers and land owners. In the *Registration of interest for healthy new towns programme* form, amongst the four questions, we can find that Question 3 asks how the proposed scheme is going to promote health and wellbeing through the built environment and how the NHS could support the partnership to deliver their ambition. Conversely Question 4 asks if there are any opportunities to redesign how health and social care is delivered in the proposed development and, again how the NHS could support the partnership to deliver this (NHS, www.england.nhs.uk, on 14/04/2017, p7).

In a recent article Urban Design magazine by Daniel McDonnell, Strategy Programme Manager, NHS England, at first we find out that *Forward View into Action* was also announced in a publication of Town and Country Planning Association & Public Health England in 2014 (www.tcpa.org.uk, on 14/04/2017). The same author (McDonnell, 2017) affirms that the built environment is not a routine territory for the NHS, but, because of increasing numbers of ageing population living longer and often in poorer health, the NHS recognises *"an opportunity to ensure that homes and neighbourhoods promote wellbeing and enable independence. Planning and urban design can play a crucial role in achieving this"* (McDonnell, 2017, p22). He also affirms that, across England, local authorities, providers and commissioners of health and social care are currently planning how they will deliver services jointly for the future; it is also noted that this kind of partnerships are also putting together Sustainability and Transformation Plans (STPs) and that, NHS Healthy New Towns programme has now selected ten demonstrator sites from 114 expressions of interest, as it was announced in March 2016 (McDonnell, 2017).

Although in most sites we see that a lot of effort was made, for example, for "walkable and cycleable community" developments, such as for Bicester Healthy New Town (McDonnell, 2017, p23), very limited information is provided about health and social care. Bicester Healthy New Town is also promoted as an Eco-Town (Figure 1.). It is noted that in some Healthy New Towns programmes, such as Barton Healthy New Town, Oxford, for example, some demonstrators of new, joined-up models of care are being developed as form of health and wellbeing centres, where several services will be co-located. However, as Strategy Programme Manager at NHS England, Daniel McDonnell discloses that the NHS has major programmes in progress *"to make healthcare provision more efficient and to improve the experience of patients by redesigning and joining up healthcare services, such as through Multi-Speciality Community Providers (MCPs) and Primary and Acute Care Systems (PACS) models"* (McDonnell, 2017, p23).

On the other hand, McDonnell refers to Barton Healthy New Town as a housing development which is being used as a driver to regenerate and connect with the existing neighbourhood; he also refers to Barton's proposals to convert an existing neighbourhood centre into a Healthy Living Centre, whilst the Oxford's John Radcliffe Hospital will bring services from the hospital to be embedded within the community. However Layla Mc Cay's article in the same issue of *Urban Design* makes more connections with what we are interested as research group inside our Arts and Dementia cluster, although the author explains a more holistic view on Designing Mental Health into Cities. (McCay, 2017).

The same author affirms that often urban living is related to mental distress; she also insists that: *"There are four main factors in urban living which can contribute to mental health problems: pre-existing risk factors, disparities, overload, and loss of protective factors"* (Mc Cay, 2017, p25).

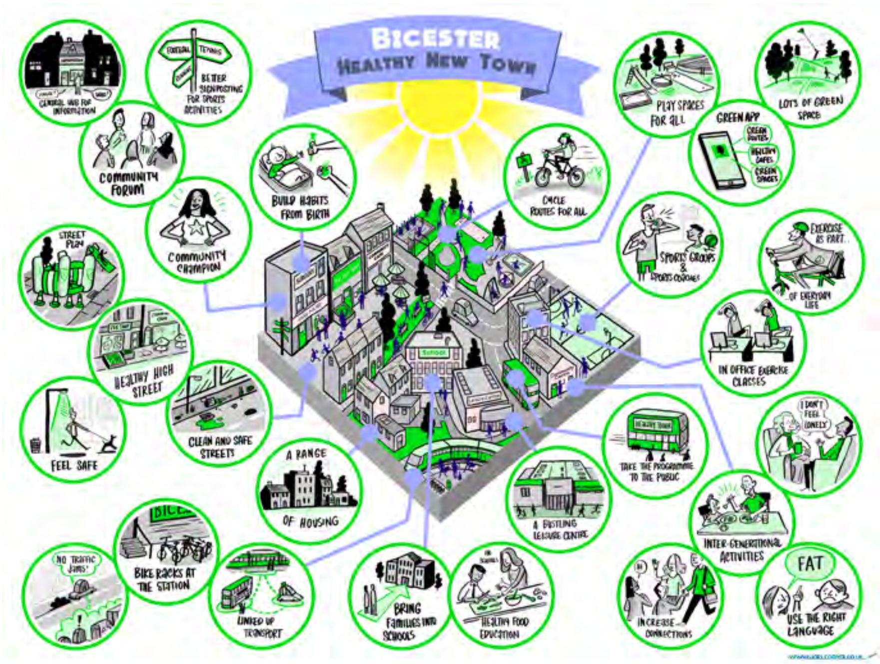

Figure 1. Stakeholders' visualisation of the programme for Bicester Healthy New Town (Source: http://www.oxfordshireccg.nhs.uk/your-local-area/localities/north-east/bicesters-new-healthy-town-programme/)

Layla McCay also refers to activity in daily routines which is one of the most important urban design opportunities for mental health. According to this author, exercise can *"reduce stress and anxiety, and help to alleviate some of the symptoms associated with ADHD, dementia, and even schizophrenia"* (Mc Cay, 2017, p27). By referring to creating pro-social places, McCay is convinced that urban strategies should *"facilitate positive, safe, natural interactions amongst people and foster a sense of community, integration and belonging"* (Mc Cay, 2017, p27).

Figure 2. New York City: An outdoor public garden courtyard hidden within the Noguchi Museum (Source: https://www1.nyc.gov/assets/ddc/downloads/DDC-Guiding-Principles-2016.pdf, p102)

Layla McCay is the Director of the Centre for Urban Design and Mental Health which was founded in 2015; this is a global think tank with main intend to explore opportunities to design better mental health into cities. This means that experts' and designers' main concerns should be towards better integration of urban design and mental health promotion, although this happens rarely in city policy making and planning. McCay praises only New York

City's *Design and Construction Excellence 2.0 Guiding Principles*, as one example, addressing mental health meaningfully. For example, on page 102 of the Guiding Principles (www1.nyc.gov/assets/, on 14/04/2017), we can see an outdoor public garden courtyard hidden within the Noguchi Museum in Astoria with the purpose to promote a design for Therapeutic Environments (Figure 2.)

Developing age-friendly cities is one of the main concerns of World Health Organisation (WHO) since 2002; three important publications/reports from 2002 to 2007 were produced and disseminated around the globe. In WHO *Global Age-Friendly Cities: A Guide* in 2007, we see that three issues require particular attention:

- First, recognising the diversity of cities and the implementations for the 'age-friendly approach.
- Second, developing new forms of 'urban citizenship' which recognize and support changing needs across the life course.
- Third, creating opportunities to involve ageing populations more effectively in the planning and regeneration of neighbourhoods.

(Buffel et al, 2012, p606)

Several authors (Buffel et al, 2012) believe that making cities more *age-friendly* will require radical interventions for involving older people as key actors in setting the agenda for future urban development; they should not be invisible in the implementation of urban regeneration, for example. It is also noted that there is need to develop strategies with awareness of contrasting issues faced by different ethnic groups, people with particular physical or mental health needs, etc.

Conclusion

The author and her colleagues in Carers/Spaces and Places group are currently considering and studying documents and reports produced for the Australian Housing and Urban Research Institute (AHURI) at University of Tasmania and University of Adelaide in June 2015 (AHURI Final Report No. 242). The main reason is that the author is currently engaging with and also working in a partnership action group with local authorities, housing associations for social and private housing, social workers, health services and other relevant NGOs in order to investigate on a rundown urban area in which issues related to all ages inhabitants have been identified. In particular, this area will be a pilot scheme for research and proposed solutions for intensive neighbourhood regeneration; an increasing ageing population with health and other problems, such as extreme poverty, has been identified in that area and mainly supported by youths often unemployed.

The author found out that Designing for Older People in the AHURI report (www.ahuri.edu.au, on 13/04/2017) and relevant attachments show that a variety of scenarios needs more inclusive interventions in housing and re-organisation of deprived areas. In the scheme to be piloted by researchers of the author's team and the local authority, there is a lot to be done as initial investigation at first, as many elderly people are still to be diagnosed for any mental health issues and other conditions, such as dementia. Whatever the condition, all people deserve to live well for the rest of their lives, including carers. Therefore, all our team has pledged for change starting from a small area and with intention to promote ideas at regional and national level in the next couple of years. This is not an ambition only; it is a professional challenge that we have duly pledged, as we are also planning to carry out extensive consultation with people with dementia and family carers by following the example of section 4 in the AHURI report mentioned above.

PLEA 2017 EDINBURGH
Design to Thrive

Co-production and Resilience in a Brazilian Social Housing: the case of Shopping Park Neighbourhood

Simone Barbosa Villa[1], Fernando Garrefa[2], Fionn Stevenson[3], Karen Bortoli[4]

Abstract: Current rapid social and climatic changes require urgent revisions of urbanization strategies globally, to reduce environmental and social impacts and develop the resilience of built environments. The poor condition of the architecture and urban situation of affordable housing in Brazil substantially affects the inhabitants of these developments. Despite this, people keep adapting their habitats, surviving the unexpected, and (re)inventing themselves according to their needs. This demonstrates their resilience, which is considered as an adaptive capacity to recuperate and regenerate from impacts (natural, social, physical). This paper presents the methods and results of the research "Adaptability and Resilience in Social Housing developments through Post-Occupancy Evaluation and Co-production[1]" as a project between a Brazilian and a UK University and a local community. This project engages with a Brazilian social neighbourhood named Shopping Park, where advanced Post-Occupancy Evaluation and Co-production techniques have been applied, aiming to co-produce knowledge about this social housing development. Data collected enables improvements on Shopping Park neighbourhood and future projects, in order to develop the resilience of families in social housing programmes and minimise social and environmental impacts derived from this sort of development in the future.

Keywords: Resilience; Adaptability; Co-production; Social Housing; Community; Post-Occupancy Evaluation.

Introduction

People are familiar with dealing with disturbances in the natural course of life around the world for many centuries, but there are distinctively modern phenomena underway now conditioning those events: urbanization, globalization, and climate change (Rodin, 2015). The current social and climatic changes require revision in urbanization strategies worldwide. Accelerated urbanization causes urban problems such as housing shortages, inefficiency of transport systems, inadequate disposal of waste and environmental depredation, among others. Climatic disasters are increasingly large, affecting urban systems (physically and socioeconomically) and involving major human and environmental losses. Such disasters

[1] Financed by Santander Research Mobility Awards (January, 2016 – October, 2016)

originate from a junction between the climatic event, predatory human activity and the vulnerability of what is exposed, namely the urban systems (IPCC, 2014).

In developing countries, the low quality of architecture and urbanism increase the social vulnerability, which afflicts particularly people struggling to purchase their own house, who end up living in precarious conditions. In an attempt to meet this deficiency, the low standards defined by government housing programmes, such as the Minha Casa, Minha Vida (MCMV) in Brazil, has led to the provision of inadequate housings for its inhabitants. Self-made interventions at the houses by residents, without any planning or technical assistance, risk their safety, waste resources and excessively burden the family income. Relating to the MCMC Programme, it is a government initiative to try solving the housing deficit by targeting a specific segment of the population, divided into social housing (0 to 3 minimum wages) and medium income range (until 10 minimum wages).

According to Villa et al (2013), the usual peripherization of these housing developments makes people dependent on motorised transport in order to access their workplace, educational and health facilities, among others. This scenario increases the negative effects of climate change due to the high rate of waterproofing the soil and the extensive use of non-renewable energy sources (Rubano, 2008; Rolnik, Nakano, 2009). These factors end up socially, economically and environmentally weakening people who benefited from these government programmes, making them more vulnerable to any impacts.

The resilience in social housing developments is related to the adaptability of the housing units to the impacts experienced. Their resilience is verified when the reaction to the imposed adverse conditions overcomes a state of perturbation. This resilience is further defined by the ability of a system to absorb changes, self-organize and thrive by increasing its capacity of learning and adaptation (Cumming, 2011). In other words, it is the ability of a community to adaptively respond to change rather than simply returning to a pre-existing state (Maguire & Cartwright, 2008). Resilience, however, needs attention in a context of accelerated world population growth, which reproduces unsustainable urbanization models.

Case Study

This paper presents the first results of a research project named "[RES_APO 1] Method of analysis of the Resilience and Adaptability in Social Housing Complexes through Post Occupancy Evaluation and Co-production", developed by the MORA housing research group from FAUeD, Federal University of Uberlândia/UFU and the People, Environment and Performance research group from The University of Sheffield School of Architecture. In order to understand resilience in social housing, it is necessary to first know the vulnerabilities and potentialities that characterize a specific study area. Thus, as a main contribution, this work discusses the resilience in Brazilian social housing developments based on a real case study involving co-production with residents and other actors

The *Shopping Park* neighbourhood is just south of Uberlândia city at Minas Gerais State in Brazil (Figures 1, 2). *Shopping Park* was chosen as the study area as the first site in Uberlândia chosen to produce over 3.000 housing units from the MCMV Programme, within the income bracket 1 (0 to 3 minimum wages) during the 2010-2013 period. Post-Occupancy Evaluation (POE) and Co-production techniques emerged as appropriate methodological tools to obtain socio-environmental and behavioural data as well as information about vulnerabilities and potentialities of the study area. The objective was to produce a concise database from the performance using a variety of tools, as summarized on Table 1. The overall aim was to outline the scenario of resilience at *Shopping Park* neighbourhood as well as to develop methodological procedures applicable to another contexts, in order to evaluate and improve their local resilience.

DIGITAL QUESTIONNAIRE
Description: Quantitative method collecting data from a series of questions answered by users. Recommended when there are a variety of people involved in an evaluation process. Its main advantages are: being quick; deals with a larger group of respondents and/or vast areas; impartial answers; anonymity allows safety and a great freedom of response; and greater uniformity in the evaluation. **Means:** Digital, through tablets taken to the study area.
WALKTHROUGH
Description: Quanti-qualitative method of analysis based on measuring and descriptions, and qualitative identification of positive and negative aspects of current environment. Includes measurement of climatic features, evaluating temperature, lighting, ventilation and acoustics on the unit scale. The analysed themes are: i) Surroundings, ii) Allotment, iii) Housing. **Means:** Script on paper and textual and photographic recording.

CO-PRODUCTION
Description: Qualitative and participative evaluation method where the impartial researcher works as a facilitator to co-produce management of space by all stakeholders. An alternative way to face unmet public demands and provide effective access to the city (Petcou and Petrescu 2015). A co-productive partnership between academics and non-academics can generate significant public benefits. **Means:** Script on paper, textual and photographic recording, meetings and group dynamics.

Developing the Tools and Techniques

Three central elements were analysed in the case study: (i) BUILT ENVIRONMENT (building complex, taking into consideration the scales of the district, neighbourhood and unit, and the relation of impact between the built and natural environments; (ii) AGENTS (agents that interfere with the local social dynamic); and (iii) USERS (residents of the complex). These elements were divided into 5 categories: general characteristics, climatic and natural order, physical-architectonic order, physical-urbanistic order and socioeconomic order.

From that division the most suitable tools were developed to collect information for each category. As an example, the physical-architectonic order was subdivided in 10 aspects to be evaluated: Design, Construction System and Materials, Maintenance, Services, Internal Layout, Adaptation and Refurbishment, Adaptation for Commerce, Comfort, Privacy and Previous Housing. For each one of these aspects, the required information was listed, for example “what are the main pathologies of the house?” or “what materials do the dwellers use on renovations?” on the Construction System and Materials aspect. The Questionnaire aimed to answer the first question while the Co-production would address the second one. Based on that mapping customized POE and Co-production tools were developed in order to collect information to properly portray the study area.

The evaluation as a whole intended to study the social, functional, behavioral and environmental issues of the built environment. Given the significant differences and specificities of the aspects to be analysed concerning resilience, the elected tools have been conceived to work complementarily. This multiple methods approach aimed to adjust any variances and inconsistencies in the obtained data as well as to strength conclusions when convenient or discard those less representative. This is because information collected through a single technique is usually seen as suspicious or even to present dubious results, since all methods have positive and negative points, and their applications depend on the characteristics of the problems addressed in the object in question (Marans and Ahrentzen, 1987).

Co-production is a relative new approach to address social, environmental and economic challenges. It can question and change the power relationships within the contemporary built environment, its production, governance and maintenance, to enable more sustainable and resilient communities (Stevenson & Petrescu, 2016). It goes much further than ‘user involvement’ or ‘participatory design’ and engages directly with the principle of equal partnership. This transforms the dynamic between those who use our built environments and those who produce it, where all stakeholders pool different types of knowledge and skills, based on lived experience and professional learning.

The specific contribution of co-production as a method allowed the research team to present their initial findings to the local residents in the case study neighbourhood as well as other activists working in the area, and to gain their insights into the findings in relation to their own concerns. Co-production requires careful facilitation to ensure that all voices are heard and treated as equally important. The use of mapping as a technique to capture stakeholders concerns in a neighbourhood is a powerful facilitation tool, providing everyone with the chance to stake out their issues and priorities, and to then debate and prioritise these collectively via the mapping exercise itself.

POE and Co-production at Shopping Park Neighbourhood

Three years after completion, the case study housing development shows clear signs of inefficiency and failure, contrasting to the original purpose of the government programme. The aim of giving people a "dignified living" failed under different constructive, social and environmental issues. Despite this, the resilience of the environment and the human being seems to coexist within cracked walls, bumpy roads, and streams clogged with litter (Figure 3) with thousands of people inhabiting this space and seeking ways to make it better. In other words, despite the deprived conditions of its houses and facilities, families are actually happy to live there (60% are happy about their neighbourhood).

Figure 3. Photos: Shopping Park's failure. Source: Gollino, 2015 (first); Arantes, 2015 (second); *Correio* Journal, 2013 (two in the right).

In order to evaluate the resilience of *Shopping Park's* residents, questionnaires were completed in 40 selected houses located in a pattern allotment of 200 houses - a good sample of 20%. The questionnaire was organised in five main aspects (related to the 5 categories previously mentioned): family characteristics, surroundings characteristics (neighbourhood), allotments' characteristics, housing characteristics and, finally, energy efficiency and sustainability.

From the application of Walkthroughs in four houses previously interviewed, reaching a 10% sample, the intent was to carry out an analysis supported by normative attributes (benchmarks), allowing the verification of the current environmental situation. The categories analysed were: i) Surroundings; ii) Lot; iii) House Unit, under sorted aspects as accessibility, urban furniture, vegetation, privacy, dimensions, sectorisation and performance of climatic features indoor, among many others.

Three Co-production workshops took place at Shopping Park neighbourhood. The first was entitled "Collective Coffee", the second as "II Meeting Renew Shopping Park" and the third as "III Meeting Renew Shopping Park". In each co-production session of 15 participants on average, new strategies were implemented in order to obtain information related to the main complaints of the residents in respect to the neighbourhood; the residents' favourite places in the neighbourhood; and the choice of effective actions to improve at the neighbourhood. Although participants expressed their willingness to improve their neighbourhood, with up to 48.6% unhappy about the amount and quality of available facilities, their complaints constantly focused on the housing unit issues. Most of the residents (82.5%) agree the main issue is the terraced house without acoustic insulation between different houses and rooms, leading to the difficulty of 25% on get along with neighbours, and another 31.6% not satisfied in terms of privacy among residents.

The fact that the houses were the main source of problems of the neighbourhood suggested that the activation of resilience at *Shopping Park* neighbourhood should first happen through the resolution of some significant pathologies, as described next.

Co-production to Activate Resilience of Built Environment

During the evaluation process, key factors drew special attention following validation through at least two of the tools, with the Co-production sessions becoming the moment when these factors were highlighted. Moreover, the negative impact they cause extends to the environmental, social and physical spheres, signifying them as strategic issues to be studied as well as improved within the local community seeking increased resilience. They represent the main vulnerabilities and sources of potentialities in the housing units. These factors, in order of significance, were: poor acoustic perform, lack of green areas, high rates of soil sealing, waste disposal and the high costs involved on refurbishments. Table 2 summarises information collected about each factor in the evaluation process, endorsed in the Co-production sessions. Some positive aspects derived from the resolution of each issue are also listed, and are considered as attributes able to improve the resilience of the neighbourhood.

Table 2. Main Issues at Shopping Park Neighbourhood. Source: Authors, 2016.

POOR ACOUSTIC PERFORMANCE
Description: More than 48.7% of respondents of the questionnaire are dissatisfied with acoustic performance. If fact, 47.5% refurbished their houses in order to solve technical problems and another 45%, to improve privacy. Performance analysis has confirmed constant noise through the shared walls between homes, which are clearly audible in most homes. In the first Coproduction, some residents reported suffering from depression due to the lack of privacy. **Positive Impacts Post-Intervention:** Increased privacy would favour the improvement of relations between neighbours, such as a better performance of activities such as relaxing, sleeping and working.
LACK OF GREEN AREAS
Description: 67.5% of the inhabitants interviewed feel the lack of landscaped areas inside the lot (52.5% paved the external area), though most of them have chosen not to invest on its cultivation due to the difficulty of maintenance and / or lack of knowledge about gardening techniques, as well as due to the scarcity of financial resources (Co-production 1 and 2 outcomes). **Positive Impacts Post-Intervention:** The practice of gardening can promote a network of learning, exchanges and trading between neighbours, as well as the planting of seedlings can be done in order to promote evaporative cooling of the house.
HIGH RATES OF SOIL SEALING
Description: 52.5% of the units evaluated have the external area paved beyond the 80% allowed by law (and 67.5% enlarged the coverage), configuring a situation of fragility to floods and landslides, once there is no vegetation enough to stabilise the soil (50% of houses visited on walkthrough analysis). Additionally, the settlement of the allotment without correct stabilisation of sloping ground increases the vulnerability of houses, since there are several cases of structural collapse due to landslides (Co-production 1). **Positive Impacts Post-Intervention:** The replacement of cement paving by alternative more absorbent materials would guarantee the soil stability and improve the microclimate while allowing the evaporation of wet soil.

WASTE DISPOSAL
Description: 92.3% reported that they have changed something from the original design of the house. Self-build is currently a recurring practice in the neighbourhood. The Walkthrough revealed the presence of construction materials stored on the front and sides of the lots, as well as on the backs and sidewalks. 65% of those interviewed reported having witnessed neighbours depositing waste incorrectly in public areas. In the first Co-production residents complained about the presence of soil, sand and other construction materials attracting insects and rodents inside the house, impairing their hygiene and healthiness. Moreover, waste harms the general appearance of the neighbourhood, which disturbs 23.7% of the interviewees. However, it is estimated that 57.5% of the interviewees carry out the separation of recyclable waste and the oil from other organic waste. **Positive Impacts Post-Intervention:** The proper disposal of waste improves life quality by ensuring the maintenance of clean, healthy and habitable spaces. Moreover, the cooperation in the collection, storage, administration and treatment of recyclable and organic waste may be a source of monetization, and consequently, community empowerment.
HIGH COST INVOLVED ON REFURBISHMENTS
Description: From the Co-productions it became clear that frequently the refurbished houses have as a builder resident, reducing the labour costs, which is not the reality for most residents. It is a consensus among residents that the high cost involved often makes it impossible to carry out quality reforms compatible with their needs, and they end up using cheaper materials of inferior performance and low durability. The main target of interventions in the house refers to the construction of walls by 77.55% of the interviewees, followed by the expansion or creation of covered areas (57.5%) and paving of the external area (52.5%). The laudry, kitchen and living room are the spaces whose size less satisfy the residents, being the target of up to 40% of them on refurbishments. **Positive Impacts Post-Intervention:** The dissemination of alternative constructive technologies and materials could allow reduced building costs. Furthermore, cooperation on administration and execution of refurbishments, through sharing of skills and labour, may become a source of income for those willing to conduct Workshops, joint efforts, etc.

Conclusion

By applying POE and Co-production techniques guided by the concept of resilience at the Shopping Park neighbourhood, it was possible to confirm that there are already high rates of resilience and adaptability there. Despite all the adverse impacts experienced by the residents regarding their poor quality neighbourhood, block and housing unit, they keep adapting and seeking for alternatives to improve their built environment. However, this is only partially resilient since little is done to develop truly sustainable and replicable solutions, due to the residents being restricted in their ability to overcome fragilities in a palliative way.

What is lacking in the neighbourhood is collective engagement and knowledge about the vulnerabilities and potentialities of the whole area. The partnership between academics and non-academics aims to share information collected as well as personal skills in order to empower the community to resist the impacts that will be imposed over time and thrive when faced to a situation of precariousness, in the next phase of co-production. The evaluation process developed at Shopping Park neighbourhood enabled the Co-production sessions as environments for experimentation and opportunities to take a close look at the community and its more acute vulnerabilities. The initial approach has focused on the issues at the urban scale, and has highlighted a difficulty to enable wider community projects, since the individual housing unit is the main source of dissatisfaction. In fact, the next stage of the research project intends to focus on the housing unit scale in order to activate wider resilience at *Shopping Park* neighbourhood.

In face of the obtained outcomes, it was realised that co-production can actually contribute to improve the resilience of place. Considering it, this research project will be continued and the co-production actions at Shopping Park defined in two subsequent stages (2 and 3) that will be carried out in 2017 and 2018. The academics are leading efforts to engage another stakeholders, such as NGOs and industry, working in the local area, in order to identify possible resources (e.g. building materials, re-used materials) to promote physical interventions to improve the housing in the first instance.

Small actions properly designed, and working directly with the residents themselves, can lead to big changes in the long term. After all, it is remarkable that simply carrying out a study with the community in fact have already improved people's perceptions and behaviours (Mallory-Hill et al, 2012) - after each Co-production session people presented more indepth information about their context. This confirms resilience as a natural and evolving attribute of human beings, sometimes needing encouraging to be fully reached, seeking to build more sustainable cities.

Soundscape assessment of a water feature used in an open-plan office

Zanyar Abdalrahman[1] and Laurent Galbrun[1]

[1] Heriot-Watt University, School of Energy, Geoscience, Infrastructure and Society, Edinburgh, UK. Email: za113@hw.ac.uk and l.g.u.galbrun@hw.ac.uk

Abstract: Research has shown that noise masking systems can successfully mitigate the detrimental effects of noise in open-plan offices. This paper provides a new approach to noise masking in open-plan offices, through the use of water sounds generated by real water features placed inside a work space. The effectiveness of water sounds in masking noise, especially irrelevant speech, has been extensively examined in previous laboratory experiments. The current paper builds upon the findings achieved so far, by extending the study into real-life settings. A water feature, designed in accordance with preference findings obtained previously, was installed in a medium sized open-plan office (12 workstations). A satisfaction questionnaire (focusing on the soundscape) was distributed prior to the installation of the water feature, to assess the work environment in the absence of any noise masking system. Then, another satisfaction questionnaire was distributed, after the water feature had remained in the office for a period of 3 weeks. The results obtained from both questionnaires suggest that the water feature had a positive effect on the soundscape assessment of the open-plan office, as shown by an increased level of subjective satisfaction that confirms laboratory findings. According to these empirical results, carefully designed water features could substitute conventional noise masking systems, with the added benefits of being affordable and contributing to an increase in the aesthetic value of the space.

Keywords: noise masking, water sounds, soundscape.

Introduction

Despite the economic benefits associated with using open-plan offices, there is a growing body of scientific evidence suggesting that open-plan offices increase workers' dissatisfaction and cognitive workload (De Croon et al. 2005), cause fatigue and difficulties in concentration (Pejtersen et al. 2006), and cause subjective impairment of work performance (Haapakangas et al. 2008). Dissatisfaction with the acoustic environment, i.e., background noise and lack of speech privacy, has repeatedly been highlighted as the main cause of the above problems (Bodin Danielsson & Bodin 2009; Jensen et al. 2005; Sundstrom et al. 1994). Irrelevant speech coming from co-workers is one particular factor that has been identified by numerous studies to have the most negative impact on the comfort level of workers. This finding is so robust and consistent over many studies to make it safe to state that little improvement can be achieved in the acoustic environment of open-plan offices without a thorough understanding and proper treatment of this type of distraction (Venetjoki et al. 2006; Virjonen et al. 2007; Hongisto 2008; Haapakangas et al. 2011; Haapakangas et al. 2008).

Masking sounds have been reported to help in reducing the intelligibility level of speech, and thus, decreasing the detrimental effects of this type of noise. Examples of masking sounds are pink noise (Ellermeier & Hellbruck 1998; Schlittmeier & Hellbrück 2009), white noise

(Loewen & Suedfeld 1992) and filtered pink noise whose sound pressure level decreases 5 dB per octave band (Venetjoki et al. 2006; Haka et al. 2009; Jahncke et al. 2011).

Among the studies reviewed, only one study used a water sound as a mean of masking speech in open-plan offices, and its findings were promising. Haapakangas et al. (2011) examined the effect of five different masking sounds on workers' performance: filtered pink noise, ventilation noise, instrumental music, vocal music and a spring water sound. The spring water sound was most beneficial in terms of both subjective (satisfaction) and objective (performance) indicators, results that none of the other masking sounds could acheive.

On the above ground, extensive laboratory research started to examine the audio-only and audio-visual preferences of water sounds and their likely impact on people's satisfaction and performance level. The results obtained were encouraging, and therefore, it was decided to further extend the research by placing a water feature in an open-plan office for a period of 3 weeks. This allowed examining the longer-term effect of having a water feature in a work space through a satisfaction questionnaire.

Design of the water feature

A water feature (dimensions, 48H $\times$ 45W $\times$ and $\times$ 49D cm) was purchased and modified to meet the criteria set out by previous stages of the current study regarding the audio-only and audio-visual preferences of different water features used as speech maskers. A cascade-like water feature was highly preferred, and therefore, a 3-step cascade was purchased and modified to provide a pleasant sound and visual apearance. The modified water feature is shown in Figure 1.

Figure 1. Three-step cascade used in this study.

After modification, the sound quality of the water feature was subjectively evaluated and the sound pressure level of the water feature was measured in the highly insulated anechoic chamber of Heriot-Watt University. The average sound pressure level (SPL) 1 meter away from the centre of the water feature was measured to be 45.5 dBA.

The open-plan office

A medium sized open-plan office with an area of 56.3 m^2 (dimensions, 7.60W $\times$8.75L $\times$2.90H m) was selected for the water feature to be installed in. Figure 2 shows a photograph of the office and its plan with dimensions. The open-plan office was located in the William Arrol building of the Edinburgh campus of Heriot-Watt University. The office accommodated 12 workstations clustered into 3 groups of working area. The finishing material of the walls was plaster and the ceiling was made of absorbent ceiling tiles. The water feature was placed at the middle of the shorter side of the space on a 0.7 m high table, as shown in Figure 2. This position was carefully chosen to minimise the space taken up by the water feature while making it both visible and audible from most of the workstations. The equivalent sound pressure level, $L_{Aeq,}$ of the background noise in the absence of employees at each workstation was measured over a period of 15 seconds, with and without the water feature in operation. The space averaged L_{Aeq} was 33.5 dB (empty room but equipment switched on) without the water feature, and rose to 39.3 dB when the water feature was switched on.

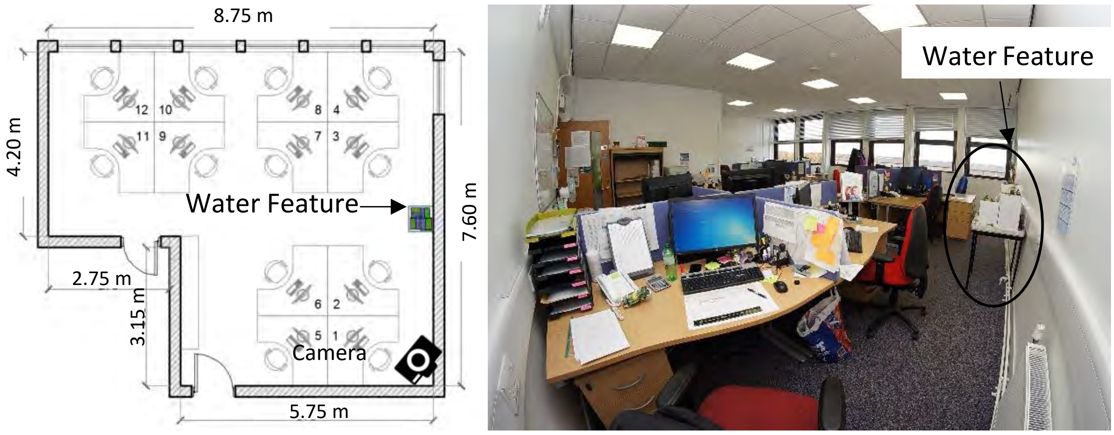

Figure 2. The open-plan office where the water feature was placed in.

Questionnaire

A modified version of the GABO questionnaire (Pierrette et al. 2014) was used to assess the initial noise environment in the open-plan office and to measure likely effects that the water feature could have on people's perception of their work environment. The questionnaire was divided into two parts, Part 1 and Part 2. Part 1 was distributed before installing the water feature, and Part 2 was distributed after the water feature had been in the space for a period of 3 weeks. The two parts were mostly identical apart from a few extra questions concerning the water feature added in Part 2.

The first section, "General information about you and your workstation", gathered background information such as age, gender and length of time working in the office. The second section, "Assessing the physical environment of your work area", assessed the employees' satisfaction with their physical working environment. This section consisted of 14 items, half of which (i.e., 7 items) measured satisfaction relating to control/privacy aspects, and the other half was about comfort/functionality aspects of the workspace.

The third section, "Assessing the noise environment of your work area", assessed employees' noise environment. Participants rated the general perceived noise level and then stated the level of annoyance caused by noise in the space. Participants were also asked about the perceived frequency of two noise sources: intelligible speech and unintelligible speech.

The fourth section, "Your perception of the sound environment", was dedicated to measuring people's perception of the sound environment in the work space. The section included questions measuring different aspects of the sound environment such as pleasantness, the possibility of concentrating on tasks, the possibility of having a meeting without distracting others, working uninterrupted, and the possibility of having private conversations. Ten questions specific to the water feature were added to this sections in Part 2 of the questionnaire, to measure how people perceived the water feature and its sound.

An 11-ponit numerical scale was used in the current study where 0 stood for "very dissatisfied/strongly disagree", and 10 stood for "very satisfied/strongly agree". The main aim of the study was to examine the likely effects that installing a water feature has on people's satisfaction and perception of their work environment, small differences being more easily detectable in an 11-point scale than, for example, a 5-point Likert scale.

The fifth section, "Your relationship with noise in general" assessed how people reacted to noise, i.e., their sensitivity to noise. This section was a shorter version of the noise sensitivity questionnaire (NoiseQ) developed by Schütte, Sandrock et al. (2007), which consists of 12 items divided into 3 subscales, namely, *sleep*, *habitation* and *work*, with 4 items in each subscale. Participants stated their level of agreement with each item on a 4-point numerical scale with 1 representing "strongly disagree", and 4 representing "strongly agree". The answer to each question was then quantified from 0 to 3 and used to calculate the average noise sensitivity score. A score of less than 1.11 is considered as not being sensitive to noise, while a score of greater than 1.63 is considered as being sensitive to noise (Schütte, Marks et al. 2007).

Statistical analysis

Data was analysed using IBM SPSS Statistics for Windows, Version 22.0. Given the small sample size (N=14), and the violation of the assumption of normality of most scores (checked using Shapiro-Wilk test and Normality Q-Q plot), it was decided to adopt non-parametric tests for the statistical analysis. The Wilcoxon signed-rank test, which is the non-parametric version of the related *t*-test, was used for comparing scores between the two parts of the questionnaire. Bias-corrected and accelerated bootstrap method, BCa, was used to derive robust 95% confidence intervals, which are reported in square brackets throughout this paper.

Where appropriate, the effect size, *r*, is given, which is a standardised measure of the size of effect observed. The effect size is not readily available in SPSS, however, the z-scores provided as a part of the Wilcoxon signed-rank test can be converted to *r* (Field 2013).

Procedure

Part 1 of the questionnaire measured the initial satisfaction level of workers within their work environment. After all participants had filled out Part 1, the water feature was installed in the space. The water feature had remained in the office for 3 weeks (5 days/week), before Part 2 of the questionnaire was distributed. Participants were asked to keep Part 1 until after Part 2 of the questionnaire was distributed. Then, both parts were collected together. The responses obtained from both parts of the questionnaire were analysed and compared to identify any change in people's satisfaction level and their perception of the work environment.

Participants

Fourteen participants (2 males, 12 females) filled out the questionnaires. These were staff members of Heriot-Watt University, aged between 24 and 61 yr (M = 39.86 yr, SD = 11.64 yr). The average time participants had spent in the open-plan office was M = 1.39 yr (SD = 1.15 yr), with an average attendance of M = 2.86 days per week (SD = 1.55 days per week), due to staff rotation. The score obtained from the noise sensitivity questionnaire revealed that, on average, participants were moderately sensitive to noise (M = 1.58, SD = 0.70). A slightly higher score was obtained when the sensitivity to noise was calculated based on the *work* subscale with an average score of M = 1.66 (SD = 0.64).

Results

Satisfaction within the physical work environment

Bias-corrected and accelerated bootstrapped 95% CIs are reported in square brackets. The results from Part 1 of the questionnaire revealed that participants were satisfied with their physical work environment, M = 7.06 [6.55, 7.64]. When the analysis was made separately for the two underlying subscales, the results indicated that participants were more satisfied with the comfort/functionality aspects of their work environment, M = 7.58 [7.09, 8.09], compared to control/privacy aspects, M = 6.53 [5.88, 7.24]. The difference in satisfaction between the two subscales was found to be statistically significant (z = 2.984, p = .001, r = .564).

After the water feature was added to the space, global satisfaction level within the physical work environment increased, M = 7.28 [6.71, 7.92], however, this increase was not statistically significant (z = 1.615, p = .115, r = .305). Having said that, the water feature significantly increased the satisfaction levels within the subscales comfort/functionality, M = 7.84 [7.35, 8.36] (z = 2.530, p = .012, r = .478). The satisfaction level within subscale control/privacy also increased, M = 6.71 [5.91, 7.56], but the increase was not statistically significant (z = 1.104, p = .295, r = .209).

The increase in satisfaction level can be attributed to 3 items within the physical work environment, namely *Item 1* "Noise environment" and *Item 2* "The cleanliness of your work area" within the subscale comfort/functionality, and *Item 3* "Possibility of concentrating in your workplace" within the subscale control/privacy. When the scores of Items 1, 2 and 3 were compared before and after installing the water feature, it was revealed that the water feature significantly increased the satisfaction level for Item 1 (z = 2.803, p = .004, r = .530), and Item 2 (z = 2.041, p = .041, r = .386), but the increase was not statistically significant for Item 3 (z = 1.876, p = .074, r = .354).

Satisfaction within the noise environment

Employees perceived the noise level in the office not to be high, M = 4.43 [3.14, 5.97], nor annoying, M = 4.14 [3.14, 5.21]. Furthermore, the water feature did not seem to have any effect on the perceived noise level, M = 4.29 [2.93, 5.64], nor annoyance, M = 4.36 [3.21, 5.43]. Statistically, no significant differences were detected for perceived noise level (z = 0.426, p = .672, r = .081), and perceived annoyance (z = -0.412, p = .680, r = -.078), before and after installing the water feature.

Participants assessed the frequency of occurrence of two noise sources, intelligible speech and unintelligible speech. Intelligible speech, M = 7.50 [6.64, 8.36], was perceived as being twice as frequent as unintelligible speech, M = 3.79 [2.14, 5.36]. After the water feature was added, the perceived frequency of intelligible speech dropped to M = 6.21 [5.36, 7.00], and the change was statistically significant, (z = -2.326, p = .027, r = -.440). On the contrary, the water feature resulted in an increase in the perceived frequency of unintelligible speech, M = 4.57 [3.14, 5.93], yet, the increase was not statistically significant (z = 0.784, p = .523, r = .148). This is understandable as the water sound must have masked a portion of the intelligible speech and made it unintelligible, hence the increase in the perceived frequency of unintelligible speech. Looking at the r values, it appears that the water sound had a much larger effect on reducing the frequency of the intelligible speech in comparisons to its effect on increasing the frequency the unintelligible speech. This implies that in addition to masking a portion of the intelligible speech and making it unintelligible, another portion of the intelligible speech might have become inaudible, hence the inequality in effect sizes.

In terms of annoyance, neither intelligible speech, M = 3.93 [2.57, 5.29], nor unintelligible speech, M = 2.43 [1.21, 3.86], was perceived as being excessively annoying. Furthermore, the water feature did not have a significant impact on reducing the perceived annoyance level caused by intelligible speech, M = 3.86 [2.64, 5.00] (z = -0.276, p = .783, r = -.052), and resulted in an increase in the annoyance level associated with unintelligible speech, M = 3.50 [2.07, 5.07], yet the increase was not significant (z = 1.689, p = .109, r = .376).

Perception of the sound environment

This part of the questionnaire included 6 questions, 2 of which examined people's perception of the sound environment, while the remaining 4 were related to the possibility of carrying out certain office-related activities within the sound environment. As shown in Figure 3, the water sound resulted in an increase in scores for all 6 questions.

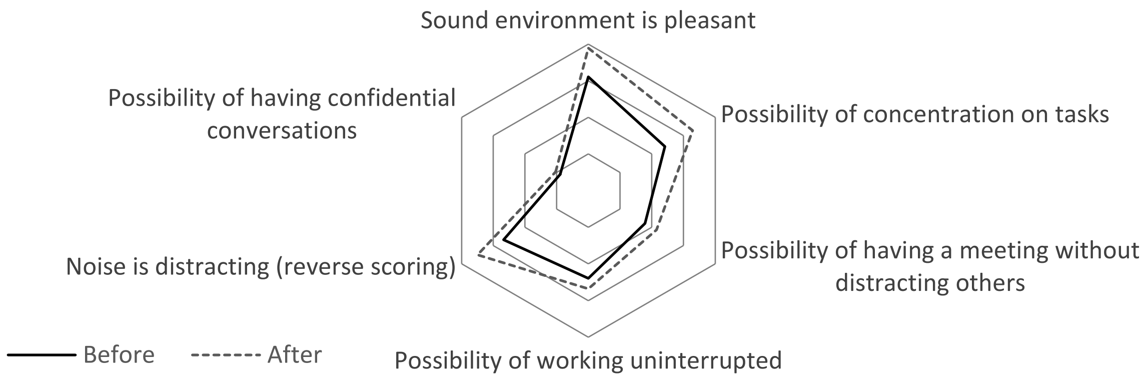

Figure 3 Satisfaction within the sound environment.

Participants perceived the sound environment of the open-plan office to be moderately pleasant, M = 6.21 [5.21, 7.14]. The inclusion of the water feature in the work space significantly increased the pleasantness level, M = 7.79 [6.86, 8.71] (z = 3.244, p < .001, r = .613). The sound environment was perceived as not being particularly effective in helping people to concentrate on their tasks, M = 4.82 [4.07, 5.61], but this score significantly increased after the installation of the water feature, M = 6.57 [5.57, 7.64] (z = 2.807, p = .003, r = .530). This suggests that the water feature was effective in helping people to carry out certain tasks. Participant were also asked if they perceived the sound environment of the work space to be distracting, and the responses suggest that they did not perceive it as being distracting even before the water feature was installed, M = 4.64 [3.71, 5.64]; however, the water feature further improved the sound environment, M = 3.00 [1.93, 4.07], and made it significantly less distracting (z = -2.505, p = 0.014, r = -.474).

Despite a slight increase, no significant differences were detected in the possibility of having a meeting without distracting others (z = 1.111, p = .344, r = .210), possibility of working uninterrupted for long periods (z = 0.905, p = .563, r = .171), and possibility of having confidential conversations (z = 0.496, p = .664, r = .094). The latter was to be expected, as confidential conversations require a greater level of privacy that the water sound was incapable of providing.

Part 2 of the questionnaire included 10 extra questions concerning the water feature. The responses to these questions revealed that the water sound was very positively perceived as being pleasant, M = 9.14 [8.64, 9.57], as improving the sound environment, M = 8.57 [7.93, 9.14], and as being visually/aesthetically pleasing, M = 9.57 [9.29, 9.86]. Furthermore, the water feature did not cause people to feel stressed, M = 0.14 [0.07, 0.36], nor its sound distracted people, M = 0.14 [0.07, 0.36]. Nevertheless, the water feature did not seem to have helped people to carry out private conversations, M = 4.43 [3.07, 5.86]. Only 2 participants thought that the water feature increased the frequency of going to the toilet with an average increase of 2 times per day, and finally, 13 out of 14 participants preferred the water feature to remain in the space on a permanent basis. The last question was an open-ended question, for which the comments were all positive; "very pleasant", "it is a pleasant soothing sound", "the feature is lovely to look at". The responses to the above questions suggest that the water feature was highly appraised by participants with very little adverse effect on the number of times that people needed to go to the toilet.

Discussion

This study provided an insight into the use of a water feature as a noise masker in an open-plan office. Generally, participants were satisfied with their physical work environment, however, the inclusion of the water feature significantly increased the satisfaction level of the comfort/functionality aspects of the work environment. This increase in satisfaction level could mainly be attributed to an increase in people's satisfaction with the noise environment and cleanliness of their work area. The water feature significantly decreased the perceived frequency of intelligible speech, which shows its effectiveness in masking speech. This was further demonstrated by an increase in the perceived frequency of occurrence of unintelligible speech, although this increase was not statistically significant.

The water feature had a positive impact on people's perception of their sound environment. After the inclusion of the water feature in the space, participant perceived the sound environment to be more pleasant, more effective in helping them concentrate on their tasks, and less distracting. The water feature did not help people in working uninterruptedly, having meetings without distracting others, and carrying out private conversations. In that respects, it should be noted that a water feature, such as the one used here, is a fairly quiet masking system that can only be effective up to a certain limit. It cannot fully compensate the disadvantages associated to an open-plan office, but it can certainly reduce its adverse effects.

The water feature itself was highly appraised, most participants asking to keep the feature in the space permanently. The water sound was perceived as being highly pleasant too, and the feature significantly improved the sound environment and added an aesthetic value to the space.

It is worth mentioning that more statistically significant results (i.e., $p < .05$) would have been possible had the sample size been larger. In a few cases, the effect sizes of the water feature exceeded .30, but no statistical differences were detected. For example, the water feature had a *medium* effect size ($r > .30$) on improving the physical work environment, and the possibility of concentrating on tasks, with p-values greater than .05. An effect size of .30 could be practically meaningful. For instance, even only a 1% increase in the performance of employees would result in a saving of around £3500 per annum. This calculation was made assuming an average salary of £25000/year and 14 employees (1% $\times$ 14 $\times$ 25000).

Limitations of the study

This study was carried out to extend some laboratory findings into real-life settings. The small sample size (N = 14) limits the generalisation of the findings. The study is also based on a relatively small and quiet open-plan office where people were already satisfied before the installation of the water feature. It is not clear whether even more positive findings might be achieved in crowded and larger offices with less satisfied people. Having said that, statistically significant improvements in the work environment were still possible despite the small sample size. In many cases the magnitude of the effect size was still above .30 which is considered a medium effect size. The study indicates a great potential for water features used in open-plan offices to mask noise, making it an attractive topic for further research.

Design of passive devices with natural ventilation and sound attenuation

Yoshiaki Ando[1], Aníbal Figueroa[1] and Silvia de Schiller[2]

[1] Bioclimatic Design Doctorate Program, Autonomous Metropolitan Univeristy, Azcapotzalco, Mexico City, Mexico, andoashijara@gmail.com, figueroa.anibal@gmail.com

Abstract: Natural ventilation, one of the main bioclimatic design strategies, when applied for air conditioning and air changes for a healthy indoor environment, may introduce urban noise impacts. This problem, produced by ventilating indoor spaces in modern cities, may provoke stress and affect physical and mental health. Products in the international market offer reductions in noise intensity in selected sound frequencies allowing proper ventilation, but they are expensive and not widely available in emerging countries, affecting cost and implementation. The focus of this paper is the design of new and innovative proposals for local natural ventilation devices. The evaluation and validation procedure is implemented during design process to insure the device effectiveness in ventilation and sound attenuation. As costs to test design in specialised acoustics laboratories are high, both initial cost and testing subsequent modifications for design improvements, an experimental low-cost test facility complying with ISO 7235: 2013 standard was developed to allow effective testing of design proposals and evaluate devices which combine natural ventilation and sound attenuation. The paper presents the testing procedure adopted to evaluate two existing models with reference data and implementation of effective procedure to assess two conceptual industrial design proposals and compare the results.

Keywords: Natural ventilation, sound attenuation, insertion loss, design, experimentation, normative, devices.

Introduction

Ventilation is the process of providing or removing air from a space for the purpose to controlling contaminated air, humidity, or temperature levels. Natural ventilation is provided by thermal effects, wind or diffusion through doors, windows or intentional openings in buildings (ASHRAE, 2007). In the bioclimatic design, the wind is used to climatize without using mechanical devices, or to generate movements and renovation of the indoor air. This flow, not only changes the thermal conditions of the space, also directly affects the occupants generating a feeling of well-being (Fuentes, 2004; Serra, 1999).

The inhabitants of the cities, when acquiring a new home or workspace, are going to realize of the acoustic problems that can have until inhabiting it. For various situations, the inhabitants will have to adapt or get used to it (Field, 2010). It may not be a problem because the adaptive capacity of the human being. But many people fail to adapt, and this affects their quality of life, their mental and physical health. One of the implementations that traditionally are done to reduce the annoyances of the noise is to change or to reinforce the windows, sealing the infiltrations of air that allow the entrance of the noise. Many windows are completely sealed and do not allow natural ventilation, and the conditioning is solved by installing mechanical systems. This increases electricity consumption, therefore, increases economic spending and affects the environment.

There are natural ventilation devices that are classified into three types: passive, active and hybrids (De Salis et al, 2002). A state-of-the-art study of device types was performed (Ando et al, 2016). It was determined that the study of passive and hybrid type devices is relevant, since there are in the global market a great diversity of active devices that have an engine that induces the air. One problem with natural ventilation devices and systems is that they allow intrusion of ambient noise. Devices that are equipped to attenuate noise are few in the global market and expensive for emerging countries.

The objective of the research is to design passive natural ventilation devices with sound attenuation. To do this, it's necessary to develop an Experimental Instrument that allows rapid evaluations for design, reduces the costs of evaluation in the laboratory, and results are valid to predict performance. Different standards such as ISO 10140, "Acoustics: Laboratory measurement of sound insulation of building elements" were revised, but the laboratory conditions are very strict and the conditioning is expensive. Finally, the design of the experimental instrument was based on ISO 7235 as "Acoustics: Laboratory measurement procedure for duct silencers and air terminal units. Insertion loss, flow noise and loss of total pressure "(ISO, 2009), whose development is described below.

Methodology

ISO 7235 conforms to the type of devices that are of interest to design. The overall dimensions will depend on the type and measures of the devices by the technical specifications of the standard. Each element has its conditions to size. In the case of the present investigation, the minimum dimensions of the commercial devices (louvers), which are 300 mm x 350 mm were taken as reference, reason why the instrument reaches a measure of 3550 mm length.

The conditions of the standard for the location of the instrument aren't strict. This can be in an acoustic non-isolated site in its entirety. Consideration should be taken to avoid contact with vibrations, not to be exposed to sources of noise and to a high level of ambient noise, which does not have extreme variations. In order to perform with the conditions, the noise generated in the test duct must be at least 10 dBA above the background noise, and there're no disturbances in the measurements by the external noise. For this purpose, the experimental instrument was designed with adequate acoustic insulation requirements in its construction.

Theory of Insertion Loss according ISO 7235

ISO 7235 defines that "Insertion Loss (D_i) of the Test object (device to be evaluated) is the reduction in the level of acoustic power in the Conduit Behind the Test Object due to the insertion of the Test Object in the Conduit instead of a Replacement Conduit "(ISO, 2009).

This means that the experimental instrument will measure the reduction of acoustic power in a duct without any element that interferes with the passage of sound. The device to be evaluated will then be installed. Sound pressure is measured at five different points on the back side of the sound source (Conduit against Test Object) with the microphone. From the insertion loss formula: $D_i = L_{WII} - L_{WI}$

L_{WI} is the level of acoustic power in the considered frequency band, which propagates along the Test Conduit when the Test Object is installed, and L_{WII} is the level of the acoustic power in the considered frequency band, which is propagated along the Test Conduit, when the Replacement Conduit replaces the Test Object.

Basic components and Model

The design of the experimental instrument was based on the specifications of ISO 7235 (Figure 1). The instrument consists of seven basic assembling sections for the measurements: 1. Module for the speaker; 2. Conduit in front of the Test Object; 3) transitions to fit the dimensions of the Test Object; 4a. Test Object; 4b. Replacement Conduit; 5. Conduit against Test Object; 10. Anechoic Termination (Figure 2).

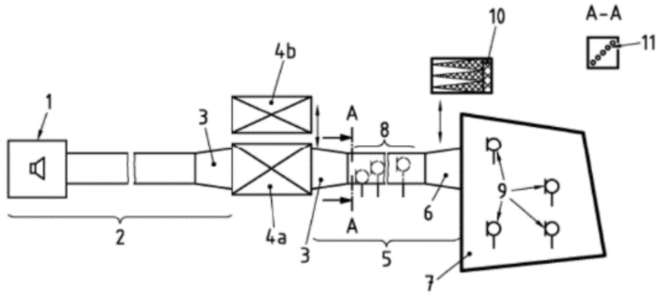

Figure 1. Examples of test facility layouts for non-airflow insertion loss measurements. (ISO 7235)

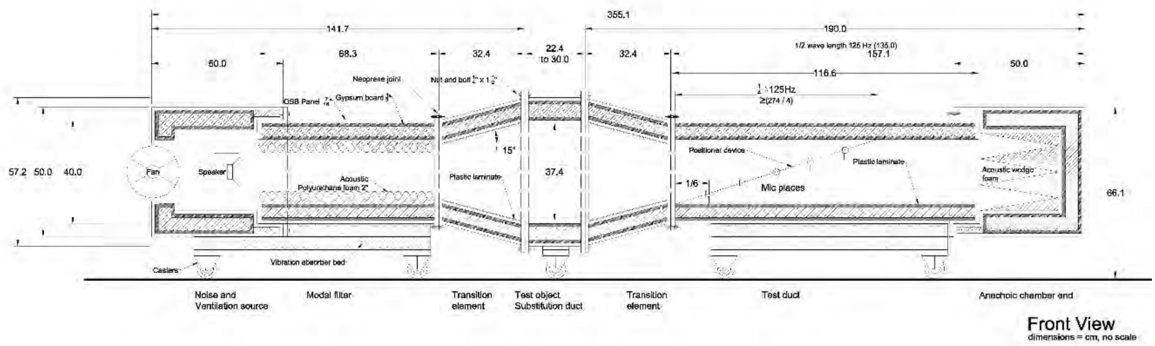

Figure 2. Diagram of elements according to ISO 7235 (Realized by the authors).

It's important to mention that the instrument can end up with a Reverberating Chamber or an Anechoic Termination according to the characteristics of the test object and the needs of the measurements. In the present case, the devices will be measured with the Anechoic Termination.

The Experimental Instrument was designed and constructed with the following characteristics:

1) The Module for the speaker is a cube built with OSB board 11 mm thick on exterior and interior walls, two layers of 11 mm gypsum board, 51 mm of mineral wool filler having a final thickness of approximately 100 mm. It has a 50 mm polyurethane foam acoustic insulation plate with "egg carton" texture to cushion the vibration transmission of the speaker that is suspended on the foam. The speaker used is a Bose Soundlink 15859, which has a frequency range of 88 Hz - 10 kHz with Bluetooth connection, and allows wireless connection.
2) The Conduit has the same characteristics as the module for the speaker. The minimum dimensions of 200 x 200 mm were applied inside the duct. The conduit engages a flange-type at the adjustment transition to the test object.
3) The Transition will increase from the size of the Duct to the dimensions of the Test Object.

4) The Test Object is a module in which different variants of devices to measure can be mounted. Based on the measurement of a frame of 300 x 350 mm, a perimeter of 50 mm is added for a seal of 200 mm mineral wool lined of fabric to facilitate the changes and the wool isn't torn. Both elements are installed in a frame constructed in the same way as the Conduit. This element has a frame that functions as a flange and facilitates changes in test (4) and replacement (5) Conduits for the necessary comparative measurements.
5) The Replacement Duct is an empty frame that allows to measure how the sound is transmitted directly from the speaker to the five microphone locations.
6) The Duct behind the Test Object is constructed in the same way as the preceding elements, with the difference that its interior is lined with an acoustic reflective material. Melamine plastic laminate was used. In this module, the microphone will be in five proportional positions from its ends.
7) The Anechoic Termination has the same constructive characteristics of the modules, in its inner wall that finishes the flow of the sound is lined with a plate of polyurethane foam of 50 mm with texture of wedges directed towards the speaker. On its back side, it has a double layer of mineral wool and a detachable top where a 6 mm x 38 mm x 1200 mm aluminum strip is inserted through a slot that acts as a microphone holder, and at the same time as a positioner with marks of the measures that place it in the five positions from the outside.

Both test ducts are mounted on casters to facilitate assembly and disassembly of the test and replacement elements, because they have a considerable weight due to the density of the materials (Figure 3).

Figure 3. Construction of the experimental instrument ISO 7235: 2003 (Realized by the authors).

The microphones are Dayton Audio brand (Ohio, United States of America) specific for acoustic measurements with USB connection. The OmniMic V2 Precision Measurement System software was developed by the same company. The microphone and the software were tested in an anechoic chamber and in a reverberant of the Center of Acoustic and Luminotechnical Research of the National University of Cordoba, Argentina. They were compared with measurements of a Brüel & Kjaer class 1 sound level meter and a Behringer Ecm8000 microphone with LabVIEW software from National Instruments.

The frequency spectrum was close to that registered by LabVIEW, with calibration the measurements can be taken as reference for the level of design tool, but if they are required to be certified, they must be tested under laboratory conditions and equipment.

Reference Models

Two models of louvers with acoustic design were built in workshop, the design specifications of commercial models were taken. The materials used were 22-gauge carbon steel sheet on exterior faces with folds, multi-perforated 2 mm diameter carbon steel sheet on inner faces, 50 mm thick mineral wool filling, metallic liquid paint finish. The manufacturer's minimum module of 300 x 400 mm (Figure 4) was considered.

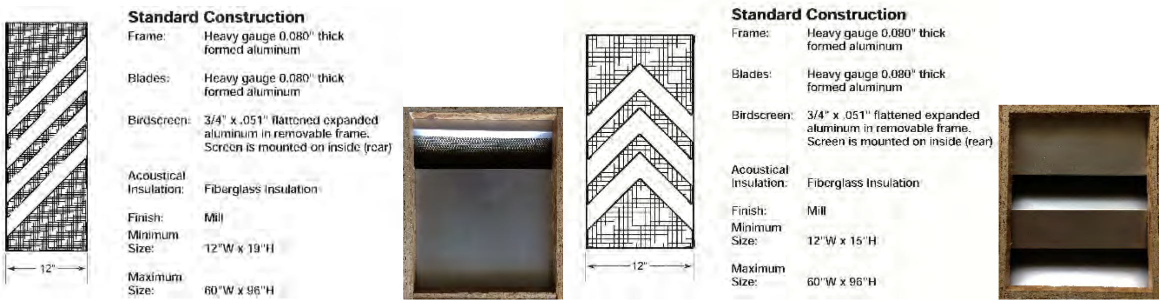

Figure 4. Analog reference models Greenheck Mod. AFJ-120 and AFS-120 (www.greenheck.com) Model A and Model B respectively (Realized by the authors).

Implementation for the evaluation of two conceptual proposals

To produce the proposals, materials traditionally used in architectural construction were considered: porcelain ceramics, wood, mineral wool, acoustic polyurethane boards, phenolic foam boards. Manufacturing processes changed according to the design and quality characteristics proposed. Diamond drills were used for the drilling of the ceramic plates and for the plates of the absorbent material.

A 20 mm OSB frame was constructed with the same exterior dimensions of the reference devices. Inside, MDF guides and spacers of 3 mm were implemented that allow the exchange of elements to be able to evaluate different configurations. Using laser cutting made templates with different configurations of holes, to combine those that allow the adequate flow of air and to be able to attenuate some frequencies. The reflective plates and absorbent materials were drilled with the templates.

According to the design hypothesis, the combination of materials with geometric configuration will achieve sound attenuations near the background noise level, allowing the air flow through the device. This air flow will allow, through a cross ventilation, the cleaning of interior air of a room. For the comparative level of airflow, the same area of entry of the outer face of the devices was maintained (Figure 5).

Figure 5. Images of the conceptual proposals evaluated. Model C and Model D respectively (Realized by the authors).

Ventilation tests

To be able to measure performance of ventilation, an experimental device was implemented for this purpose. Which consists of the emulation of a ventilation duct, it is divided with grooves each 50 mm to let slide the templates and combine different thicknesses of materials and deviations of flow. The duct at one end is fitted with a three-speed propeller fan, which was fitted with a dimmer to set the speed required for the evaluation.

The wind speed measurement was recorded with a Kestrel 4500 anemometer, which was fitted with a support to keep it fixed in the duct. The capture of results was a picture of the screen with digital photographs.

Method of recording results

The acoustic test results must be recorded according to the recommendations given in section 7.8. of ISO-7235.

Table 1 shows the results of the evaluations of the two analog reference models (A, B) and the two conceptual proposals (C, D):

	Background Noise Level	Noise Source Level	Five points Average Level	Insertion Loss	Initial Wind Velocity	Measure Point Wind Velocity	Inner Ambient Temp
Model	N (dBA)	N_0 (dBA)	N_f (dBA)	(dBA)	W_0 (m/s)	W_f (m/s)	Temp °C
A	41.9	61.7	51.08	10.62	4	0.8	20
B	41.9	61.7	53.04	8.66	4	1.4	20
C	41.9	61.7	57.26	4.44	4	2.0	20
D	41.9	61.7	50.84	10.86	4	1.5	20

Table 1. Results of the analysis in the experimental element (Realized by the authors).

The graphs were made in Microsoft Excel program according to the format of the standard. The data recorded by the Omnimic V2 program of the frequency spectrum were captured manually (Figure 7).

Conclusions

One of the contributions of the research is the development of an Experimental Instrument for the design and low-cost evaluation of different configurations of materials and geometries. This allows to modify and find better performances in terms of sound attenuation and airflow of natural ventilation devices of this type.

As an advantage, ISO 7235 allows the dimensions of the measuring instrument to be adapted according to the dimensions (area) of the ventilation devices. The insulation of ambient noise within the device is not a representative factor if a noise source with a level of at least 10 dB higher than the background noise level is used. To have accurate levels, the design was considered with acoustic insulation materials. Samples were also taken when there were no unexpected sources of noise affecting the average levels (airplanes, motorcycles, barking dogs).

The evaluated proposals are the result of the first design hypotheses. Some conceptual solutions were used as references for a state-of-the-art investigation of patents and commercial products (Ando et al, 2016). Alternative materials were proposed that can function because they have the characteristics of architectural application and has easy acquisition in any locality by its commercial use.

In the results of this experiment, one of the proposals could improve the performance of the reference models by attenuating some frequencies and airflow, although the performance in the insertion loss was similar. As future research, more designs will be proposed with other materials, alternatives and dimensions that can be adjusted to specific bioclimatic needs.

Finally, the experimental element will be able to design and evaluate a great diversity of proposals with a technological and educational purpose.

The Children´s Hospital José de Alencar is an institution located in Brasilia, Federal District, and is dedicated to the care and treatment of children with cancer. The hospital physical space is divided into wings with different functions, interconnected by a single reception hall. The hall presents problems for it is a noisy environment due to the various activities held there, the large flow of people and the building geometry. Thus, in order to improve its acoustic performance and hence the comfort of hospital patients, this study aims to investigate the cause of the problem in order to propose an architectural solution that is compatible with the environment and its demands. The research was carried out in 3 steps: Diagnosis, evaluation of the hall problems and an architectural intervention proposal. The first step was to execute an in loco research and acoustic measurements. Then, from the collected data, a computational analysis of the space followed. The simulations and results were obtained through the computer software Ease v 4.4.11.4, Sound Forge Audio Studio 10 and Smart Acoustic Tools Analysis. Thus, the results pointed out that the environmental reverberation time was not satisfying according to the acoustic standard patterns, which caused great discomfort to users. In order to improve the environmental conditions, the intervention project took into account the infant theme, the hospital guidelines and the adjustment of the existing layout.

Introduction

The José de Alencar Children’s Hospital (HCB), located in Asa Norte, Brasilia/DF, a centre specializing in integrated and multi-professional treatment, was designed by the architects Frederico Luís Carvalho and Sérgio Paulo Reis and was created by the initiative of the Brazilian Association for the Assistance of Families of Children with Cancer and Homeopathies. The HCB has adequate infrastructure, health technology and continuously trained staff. There is a large module with an entrance hall in Building 1, which is also a waiting room for patients, their companions and caregivers. In order to provide some comfort and distraction during the waiting time, the HCB offers some recreational equipment for children in this room. In addition, there is an entertainment, musical and theatrical program, as well as lectures, talks and other communication for them. Naturally, a large space with a considerable amount of people on the move generates a great deal of noise. The peculiar geometry of the space also contributes to the increase sound intensity. See Fig.1.

Figure 1. Photos of external and internal views of the entrance hall of Building 1

In Brasilia, the architect João Filgueiras Lima, also known as Lelé, innovated the conception of healthcare spaces. In other words, he revolutionized virtually all aspects of construction, infrastructure, facilities, equipment, environmental comfort, energy efficiency. Engineering and architecture are integrated in harmony. Lelé’s work is considered a point of reference for architectural solutions as a way of humanizing a hospital environment. One of his internationally recognized works became a model hospital network, called Sarah Kubitscheck, which was installed in a several cities in Brazil. He worked in partnership with the artist Athos Bulcão, creating environments where light, colours and joy fill the space. The latter’s works of art do not appear as an adornment of the surroundings. His art fulfils a functional purpose, such as environmental comfort or energy saving, as Segawa and Guimarães (2010) stated. See figure 2.

Figure 2. Photos of an internal corridor and external view the Hospital Sara do Lago Norte, Brasília.

In order to improve the acoustic surroundings in the aforementioned hall, a team of students and hospital staff got together to begin the project. Because it is a hospital environment focused on childcare, one of the project’s premises was to humanize this environment with a playful proposal. Thus, it is expected that waiting conditions will be improved, increasing users’ comfort. Another important point that drove the project was the search for a solution with the lowest possible energy and environmental impact, using alternatives with low implementation costs and taking advantage of the existing structure to improve the acoustic performance of this receptionhall.

Humanization of the hospital environment

The ambience of a hospital is often hampered by numerous guidelines because high-tech equipment and thorough sanitization processes are indispensable in such a place. In this regard, hospital models tend to follow a pattern far from being personalized and compatible with the expectations of those who work and are assisted there. The new Brazilian National Health Policy on humanization of hospital spaces (2006) states that welcoming and harmonious environments should be built in order to contribute to the promotion of well-being, thus unravelling the belief that such spaces provide health services in a cold and hostile way. This Policy also states noise treatment as one if the main concerns on improving comfort in hospital environments. A correct sound ambience can provide greaterwell-being, prolongs the length of stay in the room and promotes a sense of privacy in the space.

Ampt, Harris and Maxwell (2008) indicate in their studies that an environment with good acoustics can improve patient comfort, providing more privacy. It helps improve well-being by providing better rest conditions. It also improves physician and employee performances, helping their efficiency at work.

Project development

HCB Building 1 has an arched ceiling with reflective concavity, resulting unfavourable sound convergence. The height of the ceiling results in a very high volume- per-person ratio, which is also unfavourable to speech indexes; all the interior surfaces and walls reflect the sound. The furniture includes a few more sound absorbing items and the recreational equipment for children blends with the furniture in a confused layout. These architectural features of shape, material composition, occupation and layout are presented as issues to be focused in order to improve the acoustic performance of the hall. However, any intervention to be proposed should not change the architectural characteristics or the recreational ambience created, nor can discard furnitureitems.

Sound measurements

The objective of this step was to analyze and evaluate the acoustic conditions of the space through software simulation. For that, emission of sounds and measurements took place in loco according to the Brazilian Association of Technical Standards (ABNT), *NBR 10151*-proceddings (2003). The main focus was to analyze the Reverberation Time (RT) and the Sound Transmission Index (STI). The measurements had been made at night to avoid user´s noise at two points for sound emission possibilities: point1 (corner) and point2 (centre); the microphone were located at points A, B and C (see figures 3, 4). For the measurements had been used one PC, pink noise generated by Smaart Live 5 (Sound Forge Audio Studio10) emitted by a dodecahedral loud speaker and the microphone was the Behringer EMC8000. These measurements plus a 3D modeling of Building 1 were the inputs for the software program Ease v.4.4.11.4. Other complementary programs used: Sketchup v.5 and Smaart Acoustic ToolsAnalysis.

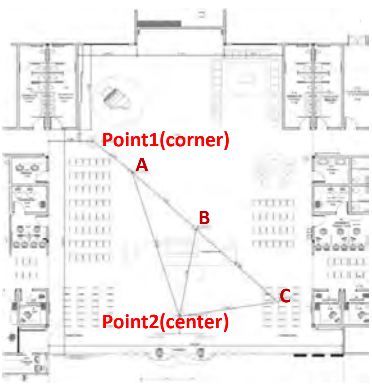

Figure 3. Plano f the entrance hall of Building 1: the sources and microphones measurements points

Figure 4. Panoramic view of the entrance hall of Building 1, with the central point of measurement

The acoustic evaluation parameters established were Reverberation Time (RT) and Speech Transmission Index (STI)

Multiple acoustical use spaces, if not designed for that, will need very criterions adaptations that should come from very precise diagnosis. In the case of a primordial use, the improvement design must focus on this objective, but IF the multiple functions are equally important, even contradictory in sound performance needs, high technology must be applied, which will be certainly more expensive.

In this case, the use adjustment of the space for speech can compromise its use for music. But the entertainment shows do not need very precise performance. Also is very important, in this space, to low the background noise level. The evaluation of the sound environment was based on acoustical standards concerning to the Reverberation Time (RT) and Speech Transmission Index (STI). The Brazilian standard for the RT by ABNT is NBR 12179 (1992. The STI indicate the comprehension of information transmitted orally; takes into account the reverberation time and noise of the rooms. “The STI indicates the correlation of the reverberation effect with background noise.” (Bertoli, 2008, apud Silva de Marco, 2009). In this case, the audience will not be in closed place, them the background noise will interfere very much in the speech, the primordial use of the space. The parameters for the STI evaluation in Brazil are established by IEC 60268-16 (2011); it consists of an index from 0 to 1, poor to excellent intelligibility.

Results and Evaluation

The values were obtained through the outputs of the mentioned Ease software in the form of tables and graphs. Here we reproduce the graph where the results are seen for the two measurement points, corner and center of the room as shown in Fig.3. The results are mean values of the various measurements made; also are shown the references values.

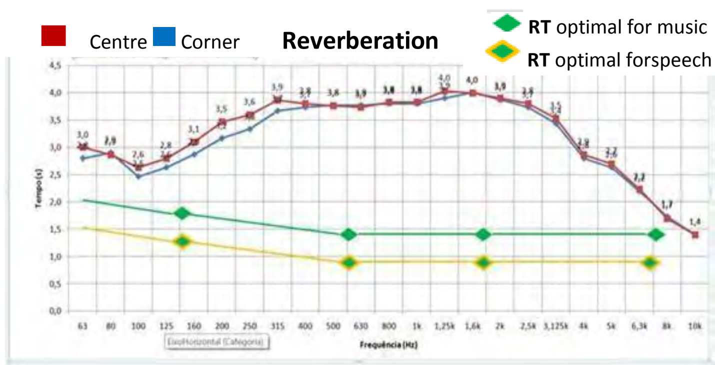

Chart 1 – RT Mean results for the two points (corner and centre of the room)

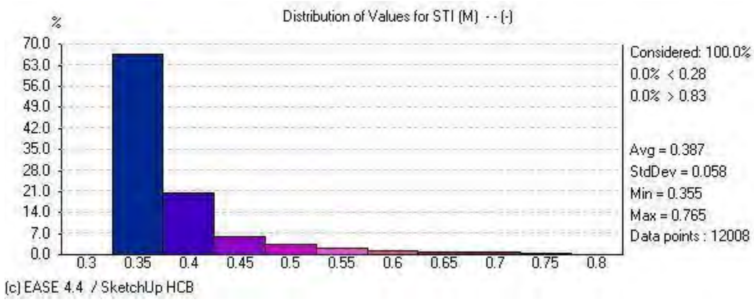
Reference values of RT(s) of NBR 12179, for the volume of 4,463 m^3, were considered for speech (conference room) in the frequency of 500Hz; the optimal values are 9s. The values obtained were 3.8s; the RT values for music are approximately 1.4 s, still far below those obtained (see Chart 1). For frequencies below 500Hz had been used the correction graph recommended by Silva de Marco (2003). A variation of 10% for more or less of RT as a result for an acoustic conditioning of a space, is considered acceptable. However, in all frequencies below 8kHz the values exceed by more than 200% the optimal values. TR values much higher than those recommended by the standard mean difficulty on understanding speech and increase the total sound intensity in the environment, thus increasing the background noise level. Another aspect to emphasize is that in the two measured places (corner and center of the room) the results were very close indicating the uniform distribution of the RT in the space.

The STI results, also obtained from simulations with the Ease program, show good values (0.75 to 0.57) only very close to the sources. The values already reach weak, 0.39 (see Chart 2) for points slightly more distant, approximately 6,0m. Lower values at increasing distance; it indicates speech intelligibility compromised within the space. Again, naturally, in both positions of the source, the results of the STI simulations were very similar as a result of the uniformity of the RT. (See Chart 2.)

Chart 2 – STI results of the simulations at the corner and at the center of the hall



Conclusions and intervention proposals

The main problems diagnosed for impairing the room acoustic performance are:
1. Large internal volume, which hinders the volume-per-person ratio for speech performance;
2. Its inner walls and other surfaces are very soundreflective;
3. The layout is unfavourable to assembling an audience;
4. Reverberation time results far beyond the Brazilian guidelinerecommendations;
5. Values of Speech Transmission Index are lower than standardreference.

Then, is conclusion of this study is that, this space can be adapted to its acoustic uses with good results, maintaining the original architecture and recreational environment with an very simple acoustic conditioning proposal. These aspects will be clear with the technical and aesthetic solutions chosen. According to the ''Health facilities humanization: design guidelines supported by statistical evidence'', a hospital waiting hall should prioritize spatial dynamics and the interactivity with the space. One should consider different types of need for privacy and socialization. In this sense, priority should be given to spaces that provide different ambience opportunities, always taking mutability into account. Therefore, to the proposal aims to boost the layout of the hospital furniture, creating audience venues for small performances, some reserved spots, and a space for games and music. See figure 5.

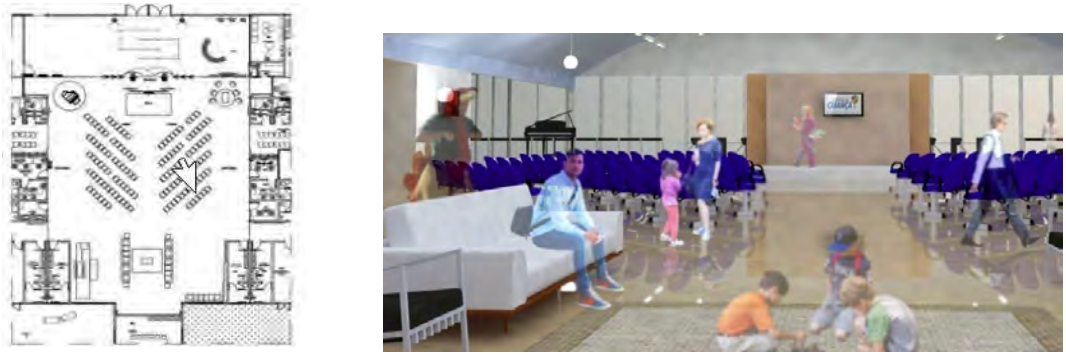


Figure 5. Layout proposal for the hall em plant and 3D image

Technical justifications for the proposals for adjusting Reverberation Time (RT)

As the results showed, a serious problem was the excessive Reverberation Time in basically all frequencies and its even distribution in the room. In order to reduce RT values and interfere as little as possible in the architecture and hygiene guidelines for hospital environments, we opted for the application of absorbent material throughout the ceiling surface. A sound-absorbing material made from PET wool was then specified, a product that uses recycling resources in the production of acoustic blankets, which satisfactorily replaces the use of rock and glass wool. We also proposed that the ceiling be printed azure with some clouds drawn onit.

Further simulations were made in the same programs with the new coating and the resulting values of Reverberation Times, now suitable; the values obtained are in the range of 0.44 to 1.83s from 100 to 10kHz; For 500Hz the value of TR is 0.75s; See Charts 3 and4.

Chart 3. RT Results at the corner

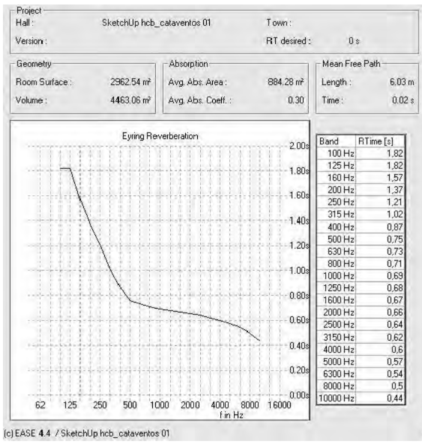

Chart 4. RT Results at the center of the room

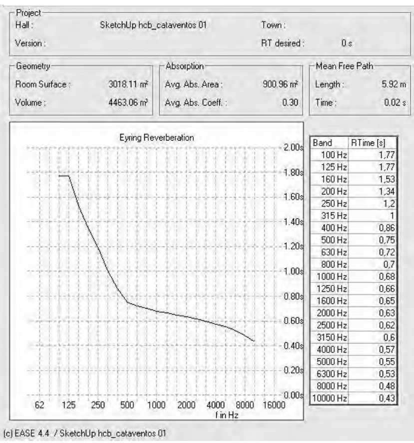
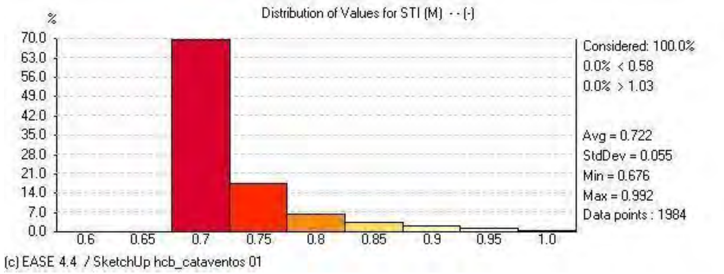


Technical justifications for the proposed adjustments of Speech Transmission index

The simulation result values for STI taking the new materials in account also resulted in very significant improvements: the lowest values were 0.68. In spots furthest from the source, the results were considered good and the results in intermediate conditions were considered excellent. These data indicate very good speech audibility too. See Chart 5.

Chart 5. STI Results of simulations of the proposals for the corner and center of the space
From software *Ease v4.4.11.4*, 2016



Proposals for inclusion of sound reflection directing elements

The first is that the surrounding space must absorb the sound well; another condition is that the background noise must not be superior to the sound to be heard on-stage and the third is that the main source, that is, the sound source to be heard, must be directed to the audience; the emitted energy must be reflected to determined points through the inclusion of sound reflection elements. These should be directed to the most distant points of the audience, to avoid reflection to the closest listeners and the production of echoes. This reduces the intensity of sound, also improves the STI values and the perception of music.

The proposal consists of suspended elements in a windmill shape, similar to the hospital logo, made of MDF material or any other material with similar sound reflection coefficients, hanging above the light fixture, also suspended in the ceiling. It is important to note that they must be installed with precise inclination for a correct orientation of the reflections. The plan below shows the application schematics and 3D drawings illustrate for better visualization, figure 7:

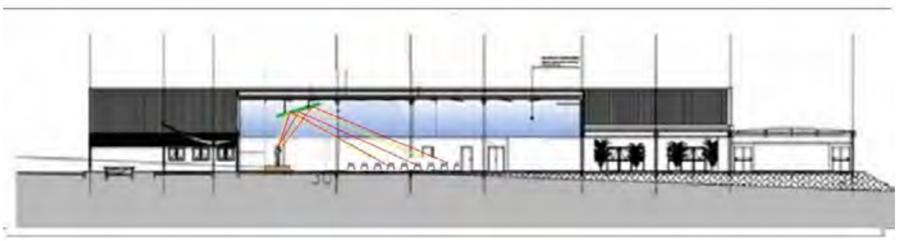


Figure 7- Illustration of the hall with the windmill and the related reflections for the audience

Figure 8 – Illustrations in 3D of the two proposal alternatives of the windmill implementations: eight smaller or three, bigger. Applied with defined inclinations.

Aesthetic justification of the proposal and conclusions

As mentioned, the application of these elements fulfills the function of directing the reflections of the sound rays. A technical function, not only decorative elements, but the aesthetical harmonization in the broadest sense of the term. There was also concern about the junction with luminaires that could not be removed. However, in addition to the two alternatives of colored varnishes, larger or smaller, were also presented the option of the same elements, colorless, transparent, made of acrylic or similar material, as "lighter" option, but of the same technical performance. See figure 8 above.

All conditions that initially seemed unfavorable and even incompatible with the acoustic use of that space, when analyzed and evaluated more judiciously, proved to fit the adequate expected result. The proposal was accepted by the team of HCB designers, and goes on to the executive design phase, adapting to the existing structure and enabling a new stage of studies on itseffectiveness.

Design to Thrive

Workplace acoustic: A new perspective on noise dissatisfaction in open-plan spaces

Farrah Jahangeer[1]

[1] Ecole Nationale Supérieure d'Architecture de Nantes-Mauritius, Laboratoire AAU CRENAU, correspondence e-mail: farrah.jahangeer1@nantes.archi.fr

Abstract: Noise dissatisfaction in workplaces is a longstanding issue and open-plan layouts are commonly associated to this. The ability to represent the soundscape visually is explored here with the use of a new variable termed 'noise geometry' which is generated by the location of perceived noise sources when present in workspaces. Geometric indicators are used to quantify workspace geometry and noise geometry. The aim of this study is to develop this visual index so that it can be applied to early designs and is part of a doctoral study. It is hypothesised that a positive correlation exists between geometric indicators of workspace geometry and those of noise geometry is in turn negatively associated with acoustic satisfaction. Three sub-categories of open-plan spaces based on occupancies are investigated in a cross-sectional field study based in Glasgow: OP1 (< 10 employees), OP2 (between 10 and 25) and OP3 (> 25 employees) with a total of 153 open-plan spaces surveyed. The study also makes use of self-completed questionnaires and acoustic measures. The findings indicated significant associations between workspace geometry, noise geometry and acoustic satisfaction in two office categories. The possibility of visually indicating some aspects of noise perception is further discussed in this paper.

Keywords: noise, open-plan, acoustic satisfaction, geometry, spatial parameters

Introduction

Different aspects of noise in workspaces have been extensively investigated in the past with the aim of improving acoustic comfort and work performance; sources of office background noise (Danielsson & Bodin 2009), intensity of background noise (Landström et al. 1995; Seddigh et al. 2015) and speech transmission index (Haka et al. 2009; Loewen & Suedfeld 1992). Background conversations remain a pervasive issue in the workplace. The association between background conversations and noise dissatisfaction is further supported by the changing state theory of Jones et al. (1992) stating that uncontrollable and intermittent speeches are more annoying that constant loud noise. It could be argued that most studies investigating noise in the workspace are within acoustic or psychological fields and only several in the architectural field. Within the latter field, few studies have looked at open-plan layouts (Brennan et al. 2002) , individual workspace area and spatial density (Frontczak et al. 2012) in relation to employee noise dissatisfaction.

The geometry of workspace in relation to noise dissatisfaction is yet to be investigated. Recent studies investigated geometry of workspace and buildings in relation to building optimization for energy savings. Wang et al. (2006) looked at the variation in lengths and angles of a floor plan polygon in relation to building energy performance while Granadeiro et al. (2013) looked at the building envelope shape in relation to energy performance values of an existing building. However, the associations between workspace geometry, acoustic measures and employee dissatisfaction have not yet been analysed.

Alternately, the increased use of noise maps adds a two-dimensional aspect to urban acoustic analysis. Urban noise maps are used to analyse noise levels of a specific area in relation to the number of dwellings, inhabitants and the limits of noise exposure and the propagation of noise around buildings. However, this method assesses mostly noise intensities in relation to limit values within an area and is more revealing on a macroscale than a microscale. Alternately, sound maps, described by Schaffer (1977), indicate the types of noise sources and the perceived intensity of noise. It is considered that sound maps are more indicative of sound quality than noise maps. In this study, it is intended to develop a two-dimensional visual index derived from the use of geometry and sound maps that would be representative of noise dissatisfaction in open-plan workspaces. This 2-D visual index is also developed with the aim of providing an indicator of noise dissatisfaction at early design stages of open-plan workspace designs.

Definition of noise geometry

Studies making use of 2-D parameters when analysing the perception of noise in the workspace so far have made use of ego-centric distances (distance between listener and noise source) (Cabrera & Gilfillan 2002) and radius of distraction (radius within which STI is considered to be below 0.5)(Passero & Zannin 2012). Nonetheless, in these two aforementioned studies, the distance between sound source and listener are predetermined which is not the case in actual workspaces. A new two-dimensional visual index, termed as ‘noise geometry’, is introduced in this study and refers to the extent to which noise sources are discernible when one is momentarily present in a workspace. It is derived by placing convex envelopes around the location of identified (or perceived) noise sources when present in a workspace. Noise geometry is considered to be representative of an individual’s noise perception in relation to acoustic quality present and to the intensity of noise sources. Noise geometry is analysed in this study in relation to workspace geometry, acoustic measures and noise dissatisfaction.

Research questions and hypotheses

It is anticipated that the floor plan geometries are related to noise geometries which in turn are associated with employee noise dissatisfaction. In this study, the following research questions are being addressed: A) is open-plan floor geometry related to noise geometry? B) Is noise geometry associated to acoustic indicators? C) Is noise geometry related to noise dissatisfaction? Two acoustic indicators being studied here are reverberation time and background sound levels. Both studies of Perham & al. (2007) and Beaman & Holt (2007) indicated that the distance between noise source and listener is related to reverberation time. Here we look at reverberation time of different workspaces in relation to the noise sources perceived and to noise geometry. For question A it is hypothesised that at least one of the indicators would indicate a positive correlation between open-plan floor geometry and that of noise geometry. The same type of correlation is expected for noise dissatisfaction variables in question C. However, for question B it is expected that the increase in at least one indicator of noise geometry would be associated with an increase in noise level but a decrease in reverberation time. The expected negative correlation between reverberation time and noise geometry are based on the results of Perham et al.

(2007) and Beaman & Holt (2007) where noise sources were more discernible when reverberation time decreased.

Research methodology

Research Sample

The study was based in commercial areas of Glasgow City centre. The workspaces of participating organisations were situated in multi-storey buildings mostly built before 1950s. Interior of workspaces had been refurbished within the last 10 years and had carpet flooring and plasterboard walls. Ceiling finishes (suspended metallic or cork acoustic panels) and the size of openings varied among the workspaces. Participating organisations were divided into three open-plan categories based on occupancy: OP1 (less than 10 employees), OP2 (between 10 and 25 employees) and OP3 (more than 25 employees). The sample consisted of a total of 153 participants with 33 in OP1, 34 in OP2 and 86 in OP3. The percentage of females in the sample were: 79% in OP1, 64% in OP2 and 38% in OP3. The median age group in OP1 was 30-39 years and in OP2 and 40-49 years in OP3.

Research design and procedures

A cross-sectional research design framework was applied to this study with the use of both subjective and objective measures. Self-completed questionnaires were used to evaluate satisfaction levels of employees on a 5-point Likert-type scale for acoustic satisfaction and work performance satisfaction. Questions for acoustic satisfaction evaluated background office noise, communication level, frequency of raising voice during a conversation and frequency of overhearing background conversations. For work performance, employees were asked to rate the frequency of difficulty faced when completing tasks, the ability to remain concentrated, frequency of distraction caused by background conversations and preference to work in a cellular workspace. Participants were also asked to identify the most annoying noise source in the workplace. Participation in the survey was voluntary and completed paper questionnaires were collected at the end of survey period.

For objective measures sound levels, workspace dimensions, type of desk layout (linear or non-linear) and location of noise sources when present in workspace were recorded in each workspace. Sound level was measured over a period of 7 hours with a calibrated sound level meter (CEM DT-8851/8852) and reverberation time was calculated using Sabine's formula $R = \frac{0.16V}{A}$ (Furrer 1964), where *R* is reverberation time, *V* is volume and *A* is total absorption surface areas. Besides acoustic and workspace measures, two shape descriptors applied to the field of Geometric Information Systems were used to quantify geometry: area and elongation ratio. Area represented the size of the geometry while elongation ratio described the form of the geometry. Elongation ratio was calculated by using Dauwalter & Rahel's (2011) method - $A/_{L^2}$, where *A* is the area of geometry and *L* is the maximum length of geometry. The values for the later vary between 0 and 1 where 0 indicates a stretched rectangle and 1 represents a perfect square. A bounding box was placed around the geometry using Toussaint's (Chan & Tan 2001) 'rotating calliper' technique and from which the maximum lengths and widths of the geometry were derived.

Data analyses

The intention of the study was to determine the nature of the relationship, if any, between workspace floor geometry, noise geometry, acoustic measures and satisfaction ratings. For the analysis of geometry indicators, areas of noise geometry were correlated with those of workspace floor geometry but not with elongation ratio values because area and elongation are two different indicative aspects of geometry and are not necessarily associated. Questionnaire answers were coded from 1 to 5 with 5 being the most positive response and each participant in the survey was considered as a case. The sample size was considered to be moderate and with a non-normal distribution. SPSS version 21 was used here for all data analyses. Kruskal-Wallis test was used to indicate significant differences among the three workspace types for objective variables. Median absolute deviation was used here and values out-with 2 absolute deviations from median were considered outliers for 95% confidence interval. Spearman's Rho test was used for bivariate analyses and *p-value* under 0.05 indicated strong associations between variables.

Results

People talking was the most annoying noise source in all three open-plan categories (see Figure 1 below). Percentage of employees satisfied with acoustic background in general was as follows in the three categories: OP1 – 59.1%, OP2- 36.8% and OP3 – 41.3%. In all three types of workspaces percentage of employees reported being distracted by background conversations were above 50%. Kruskal Wallis test indicated significant differences among the three office types for noise level ($X^2(2) = 34.9$, $p<0.05$) and reverberation time ($X^2(2) = 25.4$, $p<0.05$) highlighting that both noise level and reverberation time tended to increase from OP1 to OP3. The median noise level for each category were as follows indicating an increase in noise level with the occupancy; OP1=45.4 dBA, OP2= 48.9 dBA, OP3= 52.0 dBA. Median reverberation time for each category was as follows; OP1 = 0.40s, OP2= 0.88s and 1.14s. Geometry indicators also differed significantly among the three categories; workspace floor area ($X^2(2) = 108.9$, $p<0.05$), noise geometry area ($X^2(2) = 120.6$, $p<0.05$), elongation of workspace floor ($X^2(2) = 41.5$, $p<0.05$) and elongation of noise geometry ($X^2(2) = 114.3$, $p<0.05$).

Workspace geometry and noise geometry

The results obtained in OP1 and OP2 supported the hypothesis stating that one of the geometry indicators would show a positive association between workspace geometry and noise geometry. In OP1 workspaces, area of floor geometry and that of noise geometry increased together ($r=0.681$, $N=33$, $p<0.01$) and the elongation of noise geometry increased together with that of floor geometry ($r=0.684$, $N=33$, $p<0.01$). The increase in floor areas of OP1 workspaces above the median of 57.5m^2 had linear desks arrangements and noise geometry area above the median value of 16.0m^2 thereby suggesting that employees in larger OP1 workspaces were within closer proximities (employees were closer to each other in linear desk arrangements than those in non-linear desk layouts) and hence conversations were more likely to be heard. In OP2 workspaces, the increase in floor area above 98.6 m^2 was also associated with an increase in area of noise geometry ($r=0.664$, $N=34$, $p<0.01$) above 31.2 m^2 but no significant correlations were observed for elongation values between workspace floor geometry and that of noise geometry. The association between floor geometry and type of desk arrangement was irrelevant in OP2 workspaces because all offices had linear desk layouts. Geometry indicators showed no significant correlations between floor geometry and noise geometry in OP3 spaces. Associations between workspace geometry indicators, noise geometry indicators and desk layout were not coherent in OP3 offices and this was considered to be partly related to the fact that one workspace in the sample had a different design feature – part of the office walls were not full-height thereby producing incoherent results.

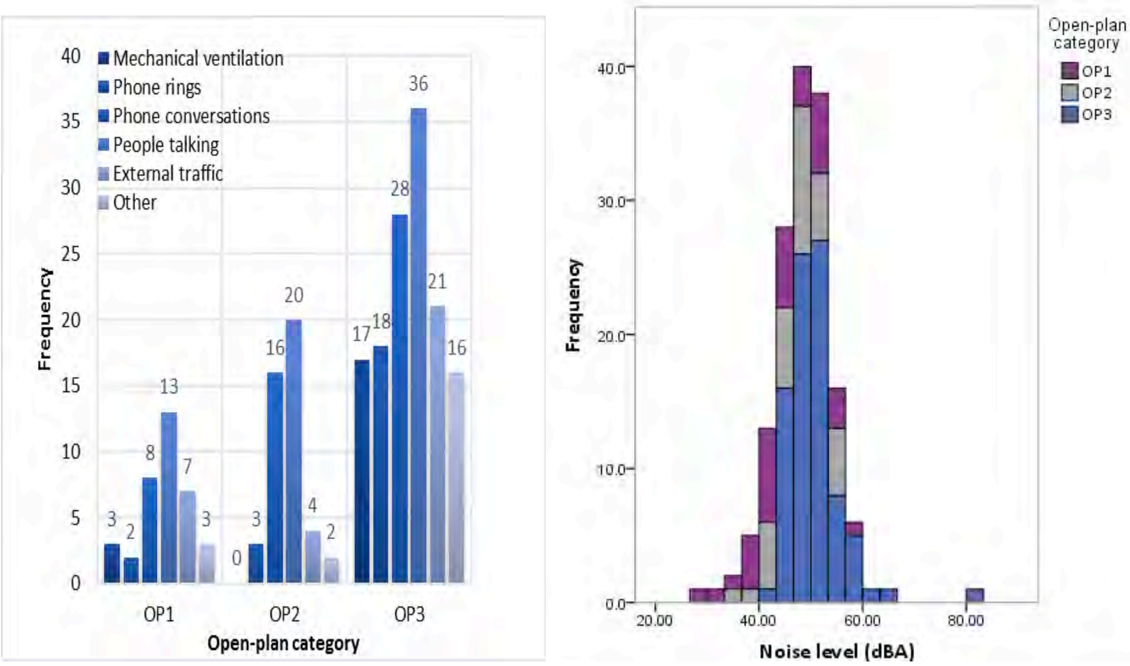

Figure 1. Graphs indicating most annoying noise sources in each office type

Noise geometry and acoustic measures

As seen in Table 1, the associations between workspace geometry indicators and acoustic measures varied according to office category thereby failing to support the expectation that the increase in floor area would likely be associated to an increase in both noise level (because of the increase in occupancy) and an increase in reverberation time (because of an increase in volume). The findings indicated that in OP1 workspaces, the increase in area of noise geometry above $16m^2$ was associated with an increase in noise level (see Table 1.0) above 44.4 dBA. No significant association was observed between area of noise geometry and reverberation time in OP1 but elongation value of noise geometry in OP1 was positively associated with both noise level and reverberation time. In OP2 workspaces, an increase in both area above 31.2 m^2 and elongation ratio value above 0.31 of noise geometry was associated with a decrease in reverberation time below 0.95s. No significant correlations were observed between noise geometry indicators and noise level in OP2. In OP3 workspaces, the increase in both noise geometry area above 76.6 m^2 and noise geometry elongation ratio above 0.69 was associated with a decrease noise level below 52 dBA. No further significant correlations were observed between noise geometry indicators and reverberation time in OP3 spaces. The hypothesis stating that the increase in at least one indicator of noise geometry would be associated with an increase in noise level but a decrease in reverberation time was not supported in any of the three workspace categories.

Table 1. Spearman's Rho correlation coefficients when analysing geometries and acoustic measures in each workspace type. Significant where ** p<0.01, * p<0.05

	Reverberation time			Noise level		
	OP1	OP2	OP3	OP1	OP2	OP3
Workspace geometry area	0.545**	-0.664**	-0.877**	0.493**	0.060	0.353**
Workspace geometry elongation	0.025	-0.664**	1.000**	0.334	0.060	-0.603**
Noise geometry area	0.096	-1.000**	0.048	0.607**	-0.099	-0.455**
Noise geometry elongation	0.378*	-0.569**	0.048	0.447**	-0.195	-0.455**

Noise geometry and noise dissatisfaction

The hypothesis stating that at least one indicator of noise geometry would be positively associated with noise dissatisfaction was supported in all three workspace types (see Figure 2). In OP1 workspaces, the increase in area of noise geometry above 16 m^2 was associated with a decrease in acoustic background satisfaction (r=-0.377, N=33, p<0.05) from 75% to 47.4% (see Figure 3.) and an increase from 53.6% to 29 % in the preference to work in a cellular office (r=0.511, N=33, p<0.01). No significant correlations were observed between elongation ratio values and acoustic satisfaction ratings or work performance ratings in OP1 workspaces. In OP2 workspaces, the increase in area of noise geometry above 31.2m^2 was significantly associated with a decrease in acoustic background satisfaction (r=-0.370, N=34, p<0.05) (see Figure 4.) from 60.8% to 29.2% and an increase in the preference to work in a cellular office (r=0.355, N=34, p<0.01). No significant correlations were observed between elongation values of noise geometry and employee satisfaction in OP2 spaces. In OP3 workspaces, it was also observed that the increase in noise geometry area above 76.6m^2 was associated with a decrease in acoustic background satisfaction (r=-0.317, N=86, p<0.01) from 80% to 35.5% and with an increasing preference to work in a cellular office (r=0.285, N=86, p<0.01). However, in OP3 spaces, elongation ratio values were significantly associated with acoustic background satisfaction (r=-0.317, N=86, p<0.01) and the frequency of perceived noise disturbances (r=0.507, N=86, p<0.01).

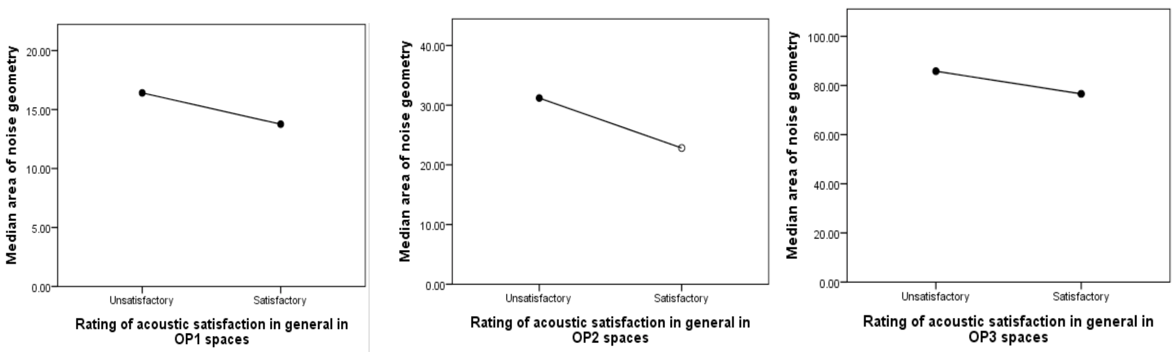

Figure 2. Acoustic satisfaction ratings in all three workspaces

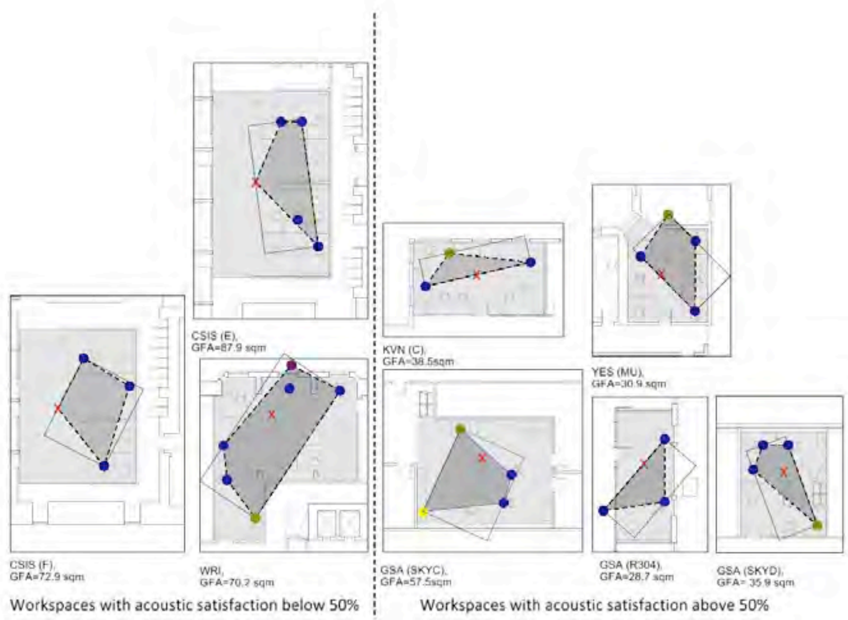

Figure 3. OP1 workspaces with associated noise geometries and acoustic satisfaction ratings

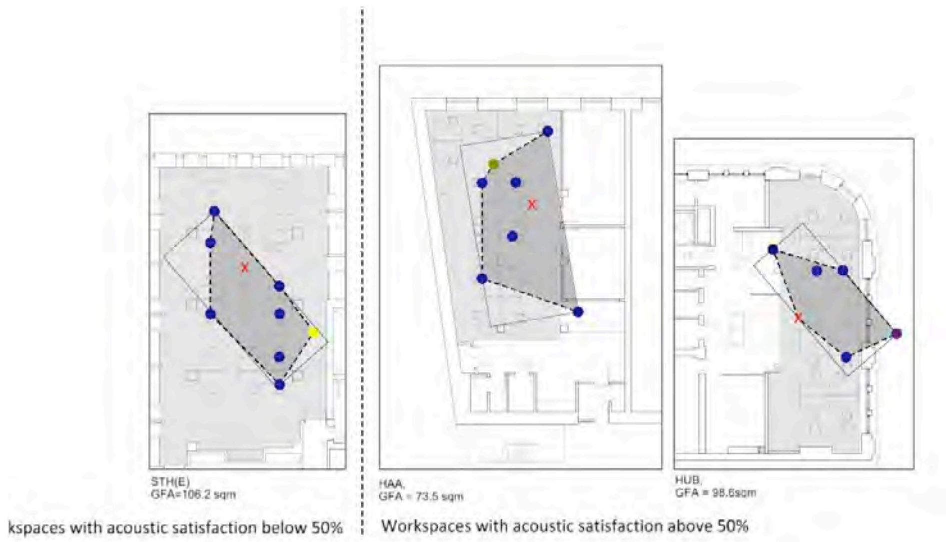

Figure 4. OP2 workspaces with associated noise geometries and acoustic satisfaction ratings

Discussion

The results supported the hypothesised positive correlation between noise geometry and acoustic satisfaction in three workspace categories which could be considered a starting point in the development of a visual index for acoustic satisfaction in the workplace. The associations between workspace variables were coherent only in OP1 and OP2 workspaces thereby indicating that workspace geometry, noise geometry and noise dissatisfaction are interrelated but not necessarily in the same way. In OP1 spaces, the increase in floor area was associated with an increase in noise geometry area and a dissatisfaction in acoustic satisfaction. In OP2 workspaces, the increase in floor area was associated with a decrease in reverberation time and a decrease in acoustic satisfaction. In OP3 spaces, it was considered that the uncommon architectural features, such as openings and gaps in partitions led to diverging and incoherent results. The negative correlation between noise geometry and reverberation time in OP2 space begins to question the common tendency of reducing reverberation in open-plan spaces. Only two GIS factors, area and elongation were analysed here and area was more significant than elongation ratio. Perhaps other GIS factors, such as Shape Index might be more relevant when quantifying the geometries. Future areas of investigation might focus on the variation of noise geometry with time in relation to acoustic satisfaction in the workplace with the possibility of determining a noise geometry pattern.

Abstract: The aim of this paper was to verify the influence of urban features on the patterns of surrounding sound pressure levels. In these study areas, 28 points were distributed into two routes located in São Carlos (Brazil). These points were taken as references to measure A-weighted equivalent sound pressure levels (L_{AEq}), as well as to determine the urban geometry parameters, such as the street height and width ratio (H/W factor), the volumetric index and the occupation rate. The results show that one of the areas presents a high correlation with the sound levels. Furthermore, among the factors studied, the building height, the volumetric index and the occupancy rate were highly important considering the increase of sound pressure levels.

Keywords: Environmental Noise, Urban acoustics, Urban Indices, Urban form indicators.

Introduction

Sound pollution interferes directly in inhabitants quality of life in urban centres, regardless of the size of the city. According to the World Health Organization (WHO, 2012), 10% of populations suffer from some type of disease caused by noise, such as hypertension, sleep disturbance and hearing loss. The European Union (EU) (Directive 2002/49/EC on the management of environmental noise) defines environmental noise as “unwanted or harmful outdoor sound created by human activities, including noise from roads, rail, airports and industrial sites”.

Even though road traffic noise is one of the main sources of urban noise, there is also a role played by urban forms considering the increase in sound levels. Sound can be absorbed, reflected or transmitted according to the characteristics of the urban geometry. In the urban environment, propagation of sound waves is affected by the existence of green areas, building heights, street widths, materials used on the façades and their absorption. The more impervious the urban mesh is, the greater the reflections causing the phenomenon of sound reverberation. Bistafa (2006) shows that various sound reflections on the facades of buildings may cause noise to amplify. Okada, Yoshihisa and Kuno (2010) observed an increase of 8dB related to the reflections of traffic noise on building facades. Guedes and Bertoli (2005) show that the influence of sound waves reflected on the urban environment can cause discomfort to some areas, and none to others.

Wang and Kang (2011) and Salomons and Pont (2012) emphasize that urban morphology (including the width of roads, squares, building heights bordering roads, green areas and urban densities) affects and potentializes sound propagation in urban centres. These authors have found a positive correlation between noise pollution and the higher density of cities. However, narrower roads, complex road networks and higher density of intersections lead to lower traffic volume, and thus, lower noise levels. Other studies have also found that various morphological elements in the urban environment can influence noise pollution, such as construction density, open spaces, as well as the shape and physical position of the buildings (Souza and Giunta, 2011; Oliveira and Silva, 2011).

This paper verifies the influence of urban features, such as street width and building height ratio, on the patterns of noise pressure levels encountered in urban areas. For this purpose, two pedestrian routes in a medium-sized Brazilian city were investigated.

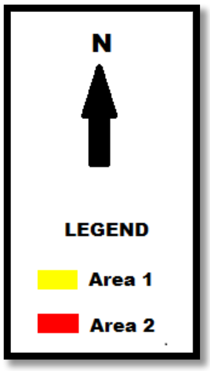
Methodology

The equivalent noise pressure levels (L_{AEq}) of two neighbourhoods in the city of São Carlos in São Paulo State, south Brazil were studied. This city is situated at 22° 01′ 03″ latitude and 47° 53′ 27″ longitude, and the average elevation is 854 m above sea level. São Carlos, located in the middle of São Paulo State, has an area of 1143.9 km^2 and a population of 221,950 (IBGE 2010) inhabitants.

The two study areas can be seen in Figures 1 and 2. The neighbourhood of Area 1 is a commercial zone and it is located in the city centre. The route that was studied connects the central area to Campus I at the University of São Paulo (USP). The second neighbourhood (Area 2) is a residential zone that resulted from new urban planning. Both routes begin in areas where there is a high concentration of services, as well as student and family residences and each one ends at one University Campus. Considering both areas, a total of 28 points were selected to determine the sound pressure level measurements: 11 points in Area 1 shown in Figure 3 and 17 points in Area 2 shown in Figure 4.

Figure 1. Studied Area 1.

Figure 2. Studied Area 2.



Data collection

First, the peak periods of vehicle traffic were identified. They are on regular weekdays from 7 a.m. to 8:00 a.m. and 5:30 p.m. to 7 p.m. Data was collected to determine the vehicle traffic at each one of the 28 reference points distributed along two routes, one for each area. In Area 1 there are 11 points along the route and in area 2 there are 17 points along the route. Figures 3 and 4 show these points and the routes. Weekends (including Fridays and Mondays) and holidays were excluded from the data collection.

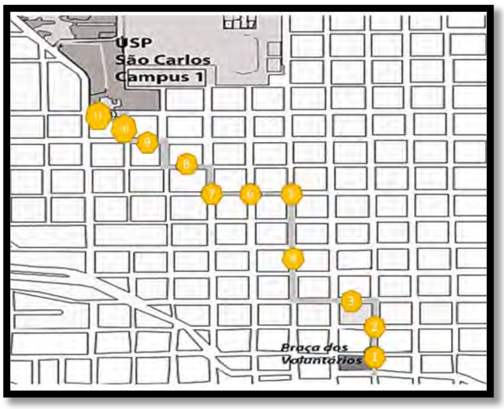


Figure 3. The eleven measurement points along the route in Area 1.

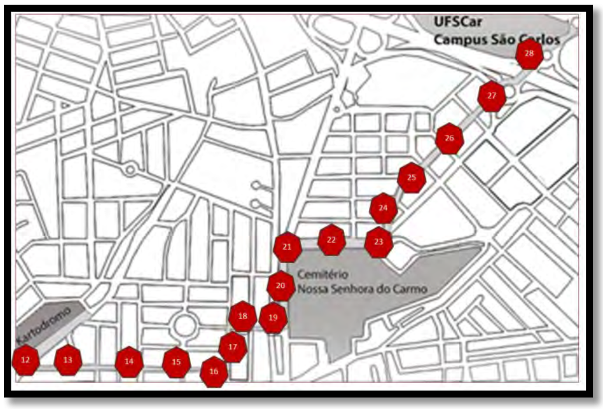

Figure 4. The seventeen measurement points along the route in Area 2.

Afterwards, characterization of the street noise was performed. Noise levels (L_{Aeq}) were registered at the same reference points for the two periods determined as peak periods. The L_{Aeq} values were obtained with the sound pressure meter Analyser 2270-L proposed by Brüel & Kjaer, which was set up to integrate levels at an A-weighted scale and in a fast response mode, over 5 min. The equipment was positioned at a height of 1.20 m from the ground, keeping a distance of at least 2 m from reflective surfaces (walls) and facing street traffic.

Afterwards, the urban features were determined. Cadastral maps of the study area were collected to identify the location of each building within the lot. The height of each of these buildings was then quantitatively estimated by visual site inspection. The estimation of the building heights had a local floor height standard of 4 m, which is generally adopted for the ceiling height of each building floor.

A statistical analysis was performed to study the influences of the Occupation Index (Construction area/Block area) and the Volumetric Index (Volumetric Index of the construction/Block area) on the sound pressure levels. These levels were also compared to the acoustic parameters established by the Brazilian technical standards NBR 10.151 (ABNT, 2000).

The sound values were compared to the geometric parameters and the urban indexes obtained for each block. For each point of measurement of the equivalent sound pressure level, the influence of the four adjacent blocks of the measurement point was analysed.

Results and Discussion

In order to verify the relation between the noise and urban geometry, in Fig. 5, the L_{Aeq} obtained in the 28 points are shown. It is noticeable that all values found are higher than the Brazilian NBR 10.151standards. As can be seen, both study areas have a high level of noise with a maximum level of 75.3 dB. According to NBR 10.151 for areas whose main use is residential, the maximum noise level allowed is 55 dB for the morning and evening, and 50 dB during the night.

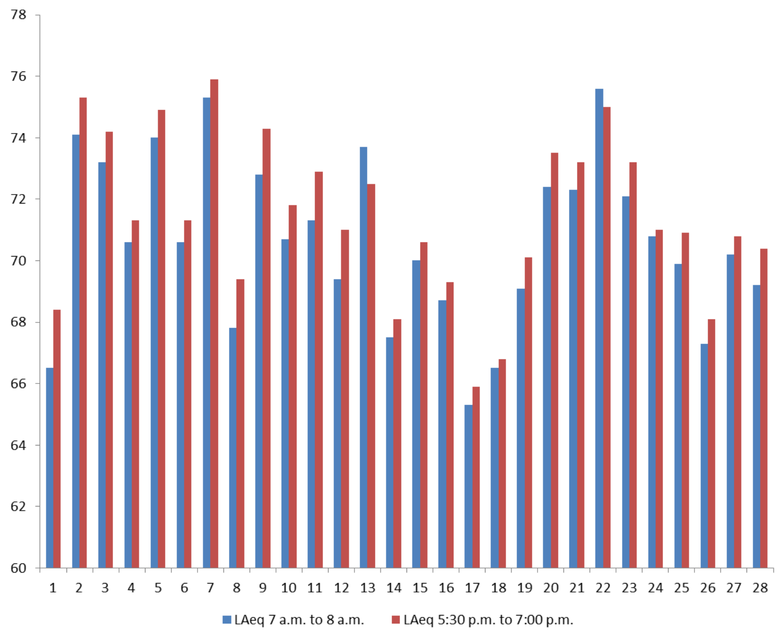

Figure 5. Measured values for each point in both periods

Therefore, both areas presented high levels of noise. When comparing them, as shown in Table 1, Area 1 (regular configuration) presents a higher noise level and a higher Occupation Index than Area 2 (irregular configuration).

Table 1. Values of sound pressure levels and landscape metrics.

	Sound pressure level			Occupation Index (%)	Volumetric index		
	Min	Max	Average		Min	Max	Average
Area 1	66.50	75.30	71.54	46%	0	3.52	1.59
Area 2	65.30	73.70	70.00	39%	0	2.88	1.48

As shown in Table 2, Area 1 shows a higher building height than Area 2, however the maximum H/W ratio (up to 2.0) occurs within both of them.

Table 2. Values of Urban features.

	Building height (m)			Street width			H/W		
	Min	Max	Average	Min	Max	Average	Min	Max	Average
Area 1	4.00	40.00	14.91	9.50	18.00	9.93	0.1	2.90	0.88
Area 2	4.00	30.00	10.64	7.50	18.00	11.24	0.1	2.43	0.53

In Table 3, the data collected in Area 1 are presented: sound pressure levels, road speed limit, street width, building height, occupancy index (Sum of built-up areas/Block area) and volumetric index (built volume / block area) and the H/W ratio. It can be observed that the highest noise indexes are related to high velocity indexes and to high H/W ratios, which always have values higher than 1.

The only point that does not respect the rule of this relation is point 11, where the sound pressure level is 71.30 dBA for the morning period and 72.90 dBA for the night period, and the H/W ratio is 0.40. This variation is probably due to the presence of traffic lights and bus stops.

Table 3. Data collected and analysed from Area 1.

Point	LAeq (dBA) - 7 a.m. to 8 a.m.	LAeq (dBA) - 5:30 p.m. to 7 p.m.	Speed limit (km/h)	Street width (m)	Building Height (m)	Occupation Index (%)	Volumetric Index	H/W
1	66.50	68.40	30.00	15.00	8.00	0.11	0.62	0.53
2	74.10	75.30	50.00	16.80	18.00	0.29	5.75	1.07
3	73.20	74.20	50.00	27.35	44.00	0.37	13.75	1.61
4	70.60	71.30	50.00	13.80	40.00	0.33	10.86	2.90
5	74.00	74.90	50.00	16.00	18.00	0.35	7.70	1.13
6	70.60	71.30	50.00	13.00	16.00	0.31	7.14	1.23
7	75.30	75.90	50.00	10.00	4.00	0.31	6.79	0.40
8	67.80	69.40	30.00	10.00	16.00	0.37	6.65	1.60
9	72.80	74.30	50.00	13.00	16.00	0.32	5.28	1.23
10	70.70	71.80	50.00	13.00	20.00	0.38	6.65	1.54
11	71.30	72.90	50.00	20.00	8.00	0.27	4.03	0.40

It can be seen that the higher the ratio of the volumetric index, the higher the sound levels obtained. Thus, the volumetric index of the neighbourhood as well as the H/W ratio are parameters, which are useful in predicting sound pressure levels.

Table 4. Data collected and analysed from Area 2

Point	LAeq (dBA) - 7 a.m. to 8 a.m.	LAeq (dBA) - 5:30 p.m. to 7 p.m.	Speed limit (km/h)	Street width (m)	Building Height (m)	Occupation Index (%)	Volumetric Index	H/W
12	69.40	71.00	50.00	13,00	16.00	0.18	1.80	1.23
13	73.70	72.50	50.00	11,50	28.00	0.22	2.89	2.43
14	67.50	68.10	50.00	14,80	12.00	0.30	4.49	0.81
15	70.00	70.60	30.00	14,15	4.00	0.32	6.62	0.28
16	68.70	69.30	30.00	14,50	8.00	0.30	6.25	0.55
17	65.30	65.90	30.00	14,00	4.00	0.26	4.67	0.29
18	66.50	66.80	30,00	9,85	10.00	0.26	4.67	1.02
19	69.10	70.10	50.00	10.00	4.00	0.32	2.20	0.40
20	72.40	73.50	50.00	48.50	3.00	0.03	1.80	0.06
21	72.30	73.20	50.00	46.00	8.00	0.03	1.80	0.17
22	75.60	75.00	50.00	18.00	800	0.15	2.89	0.44
23	72.10	73.20	30.00	55.60	4.00	0.13	3.95	0.07
24	70.80	71.00	30.00	14.35	4.00	0.31	5.16	0.28
25	69.90	70.90	50.00	14.85	4.00	0.31	5.16	0.27
26	67.30	68.10	50.00	86.45	30.00	0.31	6.87	0.35
27	70.20	70.80	50.00	92.00	30.00	-	-	0.33
28	69.20	70.40	50.00	169.00	4.00	-	-	0.02

Table 4 presents the data from study Area 2. In this region of study, a correlation between the sound pressure levels and the H/W and volumetric index could not be found. We believe that one reason for this behaviour is the recent occupation patterns of Area 2, when compared to Area 1. Area 2 presents larger numbers of empty urban spaces and less vertical constructions. Points 27 and 28 were disregarded in the analysis of the occupation index and volumetric index, because they were located near the access road to the Federal University of São Carlos, which represents a distinct noise source and land occupation.

In addition, in Area 2, the distribution of the blocks is more irregular, presenting a lack of standardization in the dimensions of the urban blocks, presenting larger urban voids as in the vicinity of points 12, 27 and 28, which are private properties with no buildings. Points 20 and 21, which are located in the vicinity of the municipal cemetery, have large areas but with little volumetric construction, thus not leading to a significant interference in the noise of the environment.

Conclusions

In the present research, the joint analysis of sound pressure levels and landscape features has shown to be a suitable and an efficient tool to describe their relationship. There is a clear positive correlation between the H/W ratio and the sound pressure levels, at least for Area 1. However, though being positive, this relationship is less important when considering Area 2 for which the configuration is irregular.

Both areas under analysis presented high levels of noise, reaching values not within the healthy levels suggested by the Brazilian technical standards. Further studies should focus on these points, if a sustainable environment is to be reached.

Developing Sound Absorbers for Health Facilities. How to meet hygienic and acoustic Requirements in one Product

Dr. Uta Pottgiesser[1], Christoph Kirch[2]

[1] Henry van der Velde Research Group, Faculty of Design Sciences, University of Antwerp, Antwerp, Belgium, uta.pottgiesser@uantwerp.be;

Abstract: The hygienic requirements in health facilities, in particular in hospitals, lead in most cases to hard and high reflective surface materials and subsequently to long reverberation times. The noise level is high and the resulting speech intelligibility is low – both indicating poor room acoustics with stress-increasing impacts. In contrast, good room acoustics will help staff members to work more concentrated and with less mistakes and patients will profit from a better prevention, regeneration and healing.
Sound absorbers generally reduce reverb and create a comfortable acoustic environment. Additionally, sound absorbers for health facilities and hospitals need to reach the hygienic requirements on cleaning and disinfecting surfaces. This means in general, that surfaces need to be non-porous and smooth to implement the hygienic requirements, however, porous materials like foams are regularly used for sound absorbers. The purpose of the project was to develop a sound absorber that can be disinfected easily and with material that is chemically resistive to the usual disinfecting products. Constructive and acoustical solutions were developed and evaluated to meet the requirements of a high effective sound absorber with an aesthetic non-technical appearance to be used in common patient rooms and for specific applications in health facilities.

Keywords: Product development, Sound Absorber, Health Facilities, Hygienic requirements

Introduction

The disinfection of surfaces in clinics and mass catering institutions not only serves the cleanliness, but also the personal protection or the protection of health to prevent infection. For this reason, rooms, machines, all installations and component surfaces (walls, ceilings, floors and in particular acoustic elements) must be cleaned and disinfected on a regular basis.
According to the “Requirements on Hygiene when Cleaning and Disinfecting Surfaces – Recommendations by the Commission for Hospital Hygiene and Infection Prevention of the Robert Koch Institute“ (RKI, 2004) the surfaces of installations (ceilings, doors, walls) must be as smooth as possible, wipeable, joint-tight and cleanable with disinfectants and disinfecting procedures. Porous materials, mostly used for sound absorbers, have neither a smooth, closed surface nor can they be easily disinfected and therefore do not meet the increased requirements of the hygiene sector.

As a rule, the hygiene requirements in medical facilities lead to reverberant building and finishing materials, and thus to unfavourable room acoustics. The long reverberation times lead to a noisy environment with a low speech intelligibility (DIN 18041, 2015). Thus communication and concentration is disturbed even at low noise levels, resulting in reduced performance and increased frequency of errors. Regeneration (sleep) and healing are already adversely affected with very low noise levels. Both aspects are of great importance especially for patients (regeneration) and personnel (concentration) in medical, nursing and care-taking facilities (Notbohm and Siegmann, 2012).

In the presented research, the development, layout and design of a porous sound absorber was carried out which is to allow reliable cleaning and disinfection measures for the use in rooms of the healthcare environment, such as clinics and nursing facilities, as well as kindergartens and associated kitchen areas.

Conception

Since a modular design and a high and broadband efficiency should be maintained, the system needs to be encased in order to prevent microorganisms from penetrating the porous absorber's core. This protective layer should also remain acoustically transparent over the entire frequency range relevant for room acoustics.

At the same time the mechanical robustness should be as high as possible for the daily clinic routine so that it is not damaged easily by scratches. The materials and surfaces must be selected in such a way that they are resistant to cleaning and disinfecting agents when applied in specific doses and cycles. Liquids or humidity should not penetrate the porous absorber's core since there are a variety of active substances and substance combinations in cleaning and disinfecting agents with the following macro-families: alcohols, aldehydes, surface-active compounds (surfactants), halogens, oxidizing substances and acids and bases (Kramer and Assadian, 2008). Resistance data provided by the manufacturers are only suitable for a rough assessment and must be followed by practical tests.

The sound absorber must be designed and optimized in terms of optimal cleanability. This refers to the shaping (geometry), its connections and joints, its installation and assembly elements and the surface finish and its tightness against internal areas, e.g. by avoiding gaps, seams, sharp edges.

Approach

Identification and selection of surfaces and construction materials with optimum acoustic properties and compliant with hygiene requirements.

First, materials had to be sought which show resistance to disinfectants, since the surface always has to be resistant against the constituents of surface disinfectants. Since practical tests are essential (Ehrenstein and Pongratz, 2008) though very time-consuming (e.g. through adjusting the wipe disinfection over a longer period), both the construction materials and the disinfectants had to be reduced to a small number by means of pre-selection so that the chemical stability of the materials could be established. On the basis of literature references and manufacturers' specification as to material compatibility (Sastri, 2010), a conventional cleaning agent on the basis of quats and a fast-acting detergent were selected as well as construction materials for practical tests.

Acoustic transparency depends on (low) sound density or mass, and their stiffness. Stainless steel which is often used in medical devices is not available in the form of the required thin layers with sufficient width (of perforation?). The same applies to glass foil, particularly since the latter is also unpractical and expensive for the use in sound absorbers. This meant that only plastic materials were suitable to provide the microbiological barrier.

For the daily routines in hospitals, a certain mechanical robustness and scratch-resistance is necessary, especially when foils have to be applied on the outside, around the cassettes. Various types of plastic materials showed strengths, which did not only depend on the thickness of the layer, but on the material itself. But also, the processing of the material matters, e.g. polypropylene (PP) foil appeared initially to be rather soft for the purpose as it scratches easily by contact with fingernails, however as a stretched version (O-PP) with surface treatment, the mechanical strength is significantly higher. A (stretched) PET foil presented much better characteristics, while PVF foil, though chemically highly resistant, turned out to be less suitable due to low mechanical stability, and moreover it is rather expensive. After sampling various foils, some were selected for acoustic tests. Additional tests (fig. 1) examined chemical stability, the microbiological barrier and disinfectability (Gebel et al, 2001).

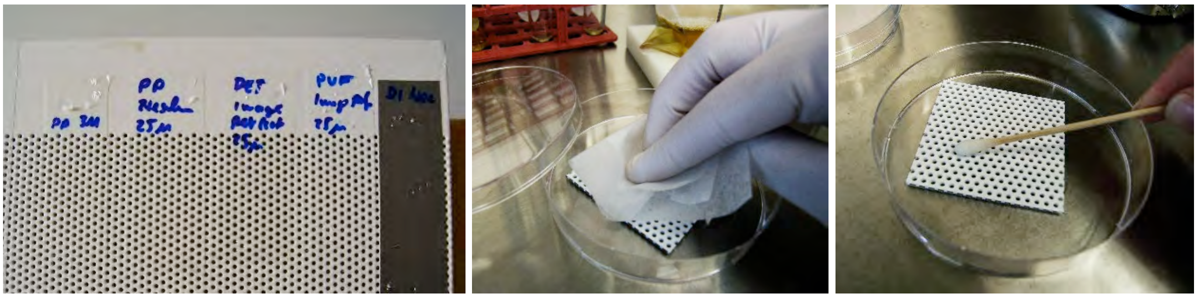

Fig. 1: Testing for scratch resistance/mechanical stability of plastic foils as well as the chemical stability and desinfectability of materials.

After analysis of the test results, the PET foil Mylar A with a thickness of 50 µm was chosen. This foil proved to be chemically stable and it provides a sufficient microbiological barrier. Measurements of the acoustic absorption properties provided satisfactory results i.e. covering the core of the absorber impaired the absorption only insignificantly [Kirch and Pottgiesser, 2016].

To meet the regulatory hygiene requirements on the sound absorber, certain aspects needed to be considered [Kramer et al, 2012]. On the side which requires disinfecting treatment, there must be no cuts or overlapping of foil. Overlapping creates areas which cannot be reached, while cuts might cause leaks. The edges of the foil or bonding layer need to be placed in an area where no disinfection takes place. Therefore, the approach was to develop a geometry for the housing which would allow mantling with foil which would require neither overlapping nor folding. This would be given by using a folded volume from one surface. The surface would thus remain intact. The housing can be wrapped without any cuts or overlapping and without the need to shrink-wrap the foil, a measure which always leads to ripples. The edge of the foil is moved to the rear area so that after wall-mounting and sealing of the joint, an area remains on the front with an intact surface that can be disinfected. This means that the disinfectant does not come in contact with the adhesive at the foil edges. It is important hereby that the edges all rest on the wall. After experimenting with this principle, geometries were worked out in detail and converted to paper models. (Fig. 2, 3).

Fig. 2: Samples of schematic models for the housing: Geometries of volumes, folded from one face.

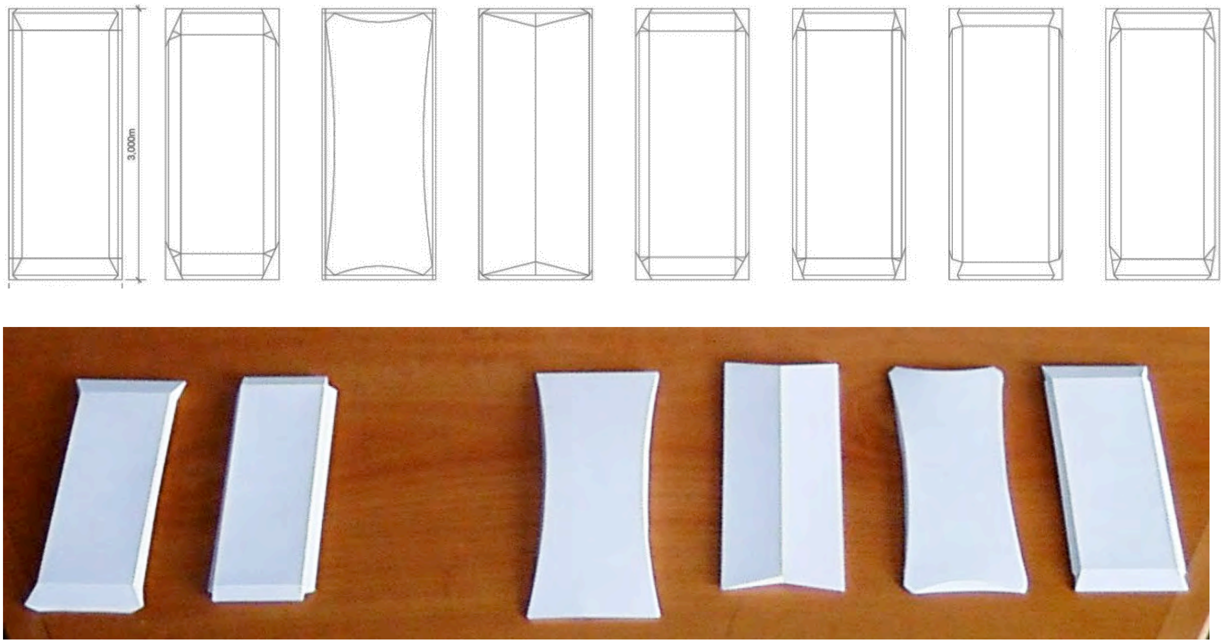

Fig. 3: For the sound absorbers, geometries that can be folded from the surface in the process (above) and as folded paper models of the geometries (below).

Designing an architectural integration based on status analyses

Medicine has developed into a service sector and health services have turned into consumer products. As a logical consequence, the trend in hospital architecture is towards more comfortable rooms with hotel character, a trend which should influence the design of sound absorbers. This allows for absorbers to be integrated easily at a later stage and for an uncomplicated retrofitting, the installation of the sound absorbers as a model was requested by the project partner.

Existing clinical architecture was analyzed with regard to the formal design and available areas for later installations, to show which installation options would typically lend themselves for the purpose. Installation variants were tried out with visualizations, which showed designs for sound absorber housings and their layouts. Here it was possible to try out how the different geometries and their arrangement could be included in various logical spatial contexts and also their effect (fig. 4).

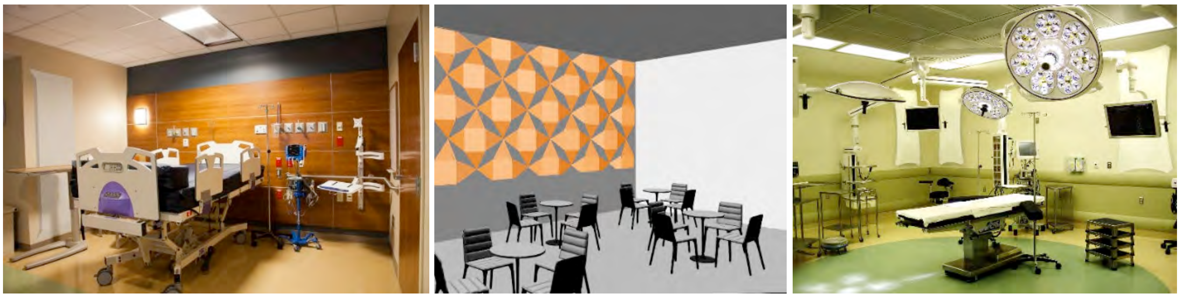

Fig. 4: Sample visualizations of different installation options of the sound absorber cassettes

Implementation of the design

After development of the form, the search started for suitable materials and methods for the production of the sound absorber housing. Deep-drawing of metal was no option for economic reasons, since the tool production would only amortise over high-volume production numbers. This led to the attempt to manufacture the housing from simple folding plate materials. Not only should the material allow folding, perforation should also be possible to let sound enter the cassette. Plate materials, in particular sandwich plates can be routed from the back to define the folded edge. This is known as routing and folding technique and is used e.g. for façade cassettes in aluminium compound sheets (Dibond). Tests were also carried out with aluminum sheets and plastics materials suitable for cold-bending (PC and PET-G) and where material thickness was routed (fig. 5).

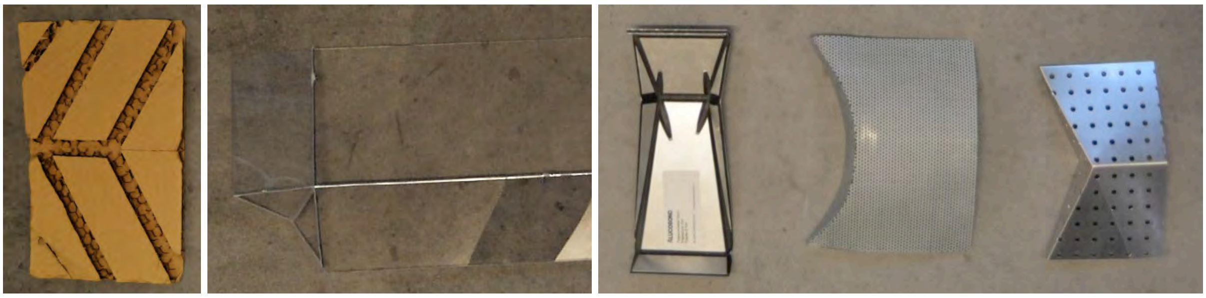

Fig 5: Functional model for different types of foldable housing materials.

After tests with functional models, scaled-down proto-types of folded cassettes were produced from aluminum composite panels, to test the suitability for the production of housing. (Figs. 6 and 7).

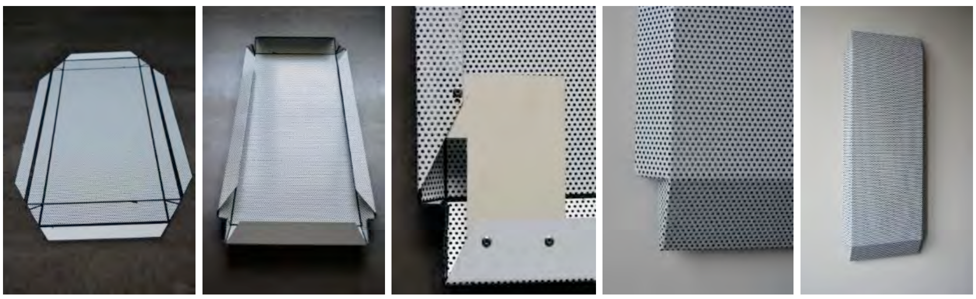

Fig 6: Prototype made of aluminum composite sheets, with routing and folding technology and corner bracing.

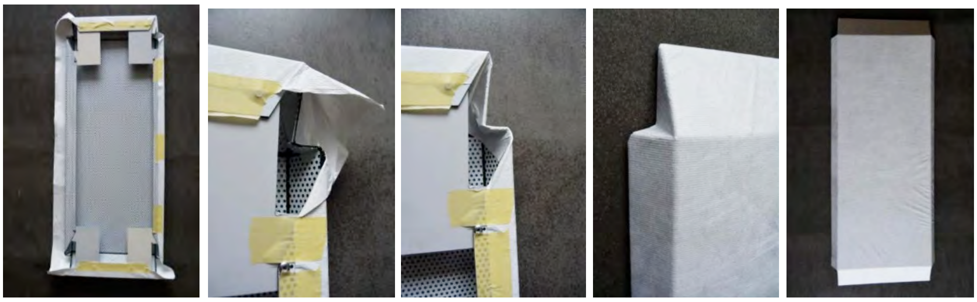

Fig. 7: Covering the prototype with PE fleece, with details of the inward fold of the foil at the inner corner (bottom). The bonding surfaces/foil edges have been moved inwards.

At the cassette, a fold is created by the material thickness where the foil is turned inwards at the edge and there it cannot be smoothly wrapped also because of the tough, rigid foil materials. This was easier to solve with the curved variant (fig. 8).

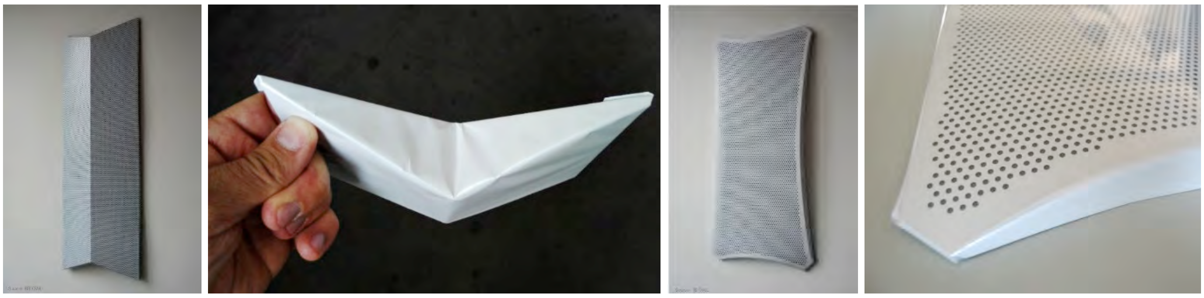

Fig 8: The edges which are turned inwards cause unevenness (left). Variant with arched edge with foil cover (right).

Since the edges of the cassette rest on the wall with a 90° angle, a flap is missing at the rounded edge to facilitate the mounting, which is only possible with the variant with the straight edge. Moreover the composite sheets led to spring tension effects at the folding edges which led inturn to retraction and imprecise geometry. The folding process also causes problems: All folds need to be achieved at the same time – a process which is not possible to carry out manually with the required precision and not doable at all at standard turning benches or in a press brake process. This would require a special 5-axle controllable robot which does not promise to be a cost-effective solution.

All these reasons led to a new approach: the housing will be made in cubic shape which allows an efficient manufacturing process with simple edging tools. The housing will remain open at the short edges so that the foil wrapping can be drawn inwards there. (Fig. 9).

Fig. 9: Detail of corner solution for the foil wrapping. The foil is drawn inwards through the open corner.

Since joints have to be sealed anyway at the point where the housing meets the wall, this joint needs only to be extended around the short housing edges where the foil turns inwards. In this way, it is possible to choose a tried and tested manufacturing process for the housing in order to wrap the same later with foil, without causing pleats or overlaps. Special adhesive tape needed to be found for the fixing of the foil to the sound absorber cassette, in particular since the powder coating of the cassette has poor adhesive properties and the adhesive tapes came off after a short while when put under tension during mounting. Good results were in the end achieved with an adhesive tape usually used for vapour barriers in buildings. This tape can be stretched lengthwise but not laterally. This is advantageous when wrapping the cassettes by hand with PET foil, which means that the inelastic PET foil can be applied without creating overlapping folds. Since the perforated sheet used for the housing shows a different thermal expansion coefficient than plastic foil, an additional foam adhesive tape is used on the back which offsets to some extent the different tensions.

The sound absorber has to be mounted tightly to the wall, according to RKI recommendation, this is to be done by applying a silicon sealant. Since the selected PET foil is a synthetic material, a sealing compound had to be found which is suitable for plastic materials. According to manufacturers' specifications (suitable for use in laboratories and food processing companies) silicones and an MS joint sealing compound were identified and purchased for suitability tests, in particular to test resistance to cleaning agents.

Trial results in real life settings

At the technology centre of the Life Science Technology department of HS OWL, it was possible to carry out a practical trial (fig. 10). After a successful installation and sealing of joints with silicone, the influence of reverberant time could be measured.

Fig. 10: Installation of a sound absorber in the technology centre of the department of *Life Science Technologies* at the University of Applied Sciences OWL.

Conclusion and Outlook

With a thin technical membrane, issues of acoustics and hygiene can be solved and suitable geometries allow efficient disinfection. It was possible to develop a product which complies with the requirements of hygiene, acoustics, material stability as well as design and construction and which thereby allows to optimize room acoustics in hospitals. There is increasing noise pollution in hospitals, nursing staff are retiring prematurely and there are multi-resistant germs, the spread of which should be prevented with consistent hygiene concepts. The same applies to office areas where noise pollution leads to a growing number of incidents of stress and burnout.

With better room acoustics (reduction of reverberation) more calm and better speech intelligibility can be achieved which in turn lead to fewer mistakes caused by stress and communication errors and to a lower basic noise level. [Fuchs, 2007]. Since sudden events and peaks are most distressing, it is possible to add soft(!) artificial noise in acoustically calmed areas which reduces the distance between background noises and sound peaks (i.e. sound masking) resulting in less stress. [Stanchina et al, 2005]. In hospital rooms these measures can result in better sleep quality and faster recovery.

Abstract: Traffic noise is among the main pollutions affecting the environmental quality of cities. This is particularly pertinent in the context of the cities in Asia and other regions where relative compact urban form as a result of high density urban development exacerbate the negative impacts of the ever-increasing traffic flows. This study investigate the impact of different building typologies on traffic noise distribution on both the horizontal level at pedestrian height for outdoor open space and the vertical level in front of building facades. Thirty generic urban block typologies representing different urban design strategies were analysed through noise mapping simulation study within a theoretically homogeneous context in which the conditions of the road traffic surrounding the site and the built density are fixed so as to control the source of noise and development density. Noise level obtained for outdoor open space with the site boundary at 2 meters height in a 2x2m horizontal grid and noise exposure level at a distance 1 meter away from façade in a 2x3m vertical grid along the façade surfaces were obtained from simulation using CRTN as the traffic noise calculation method. The findings indicate that there is a significant relationship between several planning and building geometry parameters and a variety of noise distribution performance indicators. The findings inform the planners and designers the key design factors that can be adjusted to mitigate the negative impact of traffic noise. This study also highlights the importance of performance evaluation in the early planning and design stage when the environmental performance can be optimized using different design strategies.

Keywords: Up to five, comma separated

Introduction

Traffic noise is among the main pollutions affecting the environmental quality of cities, which has been shown to have significant impact to the physiological comfort and psychological wellbeing of urban dwellers and to urban environmental quality in general (WHO, 2011). This is particularly pertinent in the context of the cities in Asia and other regions where relative compact urban form as a result of high density urban development exacerbate the negative impacts of the ever-increasing traffic flows.

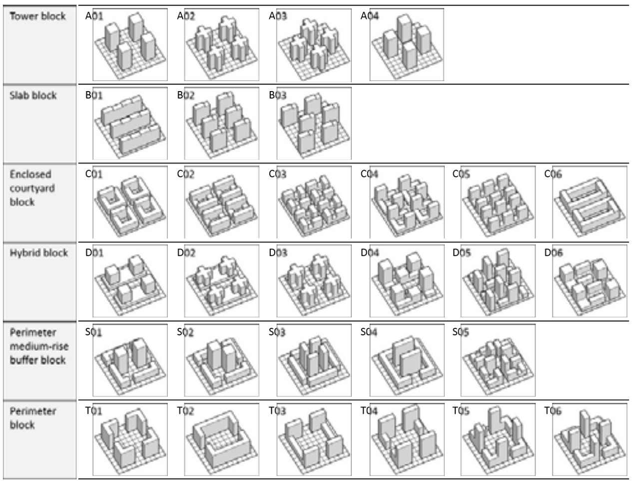
Various solutions, such as noise barriers and sound deflectors, have been implemented in many Asian cities to mitigate traffic noise pollution. However, most of them are costly afterthought measures and are not integrated with design of buildings and planning of urban infrastructures. There is a lack of studies on the planning and design factors that which shall be considered in the first place to minimize the impacts of traffic noise.

This study investigate the impact of different building typologies on traffic noise distribution on both the horizontal level at pedestrian height for outdoor open space and the vertical level in front of building facades. The objective is to identify the key urban planning parameters and building geometric variables that may help to formulate design guidelines for informed decision making in the early stage of planning and design to mitigate the negative impacts of traffic noise.

Method

Thirty generic urban block typologies representing different urban design strategies were analysed through noise mapping simulation study within a theoretically homogeneous context in which the conditions of the road traffic surrounding the site and the built density are fixed so as to control the source of noise and development density as shown in Figure 1 (Zhang et al., 2012).

For this study, the traffic noise exposure level as indicated by L10 (18-hour), i.e. the noise level exceeded for 10% of the period from 06:00 to 24:00 according to the CRTN method (Department of Transport Welsh Office, 1988), was simulated in the noise mapping software CadnaA (DataKustik, 2014) with one order of reflection considered. A validation study was conducted previously (Lau, Zhang, Lau, & Lai, 2016) and a strong and positive relationship between the measured and simulated traffic noise exposure levels was identified for measurement points along the road and that in front of the façade facing the road. In this study, noise exposure level for outdoor open space within the site boundary at 2 meters height in a 2x2m horizontal grid and noise exposure level at a distance 1 meter away from façade in a 2x3m vertical grid along the façade surfaces were obtained from simulation. A workflow was created in the Rhinoceros+Grasshopper software platform which integrate the functions of parametric modelling, simulation, analysis and visualization in a coherent and efficient manner.



Fixed Planning Parameters	
Floor Area Density (FAR)	3.0
Site Area (m^2)	10,000
Gross Floor Area (GFA) (m^2)	30,000
Width of Road (m)	15
Width of Sidewalk (m)	2.5

Fixed Simulation Parameters	
Width of Road (m)	15
Road surface correction (dBA)	-1
Total 18-hour Traffic Flows	15800
Average Traffic Speed (km/h)	31
% Heavy Vehicles	27.2
Order of Reflation	1

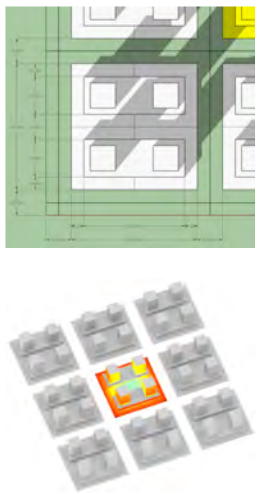


Figure 1. The thirty generic urban block typologies and the controlled study context.

Results

As shown in Figure 2, the typologies with relatively lower average ground and façade noise exposure levels include the enclosed courtyard blocks, perimeter blocks with medium-rise buffer buildings and the perimeter blocks. The buildings arranged around the peripheral of the site for these typologies may have effectively shielded the traffic noise surrounding the site, resulting in relatively more quiet ground areas and building façades for most of the spaces within the site.

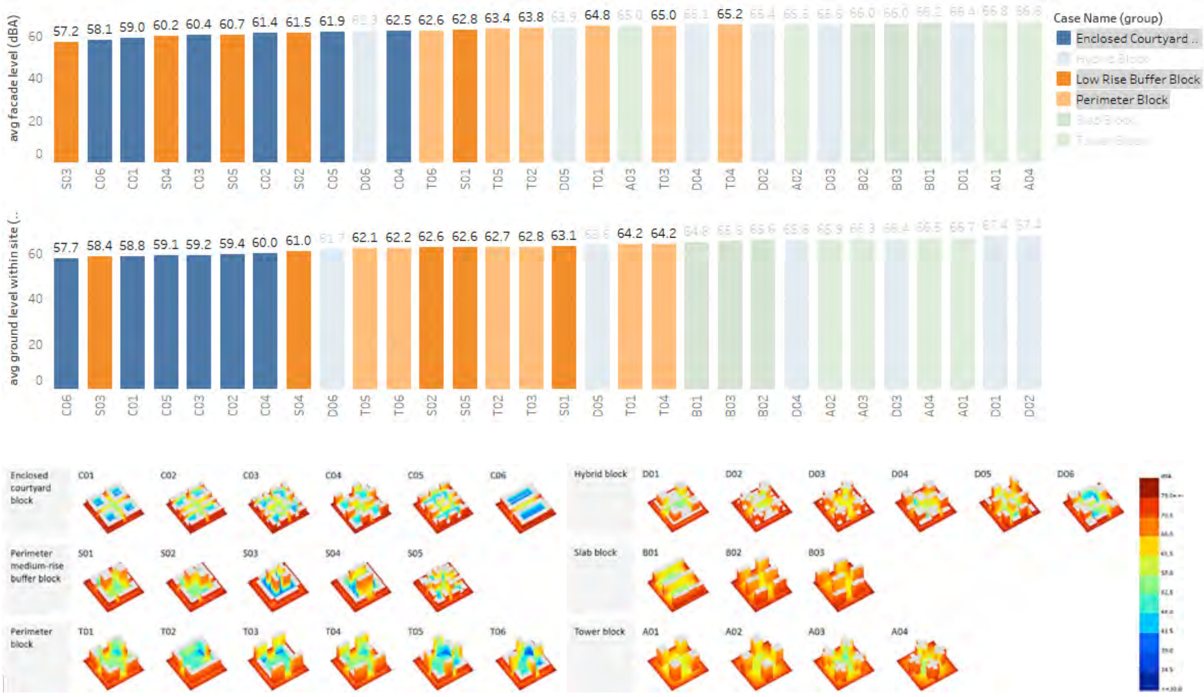

Figure 2. Urban block typologies with lower and higher average ground and façade noise exposure levels.

On the other hand, the typologies with relatively higher average ground and façade noise exposure level include the hybrid blocks, the slab blocks and the tower blocks. The relatively larger spacing between buildings and gaps between the buildings along the roads for these typologies allow traffic noise propagates relatively deeper into the site that may have contributed to higher noise exposure levels on both the ground open spaces and building facades. Depending on the urban block typologies been examined, the difference between the average noise exposure levels can be as high as 9.7 dBA and 9.6 dBA for ground and façade, respectively, as measured by L10 (18h).

Considering the potential impact of façade noise exposure level to interior spaces, the urban block typologies with relatively lower floor area normalized façade noise exposure level are shown in Figure 3, which include primarily the hybrid typologies, some cases from the enclosed courtyard typologies and perimeter blocks with medium-rise buffer buildings. However, other typologies within these three groups seem to have different façade noise exposure levels per unit floor area, and this might be attributed to the geometric characteristics of their building forms, such as compacity and floor depth, which is addressed in the next section. The typologies with relatively higher floor area normalized façade noise exposure level include primarily slab blocks, perimeter blocks and tower blocks. Depending on the urban block typologies been examined, the difference in floor area normalized façade noise exposure level can be as high as 4.2 dBA/m^2.

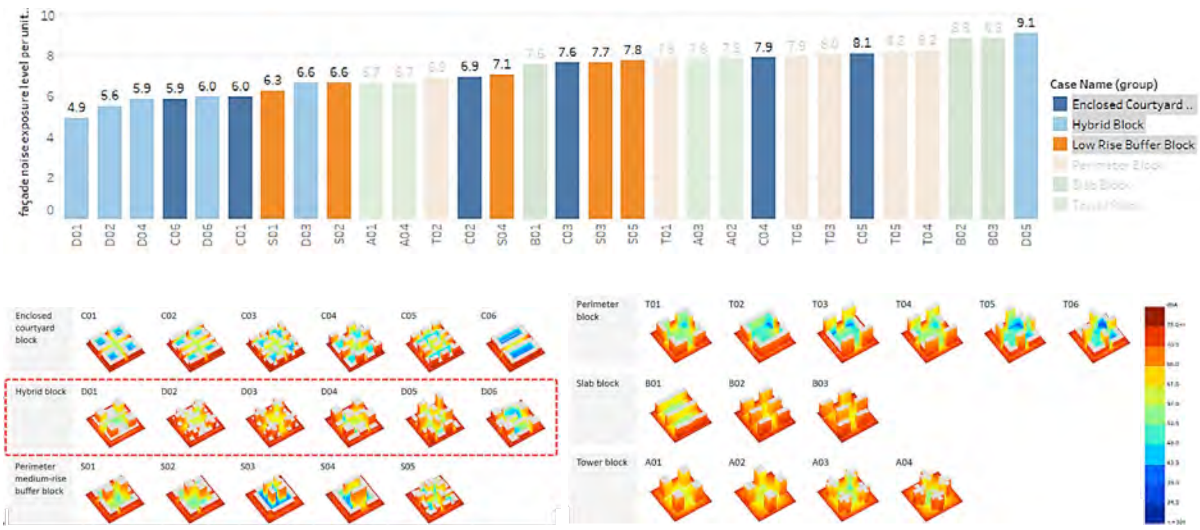

Figure 3. Urban block typologies with lower and higher floor area normalized façade noise exposure levels.

Bivariate correlation analysis was conducted for the 30 generic urban block typologies between the planning and geometric parameters and the performance indicators for both ground and facades. The significant correlations are highlighted in yellow color in Figure 4.

Performance Indicator	net building coverage (%)	compacity	avg APR (m)	OSR
% of ground within site >= threshold [%]	0.46	-0.40	0.53	-0.46
min ground level within site [dBA]	-0.53	-0.41	0.41	0.54
max ground level within site [dBA]	0.74	0.34	-0.36	-0.76
avg ground level within site [dBA]	-0.46	-0.54	0.64	0.47
90 percentile ground level within site (dBA)	-0.62	-0.45	0.49	0.62
50 percentile ground level within site (dBA)	-0.17	-0.49	0.66	0.17
10 percentile ground level within site (dBA)	0.86	0.24	-0.28	-0.86
% facade >= threshold [%]	-0.32	-0.58	0.47	0.34
min facade level (dBA)	-0.58	-0.41	0.40	0.60
max facade level (dBA)	0.46	0.35	-0.41	-0.45
avg facade level (dBA)	-0.51	-0.41	0.48	0.51
90 percentile facade level (dBA)	-0.59	-0.41	0.48	0.59
50 percentile facade level (dBA)	-0.54	-0.44	0.51	0.53
10 percentile facade level (dBA)	0.70	0.22	-0.30	-0.71
façade noise exposure level per unit floor area (dBA/m2)	-0.52	0.82	-0.76	0.49

Highlighted correlation is significant at the 0.05 level (2-tailed).

Figure 4. Significant planning and geometric variables for noise distribution performance indicators for the 30 generic urban blocks.

The impact of net building coverage on the different performance indicators vary a lot. Increasing building coverage is likely to result in higher ratio of overexposed ground area and higher maximum and 10 percentile ground noise exposure levels. Building coverage is negatively correlated with the other three ground noise distribution performance indicators, i.e. the minimum, average and 90 percentile ground noise exposure levels. Similarly, increasing building coverage may lead to higher maximum and 10 percentile façade noise exposure levels, and lower minimum, average, 90 and 50 percentiles and floor area normalized façade noise exposure levels.

Building compacity is negatively correlated with majority of the performance indicators, except floor area normalized façade noise exposure levels. On the other hand, average Area- to-Perimeter Ratio (APR) is positively correlated with most of the performance indicators, except maximum ground and façade noise exposure levels and floor area normalized façade noise exposure levels. The propensities of the correlations for compacity and that for APR are opposite to each other due to the negative correlation between these two geometric variables (R=-0.926). Similarly, the relationships between Open Space Ratio (OSR) on the performance indicators are almost exactly opposite to that for building coverage due to the significant and negative correlation (R=-0.993) between the two variables.

Linear regression analysis was conducted for the significant predictors of the average ground noise exposure level, and the results are shown in Figure 5. Average Area-to-Perimeter Ratio (APR) has the strongest and positive effect, and it can account for 41% of the variation in average ground noise exposure level. This is followed by compacity which has negative effect (R^2=0.29), Open Space Ratio (OSR) which is a positive predictor (R^2=0.22) and building coverage (R^2=0.21) which is a negative predictor. The results suggest that to reduce the average noise level on ground, the most effective design strategies in descending order, relatively speaking, include reducing building depth, increasing compactness of the building form, reducing open space per unit floor area, and increasing building coverage.

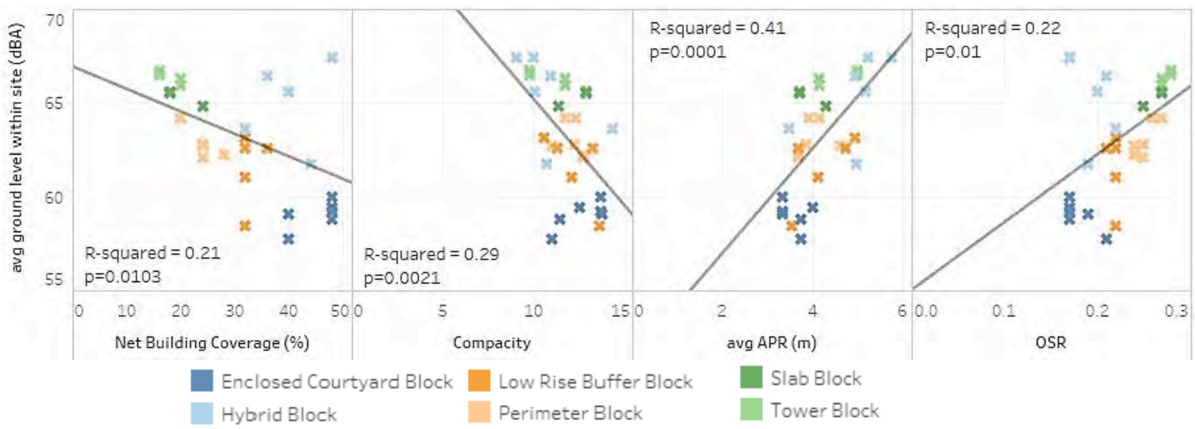

Figure 5. Significant planning and geometric factors for average ground noise exposure level for the 30 generic urban blocks.

The impacts of the four planning and geometric variables on the average façade noise level are in similar trend but to different extents as shown in Figure 6. Building coverage and Open Space Ratio have relative the strongest influences, though in different propensity, and each of them accounts for 26% of the variations in average façade noise exposure levels. This is followed by average APR (R^2=0.23) and compacity (R^2=0.17). The results suggest that to reduce the average noise level on ground, the most effective design strategies in descending

order, relatively speaking, include increasing building coverage or reducing open space ratio, reducing the depth of the floor plan, and increasing the compactness of the building form.

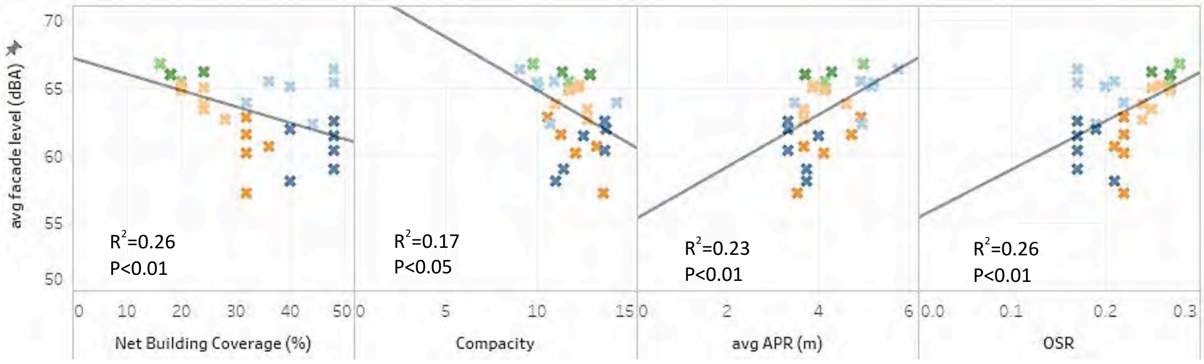

Figure 6. Significant planning and geometric factors for average facade noise exposure level for the 30 generic urban blocks.

Floor area normalized façade noise exposure level is a performance indicator that implies the impact of the noise receivable on facades to interior floor areas. The results of regression analysis for the significant predictor variables for this performance indicator area shown in Figure 7. Compacity is the strongest and positive factor which explains 67% of the variation in the floor area normalized façade noise exposure level. This is followed by average APR (R^2=0.57) and building coverage (R^2=0.27), both having negative effects. Open Space Ratio is the factor having the least impact (R^2=0.24). The results suggest that to reduce façade noise exposure level as shared for each unit floor area, the most effective design strategies in descending order, relatively speaking, include increasing the compactness and floor depth of the building form, increasing building site coverage, and reducing open space per unit floor area.

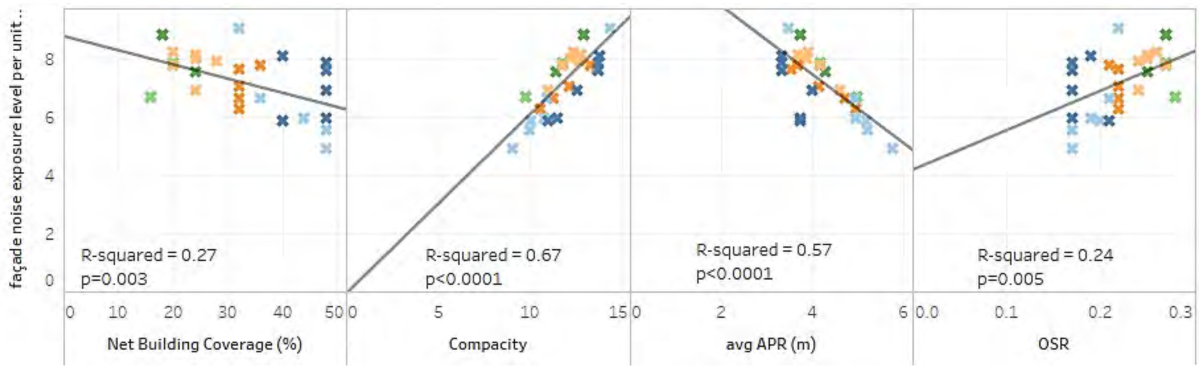

Figure 7. Significant planning and geometric factors for floor area normalized façade noise exposure level for the 30 generic urban blocks.

For the three performance indicators examined there, i.e average ground and façade noise exposure levels and floor area normalized façade noise exposure level, the propensity and magnitude of influence of the two planning parameters, i.e. building coverage and Open Space Ratio, are similar, the former having negative effects and the latter having positive effects and each accounting for 21% to 27% of the variance in the performance indicators.

The propensity and magnitude of influence of the two building geometric variables compacity and average Area-to-Perimeter Ratio vary to a greater extent, comparatively speaking. The variances in the performance indicators accounted for by the two variables range from 17% to 67%. For both the average ground and façade noise exposure levels, compacity and average APR are negative and positive predictors, respectively. However, if façade noise exposure level per unit floor area is considered, the impacts of the two geometric variables change to the opposite. This suggests that the observations on the impacts of certain design factors are dependent on the performance area been examined and the performance indicator adopted for evaluation.

Discussion and Conclusions

This study identified some of the key planning parameter and geometric variables that are significantly related to the traffic noise distribution on both ground and façades across different building typologies. The findings inform the planners and designers the key design factors that can be adjusted to mitigate the negative impact of traffic noise. This study highlights the importance of performance evaluation in the early planning and design stage when the environmental performance can be optimized using different building typologies and design strategies.

Peri-urban communities in transition: transformation scenarios of neighbourhoods towards sustainability

Judith Drouilles[1], Sophie Lufkin[1], Emmanuel Rey[1]

[1] Laboratory of Architecture and Sustainable Technologies (LAST), Institute of Architecture (IA), School of Architecture, Civil and Environmental Engineering (ENAC), Ecole Polytechnique Fédérale de Lausanne (EPFL), Switzerland, judith.drouilles@epfl.ch

Abstract: The paper outlines the theoretical context and preliminary outputs of the investigation on the prospective evolution of existing peri-urban neighbourhoods of single-family houses toward lower carbon and more resilient communities, for 2050, in Switzerland. Embedded within the Helvetic territorial and administrative context, the paper introduces a multi-scale definition of "peri-urban residential municipalities", as a basis to set up a typology of peri-urban neighbourhoods of single-family houses. The typology results from the close observation of peri-urban neighbourhoods in Lausanne's urban region. It identifies five neighbourhood types among which five representative case studies are selected for the next steps of the research. The paper focuses on one of the most common types and presents the application of three exploratory scenarios of mid-term transformations on the selected case study. The current policy framework and multiple prospective studies about demographic dynamics, sustainable neighbourhoods, single-family houses adaptation, etc. are the main guidelines of the design process. The selected design paths investigate several scales of mutations, from the perpetuation of current life-styles to deeper social and environmental transformations. Finally, several indicators, proceeding from current major issues faced by the residential peri-urban neighbourhoods, highlight the performances and challenges of each scenario, through the spectrum of sustainability.

Keywords: Peri-urban, neighbourhoods of single-family houses, typology, prospective scenarios, sustainability.

Introduction

Peri-urban neighbourhoods of single-family houses are facing growing sustainability challenges. They are responsible for and subjected to numerous threats on different levels: environmentally, urban sprawl and landscape modification; economically, land fragmentation into small private properties, and services and public equipment funding; socially, individualism and segregation, and energetically, inefficient buildings and car dependency (Drouilles et al, 2016a).

The paper investigates the conditions for a sustainable peri-urban renewal. It aims at presenting some preliminary outputs about the design of exploratory transformation scenarios for 2050 of an existing peri-urban neighbourhood of single-family houses located in the periphery of Lausanne, in Switzerland.

Developed in four parts, the paper first presents a deeper understanding of the research object through the elaboration of a typology of peri-urban neighbourhoods of single-family houses. Then, it focuses on one of the most representative type of neighbourhoods and sums up the main features of the chosen case study. Third, it gives the theoretical framework for the design and application of three prospective scenarios on the neighbourhood chosen as case study (CSN). Finally, the current state and the scenarios are assessed through the three pillars of sustainability (environment, economics and society).

Research framework

Since the 1950s and the democratization of cars, urbanisation has spread farther around the main cities. Adopting new forms and combinations of land uses, the resulting "in between territories" (i.e. neither within the city-core nor entirely rural) are almost not defined. When attempting to delimitate clear territorial entities, we witnessed how unsettled were the existing definitions to set the limits of peripheral and peri-urban spaces. Statistical institutions, in France and Switzerland for instance, tend to consider only the daily commuting features, to determine the peri-urban or peripheral character of a municipality. Some limitations may emerge from the choice of qualifying peripheral municipalities entirely through the relation they maintain with the central city. Population densities (OECD, 2011; Eurostat et al, 2011) and land uses (Gonçalves et al, 2017) could represent resourceful complements to identify urban or rural influences, as well as specific features within the peripheral entity.

Two preliminary steps are necessary to elaborate a typology of peri-urban neighbourhoods of single-family houses. The first step has to do with the precise definition of the "peri-urban residential municipalities" territorial entity, which the overall research project investigates. An extended literature review has enabled the formulation of this six criteria definition highlighting the main recurrent peri-urban features of the post-industrial European city (Drouilles et al, 2016b). Considering the municipalities' location within the urban region, their specific demographics, and their building stock composition, the identified "peri-urban residential municipalities" are more likely to be burdened with increasing environmental, economic and social pressures, than any other peripheral area. In a second phase, the research project focuses on neighbourhoods of single-family houses located within the defined "peri-urban residential municipalities". The neighbourhoods' inventory and various statistical analysis in the representative urban region of Lausanne (Switzerland) resulted in the determination of five types of peri-urban neighbourhoods of single-family houses.

Current research on peri-urban areas reveals that the most significant issues are the building related energy consumptions and mobility aspects that derive from the lifestyles of peri-urban populations (Drouilles et al, 2017). These elements, in line with the broader ambitions of the research project, have influenced the choice and weighting of the variables for the elaboration of the typology. Three main variables were used for the classification of the neighbourhoods:

1- Distance to train station: Federal office for territorial development (ARE) provides some reference values to measure public transport accessibility quality (ARE, 2011). Farther than 1 kilometre, ARE evaluates the accessibility as inexistent. This distance represents a valid threshold in a peripheral context.
2- Date of neighbourhood's first constructions: setting a threshold in 1976 allows taking into account policies' evolutions, in terms of land use planning (Garnier, 1984) as well as energy efficiency. Following the 1970s' oil crisis, many European countries implement new regulations around the 1980s (Summerfield et al, 2015; Aksoezen et al, 2015).
3- Neighbourhood's size: we consider the effects of this criterion on the project design. The average size of neighbourhoods in Lausanne – 5 hectares – is set as threshold.

Five types of neighbourhoods of single-family houses in Lausanne's "peri-urban residential municipalities" emerge from the weighting of those three variables (Tab 1).

Table 1: Typology of peri-urban neighbourhoods of single-family houses in Lausanne
classification criteria and average reference values *(nbhd = neighbourhoods)*

Criteria	Type 1	Type 2	Type 3	Type 4	Type 5
Distance to train station *(km)*	< 1		> 1		> 1
First constructions	1950 - 1976		1950 - 1976		1976 - 2000
Nbhd size *(ha)*	> 5	< 5	> 5	< 5	< 5
Average values	*7 nbhd*	*7 nbhd*	*27 nbhd*	*42 nbhd*	*16 nbhd*

Population density *(inhabitants/ha)*	24	27	22	24	24
Proportion of detached houses	68%	68%	71%	74%	74%

In most of the neighbourhoods (77%), the first constructions occurred between 1950 and 1976. We would like to emphasize that neighbourhoods of all types are bordered by agricultural areas on at least 40% of their perimeter. Residential density is relatively low: between 8 and 10 dwellings per hectares, mainly due to large private plots (average size of 1’250sqm) and a majority of single-family houses. The internal road network mixes mostly dead-ends and few local or regional roads bearing external traffic.

Types 1 and 2, thanks to their closer location to a train station, show a slightly more compact land use, i.e. a higher proportion of terraced houses. Types 3 and 4, the oldest and worst connected, gather 64% of the total amount of peri-urban neighbourhoods of single-family houses. According to our hypothesis, the latter are in a more delicate situation in relation to sustainability issues.

Type 3

In the scope of the paper, we focus on one of the most representative type of peri-urban neighbourhoods of single-family houses in Lausanne’s urban region (25%). Type 3 gathers older and bigger neighbourhoods that are badly connected to the regional public transport network. In average, the neighbourhoods sprawl on approximately 10 hectares and host more than 200 inhabitants. They present a lower density than other types: plots tend to be bigger, with an average value of 1’300sqm; some plots remain unbuilt and detached houses represent 70% of the building stock. They are also mostly isolated from other built-up areas, with natural or agricultural lands bordering three forth of the neighbourhood.

The chosen case study neighbourhood (CSN) is located in the municipality of Echichens bordering the city of Morges (the second city of Lausanne’s urban region). The municipality of Echichens has a population of about 2’500 inhabitants (2015). Formed as a result of the merger between four villages in 2011, the territory of the municipality is characterized by a dispersed urbanisation and the domination of agricultural land use (80% of the municipality’s area) (OFS, 2013). The CSN is composed of 61 private plots, among which are 26 detached houses, 24 plots with terraced-houses of two dwellings, 4 plots with multi-dwellings buildings, and 7 free and unbuilt plots. In total, about 245 people inhabit 93 dwellings and 119 people share the ownership. (Fig. 1- E0).

Scenarios

The object of the research project is the proposition of three prospective transformation scenarios of the CSN by the year 2050, which embody – for inhabitant and authorities – different ways to undertake changes. The current Swiss policy provides a strong framework for the scenarios' design, in particular the revision of the territorial planning law (2014), which contests urban sprawl and promotes urban renewal and densification processes (CH, 2013). Its regional application (Etat de Vaud, 2016) implies that:

1- The city centres and the well-connected sectors in the urban regions will absorb most of the future demographic growth. Outside those strategic areas, i.e. where the CSN is situated, the aim is to limit growth rate at 0.75% per year.
2- No more natural or agricultural land should be lost to built-up areas.

Consequently, all three scenarios assume the same population growth of 65 inhabitants (+26.5% by 2050) and implement CSN's transformation within its current boundaries. The following scenarios represent an exploratory phase of the research. They explore the CSN's internal transformation from an exclusive residential approach. At this stage, contextual issues such as mobility, work and leisure aspects are not addressed. For future works, this suggests a wide margin of improvement with more advanced scenarios.

The common starting point of the scenarios design is the identification of over-sized plots and dwellings that are likely to generate economic issues for their owners, in terms of maintenance and retrofit, as well as sale or inheritances.

First scenario S1 (Fig. 1 – S1)

The scenario follows the current trend of evolutions in neighbourhoods of single-family houses. The transformations result from the implementation of individual and private initiatives on each private property, mainly led by economic motivations. It implies three types of actions, such as i) daily maintenance but no significant retrofit, ii) low carbon retrofit and iii) densification: house extension or subdivision, dwelling substitution, plot subdivision, etc. (Fawcett, 2014; Beyeler, 2014; Bosshard et al, 2014).

The housing demand by 2050 is exclusively addressed by the construction of new single-family houses or the subdivision of over-sized existing houses. The main actors are the owners and real-estate developers in case of over-sized plots, and the targeted households are families

Second scenario S2 (Fig. 1 – S2)

Local authorities play a significant role in the CSN's renewal. They guide and frame individual and private initiatives and help shifting from transformations at plot scale to planning at neighbourhood scale. Internal mobility issues are also managed at the neighbourhood scale to unlock dead-ends and provide a variety of public spaces and direct paths for pedestrians. Local authorities enable the construction of new building types and smaller and more affordable dwellings. They encourage new stakeholders to take part in the neighbourhood planning and smaller households to invest and stay in the neighbourhood.

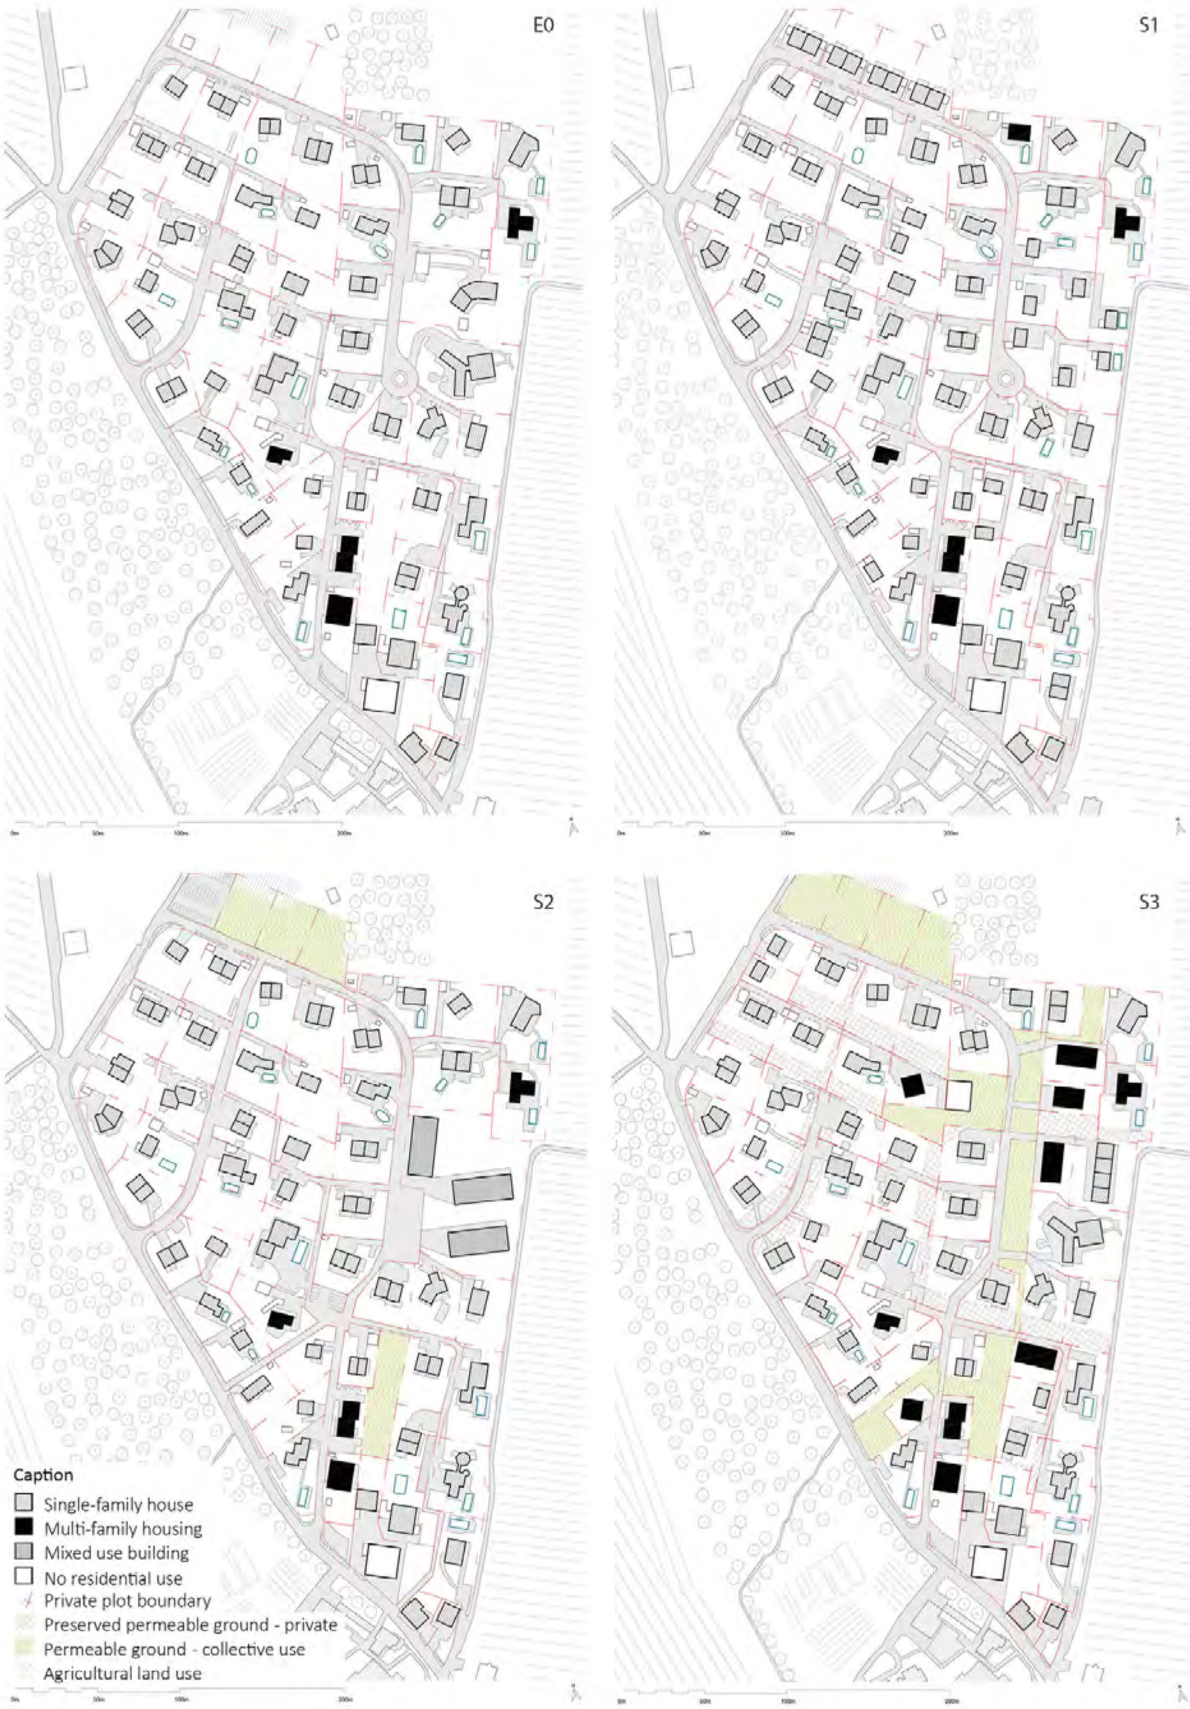

Figure 1: Current state (E0) and three prospective transformation scenarios of the CSN (S1, S2, S3)

Public planning enables private-public partnerships. A unique project answers the housing demand and provides enough capital gain to enhance an ambitious redistribution of internal circulations and collective areas, as well as the preservation of existing green grounds and the creation of car park areas. The main challenges are related to the regulation of private initiatives.

Third scenario S3 (Fig. 1 – S3)

Also led by local authorities, the CSN's renewal seeks to address the issue of loss of green grounds through densification processes and the question of biodiversity quality of both domestic gardens and farmed landscapes (Goddard et al, 2010). Town planning regulation indicates private permeable ground to be preserved and kept unbuilt. Additionally, the mutualisation of green community spaces allows the accentuation of a green corridor within the neighbourhood and provides an example of "wildlife-friendly" garden-management. Many mechanisms of land compensations and density bonuses are required to preserve non-constructible areas and compensate every involved private owner.

The intervention's direct effect is a more significant densification. Local authorities may also regulate the densification with housing requirements targeting smaller households. The actions generally improve the quality of the living environment by opening fences and managing nature at neighbourhood scale. Local associations could manage common areas; oversee management and pedagogy.

Preliminary assessment

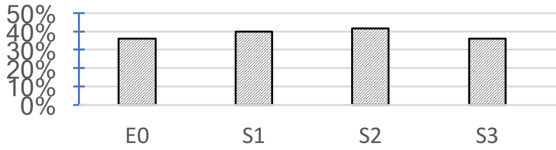
This preliminary assessment takes into account only a short list of indicators, which relate to the three pillars of sustainability. They are chosen to assess the performance of each scenario as well as the current state of the CSN. When final scenarios are assessed, in future works, more elements will be added, such as neighbourhood's energy performances evaluations, which will be compared to the "2'000-watt society" requirements (Drouilles et al, 2017).

Environment: proportion of impermeable ground (SIA, 2004) within the entire neighbourhood (Fig. 2a) and within the private plots only (Fig. 2b)

The proportion of impermeable ground underlines the effects of horizontal densification in S1, with an increased proportion by 4% within the entire neighbourhood and within the private plots. The results for S2 at neighbourhood scale are explained by the creation of new paths, streets and places. S3's intentions of preserving green ground are achieved, with a proportion that remains stable in the neighbourhood between E0 and S3 despite the construction of new buildings. At the scale of the private plots, the proportion is equal in S2 and S3 and lower than S1's.

Economic: average plot size per household (Fig. 3a) and living area per person (Fig. 3b).

The economic indicators show, for each scenario, a reduction of both the plot size and the living area compared to current state. Therefore, purchasing and selling real estate should result easier and more affordable due to an overall moderation of the real estate value. S2 and S3 present the most promising situations with significantly smaller dwellings or plots.



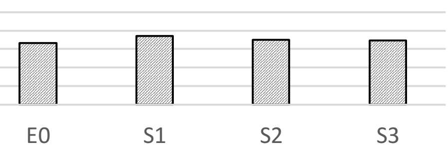


Figure 2a: Proportion of impermeable ground in the neighbourhood

Figure 2b: Proportion of impermeable ground in the private plots

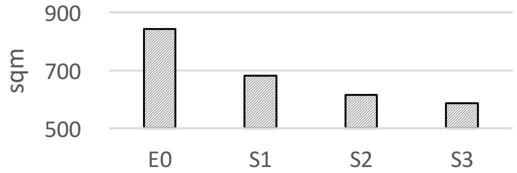

Figure 3a: Average plot size per household

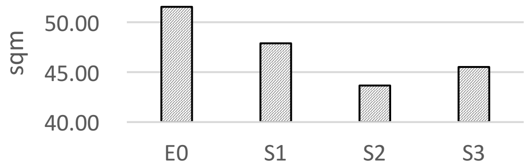

Figure 3b: Average living area per person

Social: diversity of building types (Fig. 4a), and diversity of dwelling sizes (Fig. 4b).

Finally, the social indicators show on which residential segments the scenarios focus their development. S1 follows E0's trend regarding building types, and probably also in terms of sociocultural profile. S2 and S3 are more likely to present a higher social mix, at least in terms of generation and household types, with the development of mixed or multi-family buildings. Regarding dwelling sizes, S2 focuses on smaller dwellings, i.e. less than 100sqm, while classic single-family houses between 100 and 150 sqm are still the common practice in S1. S3 favours the construction of a dwellings' diversity in the multi-family buildings, from small apartments for smaller households (less than 60sqm), to medium units for families (between 100 and 150sqm).

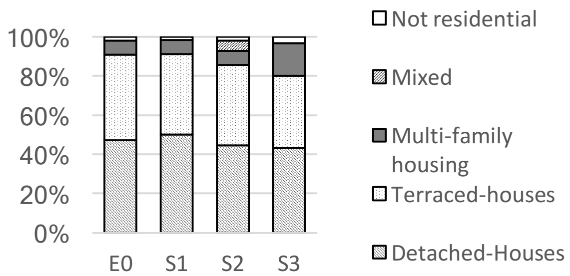

Figure 4a: Building types (building stock)

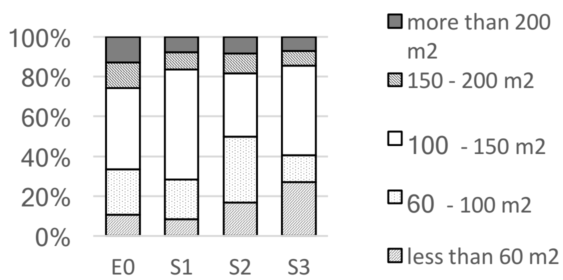

Figure 4b: Dwelling types (dwelling stock)

Conclusion

The exploratory transformation scenarios applied to an existing peri-urban neighbourhood of single-family houses are meant to enrich our ongoing research about sustainable peri-urban futures. The trend scenario (S1), which implements a progressive horizontal densification, highlights the difficulty to control individual initiatives. Regulation or public guidance could help to surpass transformations happening at the scale of private pots and depending on individual economic interests (Beyeler, 2014). The scenarios implementing a neighbourhood planning (S2, S3) give some clues to consider a sustainable renewal of peri-urban neighbourhoods. Their strengths rely on the preservation of green grounds or on the development of diverse and affordable housing that are likely to support the shift towards lower carbon and more resilient peri-urban communities.

Although they still raise many questions especially regarding their feasibility, those exploratory scenarios provide some elements that can be built upon in the next steps of the research. Embedded within the Swiss policy framework, the scenarios illustrate the limitations of changes implied by a regulated demographic growth and the importance of retrofit actions to reduce the buildings' environmental footprint since the major part of the current building stock persists until 2050. To address the future development issue of every type of peri-urban residential neighbourhood, a deepening of the assessment is imperative. The prospective transformation scenarios applied to all case studies will also have to address broader aspects of accessibility, work and leisure-related motilities, energy and economic performances, etc.

Real estate and sustainable construction: Private perspectives for progress in energy regulation of a liberalised market

Abstract: In real estate markets such as Santiago de Chile where energy efficiency certificates are not mandatory, incorporating solutions that respond to the growing demand for sustainability entails a natural tension between their acceptance as necessary measures and the way they are addressed by the market. Under this mechanism, the market has introduced housing features that are communicated individually through real estate marketing. Energy efficient elements are more commonly seen in higher-end homes, where they are treated as standard features, while they are still considered innovations at the lower end of the housing market. However, it has been shown that energy efficient features decline in relative importance over time, ceasing to be considered marks of distinction. In contrast, energy efficiency certification shows great potential for generating a proposal to create sustainable value over time, particularly due to its ability to objectively communicate a buildings' energy performance. This suggests that this model should be reviewed from a public policy perspective, with the understanding that the current voluntary standards must compete with other features, in addition to improving the minimum required standards.

Keywords: real estate market, real estate marketing, energy efficiency certification, sustainable features

Introduction

In most countries, home energy efficiency beyond certain minimal requirements has been left largely to the dynamics of the real estate markets at the residential level. In certain cases, this regulatory requirement is supplemented by required energy efficiency certification, which typically takes the form of ranking by categories, giving rise to labelling (Pérez-Lombard *et al.*, 2009). The European Directive on Energy Performance in Buildings has introduced the universal use of energy certificates in the European housing market (Official Journal of the European Union, 2003). This policy aims to provide energy transparency in real estate transactions so that the public can make more informed purchase or leasing decisions. This method banks on the indirect promotion of more energy-efficient buildings, as it is believed that their lower energy use costs will convince consumers to pay a premium for them, thereby offsetting the higher production costs and encouraging real estate developers to build them.

The real estate market of Santiago de Chile was selected as a case of a liberalised market where energy efficiency certificates exist as a tool but are not mandatory in housing transactions. In general, the housing market in Chile has a low government presence, which was defined by López-Morales, Gasic and Meza (2012) as “pro-business urban planning”. The country has, however, adopted regulations – in a prescriptive manner – that affect the energy performance of residences. In 2000, the rules known as the "Thermal Regulations" established requirements regarding maximum permissible thermal transmittance for roofs, while the 2007 update added requirements for thermal conditioning of perimeter walls, windows and ventilated floors (MINVU, 2016). While these standards have been welcomed as an initial effort, their actual contribution to household savings in energy efficiency is suboptimal (Collados and Armijo, 2008; Bustamante *et al.*, 2009), as they have not been updated in 10 years. In the case of Santiago, for example, this regulation defines 1.9 W/m^2K as the maximum permissible thermal transmittance for perimeter walls, which can be achieved by building thicker brick walls rather than by using thermal insulation. The OECD itself, to which Chile belongs, has addressed the matter, strongly recommending that the country improve its standards for thermal envelope (Caldera, 2012). Nonetheless, the "Energy Rating," an instrument that evaluates a home's energy efficiency, has been in use since 2013. While plans originally called for the system to be implemented gradually as a requirement beginning in 2016 (DITEC, 2015), this was postponed indefinitely, becoming a voluntary practice. Furthermore, the market has been very slow to adopt the system. For example, of all the homes that have achieved the final rating, only 5.4% are private market homes, which, in absolute terms, translates into 404 homes in all of Chile from the system's introduction in 2013 to October 2015 (MINVU, 2015). This is clearly a minuscule fraction of the total national housing stock, which has fluctuated between 70,000 and 90,000 units during the same period (CChC, 2016).

Given that the national market has not widely adopted any objective tool such as the energy efficiency rating to inform consumers of energy efficiency in real estate transactions, the approach to communicating the competitive advantages of energy efficiency or sustainability has been to treat it as one of the home's marketing features. These can be defined as the characteristics of a real estate product that differentiate it from other homes, adding to its aggregate value. As defined by Lancaster (1966), housing is desired not in and of itself but as the sum of each real estate product's features, where the most important have a greater impact on determining preferences and choices (Jansen, 2011), according to the compensatory logic of trade-offs. Thus, from the buyer's perspective, the price of a home is based on two points: the features the buyer requires (associated with the image of the future home) and the buyer's purchasing power (associated with future debt). It is therefore possible to propose an approach that observes and values property features based on what they contribute to this model. This observation is contextual and therefore analyses the set of features of an existing known supply as a whole, with the advertising emphasis determined by each supplier.

This article aims, first, to describe how the real estate market adopts and advertises energy efficiency and sustainability in a context where energy efficiency certification is not compulsory. Moreover, it seeks to assess whether a proposal can be formulated for the construction of long-term sustainable value based on the logic of the features proposed by the residential market in Santiago de Chile, and whether this is the best option for encouraging the adoption of sustainability in construction.

Methodology

The methodology of this study consists of using two approaches to investigate property features. First, to perform a cross-sectional analysis of features by geographical area, two submarkets in the city of Santiago were selected. While both are becoming increasingly densely populated, there is a significant difference in the forms of development they exhibit. While the submarket of Santiago Centre, the historic centre associated with middle-income residents, offers one- and two-bedroom apartments with a significant amount of infrastructural features (such as gym, multi-purpose room) and mid-level finishes, highlighting their proximity to public transport, the Las Condes Avenue submarket is entirely distinct. In the latter neighbourhood, located in the eastern part of town and associated with higher-income residents, buildings generally have a lower average height, larger size, high-end finishes and prime locations. For both cases, the entire supply of apartments was collected during the second half of 2016, based on their website, printed and billboard advertising. Additionally, a survey of housing applicants in these sectors was conducted, inquiring about the level of importance they attached to each of the property features listed. Second, a longitudinal analysis of the evolution of the various sustainable features in real estate marketing was undertaken by cataloguing all advertisements appearing between 2012 and 2016 in the "Housing and Decoration" magazine of the newspaper *El Mercurio* and the "Houses" supplement of the newspaper *Publimetro*. The former is a national newspaper, while the latter is a free publication with circulation restricted to the city of Santiago. A total of 7,290 advertisements were catalogued and examined for mentions of various features as well as the degree of importance attributed to each.

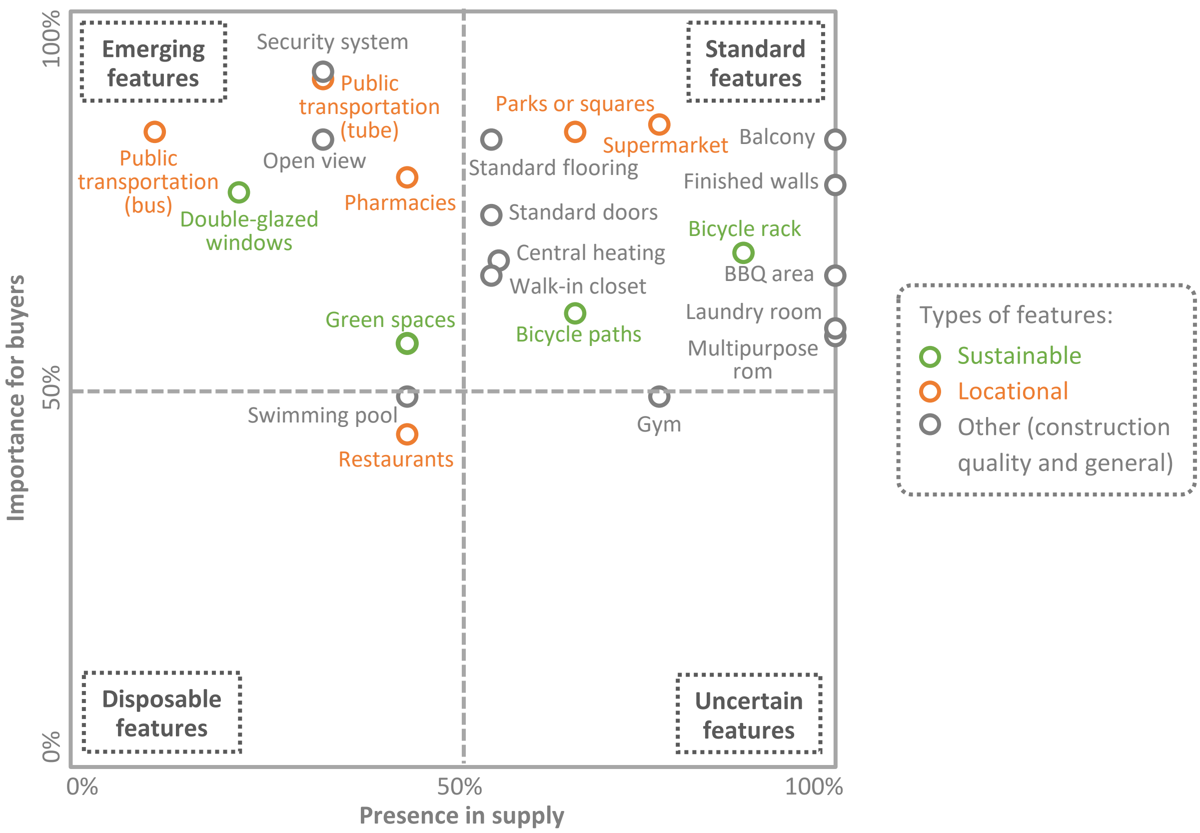

Figure 1. Value of features on the supply and demand sides for the Santiago Centre submarket

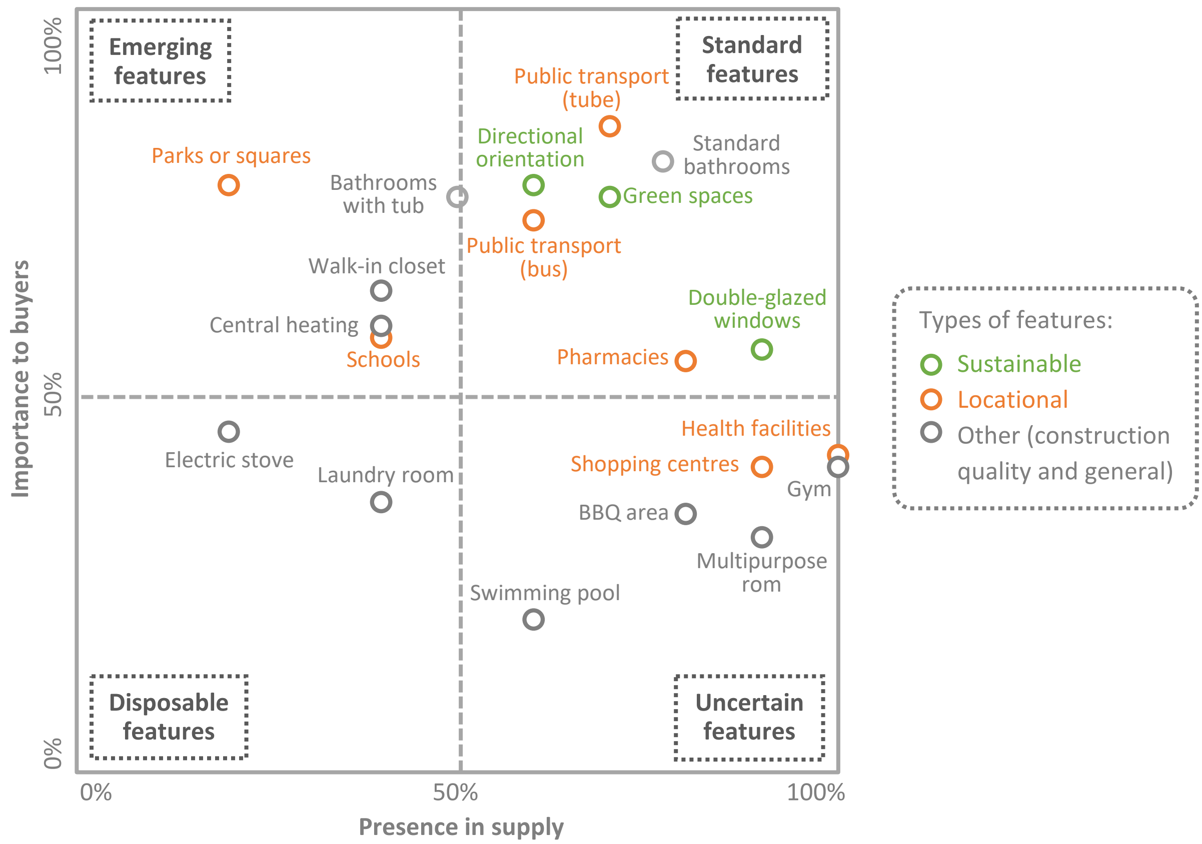

Figure 2. Value of features on the supply and demand sides for the Las Condes Avenue submarket

Results and discussion

Cross-sectional analysis of features offered and sought

Figures 1 and 2 present the assessment of supply/demand for various features in the two submarkets. These figures show how the features are strategically positioned in four categories, expressed as quadrants: standard features (high presence on the supply side and high importance on the demand side); emerging features (low presence on the supply side and high importance on the demand side); uncertain features (high presence on the supply side and low importance on the demand side); and disposable features (low presence on the supply side and low importance on the demand side). It may be observed that the features in each quadrant vary between the two submarkets at the same point in time, from which one can infer that the submarkets display different positioning strategies and different values among their consumers. In the case of Santiago Centre, the business strategy relies on pricing and is oriented mainly to investors, while on Las Condes Avenue, the strategy is clearly one of differentiation and meeting the consumer's desires. Accordingly, it can be inferred that the way sustainable features are positioned differs by neighbourhood and is associated with the strategies for different submarkets. For example, in Santiago Centre, these features may be present and highlighted whenever they may enhance value without significantly increasing the price. Thus, the sustainable features of a "bicycle rack" (very low cost) and "bicycle paths" (an external feature) are the only items positioned in the standard features quadrant in this case (Figure 1). In contrast, for the Las Condes Avenue submarket, sustainable features that add value to the real estate product ("double-glazed windows," "green spaces", "directional orientation") become standard features even when they raise the price of the property (Figure 2). However, there exists a risk of *greenwashing* wherever the project's sustainability (and therefore its marketing) is based solely on individual features without validated information, particularly when the minimum standards for energy efficiency are very low.

Longitudinal analysis of sustainable features in real estate marketing

The results obtained for the total number of projects in the real estate marketing database present an overview of the sustainable features mentioned in the advertisements. The five most commonly mentioned terms related to sustainability are "double-glazed windows" (5.4%), "solar panels" (5.3%), "energy efficient" (4.5%), "bicycle rack" (2.3%), "sustainable" (2.1%) and "energy efficiency certification" (1.9%). While the percentage of overall market penetration is relatively low, the complexity of the real estate market suggests that this ranking may appear differently in different market categories. For the purposes of this study, the price categories will be defined as under £70,000; between £70,000 and £130,000; and over £330,000. These segments represent buyers with different purchasing power, and in a city as residentially segregated as Santiago de Chile, they also correspond to different neighbourhood submarkets. Broadly speaking, the under £70,000 category and the over £330,000 category correspond to the submarkets of Santiago Centre and Las Condes Avenue, respectively.

Figure 3 shows the development of how two features have been positioned in real estate advertising aimed at these different price segments. It may be observed that the feature "double-glazed windows" appears prominently in advertising aimed at the high-end market at the beginning of the period studied but declines in prominence over time for that price range; by the final semester, "double-glazed windows" is mentioned more frequently in advertising to the under-£70,000 category than in high-end advertising. This may be explained by the fact that such features become expected standards in high-end construction, particularly in a context where weak minimum requirements diminish such features' capacity to provide differentiation. However, the popularization of this feature may favour lower-priced homes, which are capable of assuming the higher associated cost. In contrast, the feature "energy efficiency certification" appears almost exclusively in the higher-priced segment studied, where it remains prominent throughout the study period.

Finally, it is relevant to examine the results regarding the prominence of different features, as data on their presence and importance may shed new light on the evolution of real estate marketing's approach to sustainable construction. Thus, the findings on the "double-glazed windows" feature reveal a critical situation: while initially appearing in the higher and middle importance categories, these energy efficiency features were completely relegated to the category of low importance by the final year of the study (Figure 4). The exception is the "energy efficiency certification" feature – in this case, mainly related to the "Energy Rating" and LEED certification – which maintained its level of moderate importance. This highlights the considerable potential of multi-dimensional certification models for guiding the communication of supply in terms of sustainability, rather than the attributes being presented as a function of one single feature.

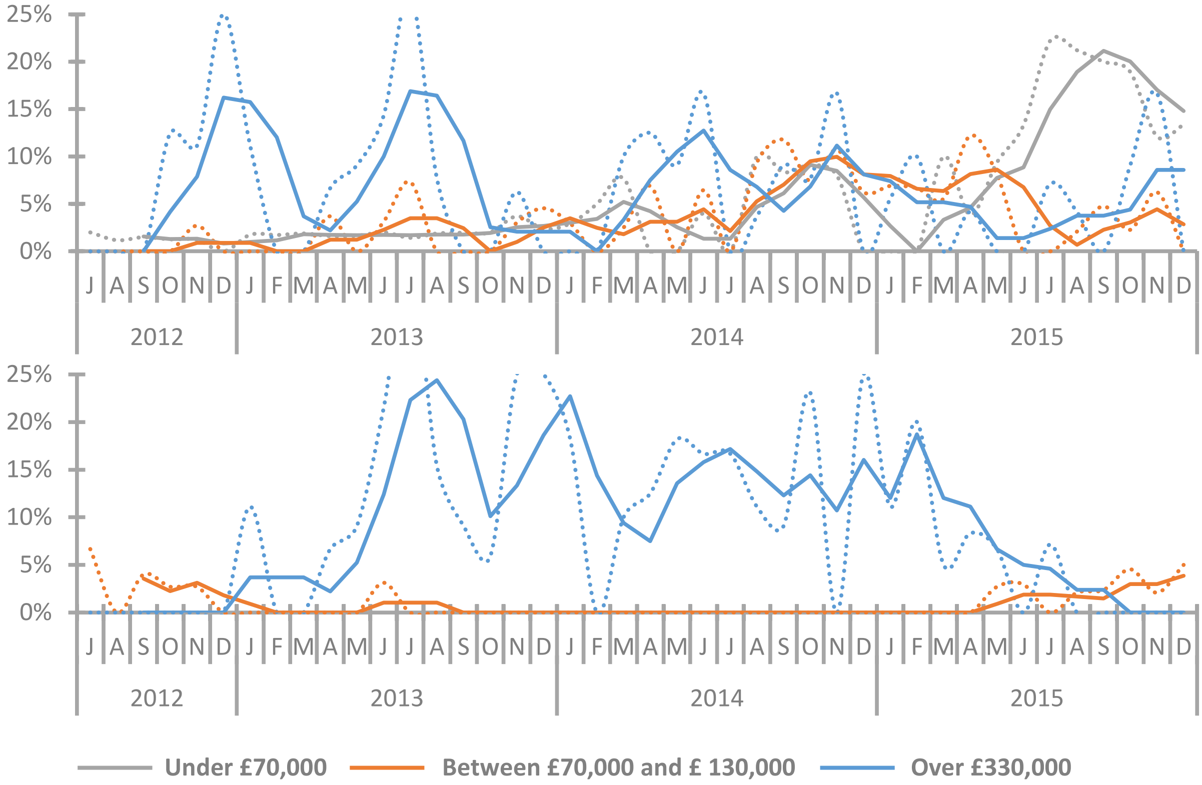

Figure 3. Presence of the features "double-glazed windows" (above) and "energy efficiency certification" (below) in real estate advertising by rolling quarter according to housing price range

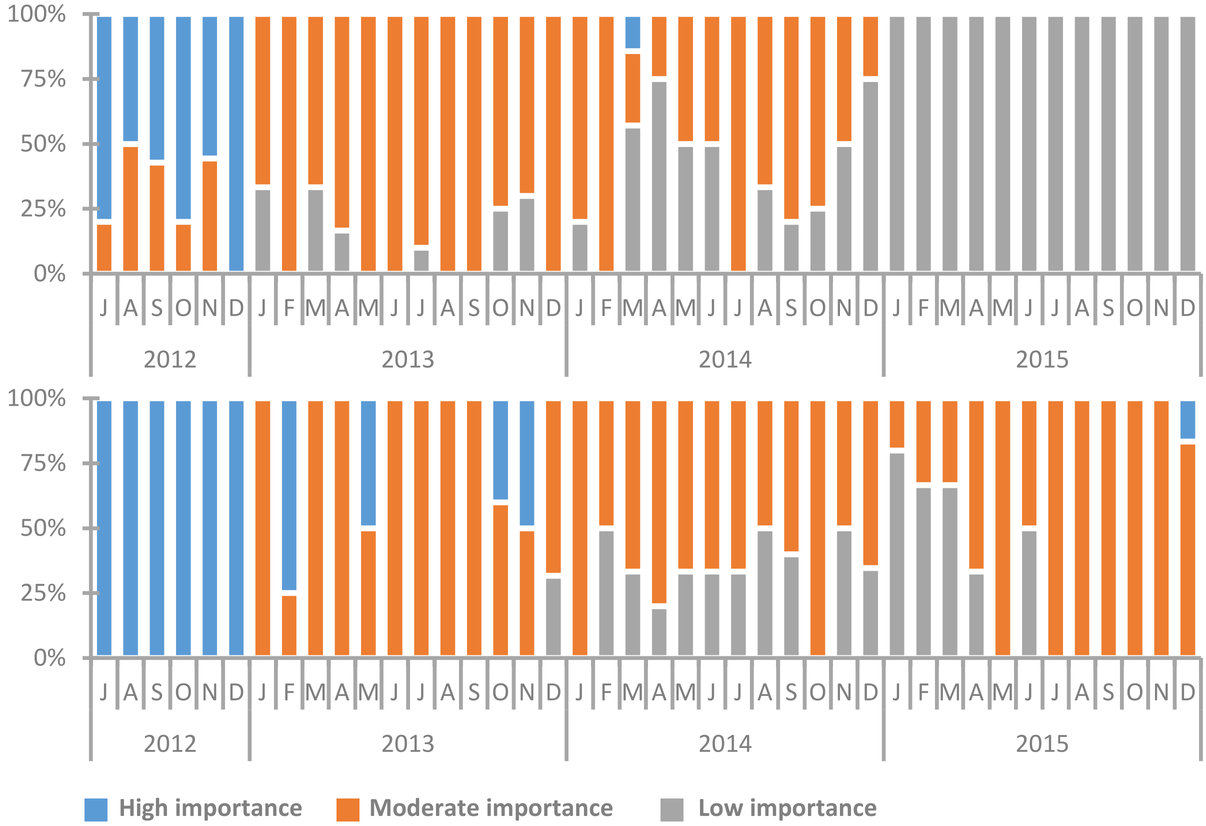

Figure 4. Level of importance of the features "double-glazed windows" (above) and "energy efficiency certification" (below) in monthly advertisements

Conclusions

The logic of attributing and promoting features associated with real estate stems from the perception of how these add value to the product and, therefore, increase its demand. Therefore, the industry gauges how consumers value each feature. This assessment of value differs for each of the submarkets, which in a city as residentially segregated as Santiago de Chile also entails segregation by housing prices. Thus, developers interpret these features differently, promoting them according to the segment where they are most competitive. Buyers, for their part, generate a type of zero-sum balance of trade-offs between their purchasing and borrowing power and their assessment of the value of each of the property's features. This accounts for how the buyer understands, recodifies and values the advertising stimulus.

At first reading, most sustainable features appeared more prominently in higher-income markets (defined as standard features in the cross-sectional analysis) than in lower-priced markets, where features (such as bicycle racks) that do not significantly affect the developers' profit margin were highlighted. However, longitudinal analysis revealed that over time, these features were gradually included among the standard expectations for a building, losing their relative importance as a mark of distinction and thus their prominent place in advertisements. Thus, "energy efficiency certification" is virtually the only feature that has the potential to maintain its role as a mark of sustainable construction over the long run, particularly due to its ability to provide the buyer with an objective measurement of a building's energy performance, overcoming the asymmetries of information affecting consumers. International experience, in particular with respect to European energy certificates, suggests that these instruments are indeed capable of encouraging the market to move towards supplying real estate products with higher levels of energy efficiency, as noted in the market premiums associated with homes that receive the highest energy efficiency ratings, as has been noticed by Bio Intelligence Service, Lyons and IEEP (2013), Fuerst *et al.* (2013, 2016), Gelegenis *et al.* (2014), de Ayala, Galarraga and Spadaro (2016) and Marmolejo (2016).

In addition, having weak minimum standards for energy performance creates easy access to minimal improvement that does not actually represent a significant contribution to energy efficiency, opening the door to greenwashing. Thus, improving the minimum required standards set out in the new national thermal regulations could boost competitiveness not only within the market, generating better products in terms of quality and post-sale service, but also among suppliers of constructive solutions and energy efficient technologies. Furthermore, the advertising-focused approach adopted in this article suggests that policies on energy efficiency certification should be reviewed, as the current voluntary approach forces energy efficiency certification to compete with other features on equal footing (compared, for example, with location, which is very important to certain middle-income buyers). Finally, the results show how information asymmetries are also segregated, with different housing submarkets attributing different degrees of value to sustainability. Public policy should be sensitive to these differences, in particular because at the lower end of the market, there is a much closer relationship between sale price and real estate financing that limits how much buyers can pay for housing.

Design to Thrive

The Role of Intermediaries in Transitioning Photovoltaic Systems into Low Carbon Housing

Ziyad Frances[1, 2] and Fionn Stevenson[1]

[1]School of Architecture, University of Sheffield, Sheffield, UK, Western Bank, S10 2TN
[2]Department of Architectural Engineering, Koya University, University Park, Erbil, Kurdistan Region of Iraq

Abstract: Housing is responsible for one-third of CO_2 emission in the Western world, yet there is still limited understanding of why housing often uses up to three or more times the amount of energy than predicted by simulation, resulting in a performance gap. Previous studies have examined the role of various intermediary actors (both human and non-human) in shaping the professional governance of PV systems only in the provision stage, this study combines Actor Network Theory (ANT) and Practice Theory to explore the role of these intermediaries, or/and other intermediaries, during the occupation stage, a vital omission in the previous PV studies. To achieve this aim, 38 semi-structured interviews and 18 video tours were used in 6 case study housing projects in the UK (4 participative and 2 non-participative projects). Key findings indicate the significant role of the non-human intermediaries in impacting the system design and use beside human intermediaries. PO was the most significant human intermediaries in both the design and use stages, while FIT, location and aesthetic values were the key non-human intermediaries. New intermediaries are needed in particular for the utilisation of PV products, practices, and energy use management.

Keywords: Photovoltaic, implementation gap, energy transition, intermediaries

Introduction

Climate change presents a critical international challenge and opportunity to achieve a successful energy strategy and carbon emissions reductions in the built environment (NHBC, 2015). Homes are responsible for one-third of all energy consumption and CO_2 emissions in the Western world (DECC, 2013). Despite efforts to install domestic low carbon energy generation technologies, there is still limited understanding of why the predicted energy savings are not being achieved creating a significant performance gap between the predicted and use (Gram-Hanssen et al., 2016).

This performance gap is related to the way *occupants* use energy in their homes (Gram-Hanssen et al., 2012), and to occupants' limited understanding of these technologies (Stevenson et al., 20113, Brown & Gorgolewski, 2015), as well as the poor capacity of policy and standards to deliver the projected energy performances (Baborska-Narozny et al., 2016). Further studies detail the role of *provision actors* in shaping the material configuration and integration of these technologies, and occupant use as a result (Gram-Hanssen et al., 2016).

The UK government aims to develop new collective governance and action between multiple actors including, government, industry and community groups (Moss, 2009). This is to encourage wider user participation in governing their building environment and to produce solutions that respond to their preferences and capacities, which can improve the use of home technologies and reduce the implementation gap (Chang & Taylor, 2016). Community housing projects provide an optimal condition for understanding the collective and individual governance by users of their home environment. Governance here is defined as "the sum of all ways in which individuals, public agencies, and private organisations govern their common affairs in a continuous process of negotiation and cooperation" (Commission on Global Governance, 1995: 4).

I*ntermediaries* are broader agents who can also shape governance through their impacts. They can either impact actors agency or their capacity to do an action (Parag & Janda, 2014). For example, the home owner may have agency to decide to install a photovoltaic (PV) system, but the capacity might be low due to lack of money, knowledge and social support as intermediaries. Both human and non-human agencies performing as 'intermediaries', can have a critical impact on the decisions made by PV professionals during the PV system design stage (Frances & Stevenson, 2017). The main aim of this paper is to further explore the various intermediaries impacting the PV system in operation and practice, and identifying which key roles and impacts have been sustained from provision stage to occupation stage, and why.

The next section of this paper shows how Latour's Actor Network Theory (ANT) can be integrated into the framework of Schatzki's Practice Theory in order to conceptualise a sociotechnical phenomenon (Reckwitz, 2002) relating to the governance of PV technology in homes. This is then translated into methods in the next section. Next the findings section summaries the key intermediaries that impacted PV design during the provisioning stage, while the detailed discussion section shows how further intermediaries enrolled in the network and shaped occupants' interaction with PV appliances. The conclusion brings all these issues together and outlines some key recommendations.

Actor Network Theory and Practice theory

ANT examines how actors (both human and non-human) are enrolled in networks to achieve particular goals (e.g. PV design and use), and suggests that actors only shape their agency (the ability of doing an action) through their *relations* with other actors in a network (Latour, 2005). This process is defined as a 'sociology of translation', where the action of an actor is not fixed in form, but subject to 'a series of transformations' as a result of the negotiation of conflicting priorities and visions embodied in a variety of actors who are enrolled in a specific network (Latour, 1999). Various intermediary actors frame the agency and action of occupants when using their PV systems through the network of relations between them. Intermediaries are passive entities in an actor network that "transports meaning or force without transformation" (Latour, 2005: 39). Their priorities are decided by 'mediator' actors, who have governed the system design and influenced the subsequent use (Hodson et al., 2013). Crucially, the term agency is ascribed to both human and non-human actors (Callon, 1986). This opens an analytical space to examine non-human actors as significant intermediaries in a network, beside human intermediaries, who impacted PV system design and use.

Schatzki's (2002) Practice Theory goes further than ANT and aims to understand the *actual* application of a phenomenon within its real *context*, and explores the co-evolving of different elements that are significant to any practice: product, know-how, rules, and engagement (Gram-Hanssen, 2011). Those elements have crucial implications in this paper in terms of identifying and understanding further non-human intermediaries that impact the governance of PVs.

Research design and methods

A mixed methods empirical case study approach (Yin, 2013) was used to identify the governance of PV provision and use in two sets of contrasting housing projects across England. The four selected 'Participative community' (PC) housing projects (A-D) each had a representative 'Provisioning Occupant' (PO) as a key decision maker in the PV provision process. Two 'Non- participative community' (NPC) housing projects (E-F) had occupants who bought and lived in houses constructed by a developer without their involvement in the PV procurement process and no PO.

38 semi-structured interviews and 18 ethnographic video tours (Pink, 2009) were carried out with occupants and PV professionals, to illustrate the PV provision and use practices. The innovative home *video* tours (Stevenson & Rijal, 2010), developed from an ethnographic walkthrough method commonly used in an energy and building context, enabled the researchers to observe and understand the actual occupants' perceptions, practical knowledge and skills when using their PV controls in different contexts (Pink & Mackley, 2012). All interviews and video tours were, recorded, coded (Schreier, 2012) and linked to mapping (Yaneva, 2012) which is entirely novel. This is to understand the different capacities of actors in each case study when governing the PV system design and use, and to uniquely compare the governance structure between the two contrasting sets of housing projects.

Findings and discussions

PV provision stage intermediaries

In the PC projects, the POs performed both mediator and intermediary roles during the PV provision process. They made the key decisions during their discussions with other professionals, while also acting as intermediaries by passing on decisions to the occupants. The project manager acted as an intermediary in project A, impacting the decisions of the PO in terms of achieving the designed Code for Sustainable Homes (CSH) by passing on specified government policies and requirements. In projects B, C, and D, the installer made all the PV decisions with the PO because the PV system was independently installed from the main building construction. However, in projects A, he acted as an intermediary by only installing the equipment that has been specified and selected by the mechanical engineer. Surprisingly, the architect only acted as mediator in project A, while in the other projects, he performed as a passive intermediary by maintaining the assembly of the network. The mediating grant bodies required a monitoring system to be installed (C, D) and determined the overall size of the PV systems (D). In the NPC, the service consultant was the only human intermediary that impacted the decision of the client and the main contractor in project F, by passing on the assumptions made by PV installers in terms of cleaning requirements, which resulted in non-accessible PV panels.

In terms of non-human actors, professional knowledge proved to be the most significant intermediary in terms of impact (all projects), followed by standards and ethics (NPC projects), and FIT, environmental motivation and aesthetic (PC projects). In terms of knowledge, the professional *assumptions* about PV system interaction clearly reduced the potential role of the POs in terms of deciding the system affordance and occupants' capability to interact with these systems effectively as a result. The Feed in Tariff (FIT) standard intermediary clearly impacted the PV outcomes in the PC projects in terms of scale, system design and the installation time frame - all designed to improve the energy generation from the supply side and to increase the financial benefits. By contrast, the FIT had no impact on the system design in the NPC projects; instead, the CSH energy standard and developer ethics usefully impacted the developers' decision to install PV systems in the first place, and greatly impacted the scale of the systems alongside other intermediaries, such as the roof size and cost. The next section moves on to explore how these intermediaries further impacted occupants use of their PV systems. Figure 1 illustrate the different intermediaries that impacted the decisions made by professionals who acted as mediators.

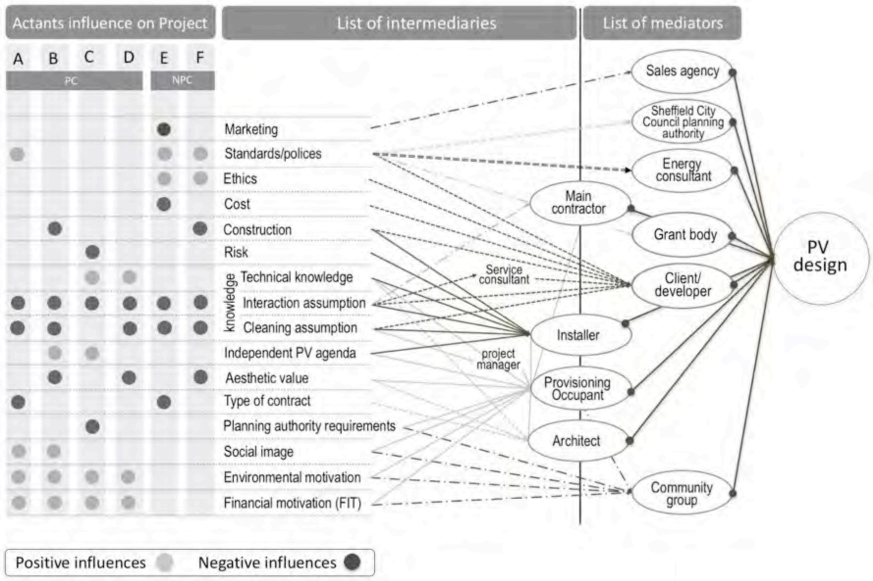

Figure 1. Professional and Occupant intermediaries during provision stage

PV interaction stage intermediaries

Non-human intermediaries

Nine non-human intermediaries were identified in all projects: Four existing ones from the provision stage (location, aesthetic value, ethics and FIT) and five new ones (cost, digital forums, skill, graphs and social structure) (Figure 2).

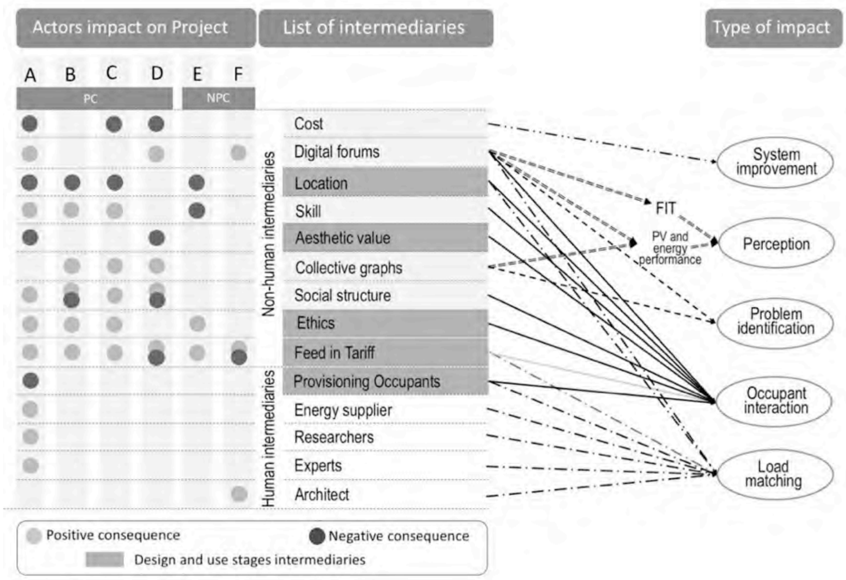

Figure 2: Intermediaries impacts on occupants during interaction stage

- *Feed in Tariff (FIT).* FIT was the key continuing intermediary in terms of occupant's interaction with their PV meters in all the projects with rules stating that occupants had to send their meter reading every three months to their energy supplier company to claim the financial payback from their system. Because two tenant occupants were unable to claim the FIT (E), they had no interaction with the meter and did not know if the system was working or not. The high rate of the FIT stopped three occupants (D, F) from managing their energy loads appropriately: *"…the issue of whether we use energy during the day or not was not so important because the attraction was the FIT. The FIT was very high"* (F4).
- *Social structure.* Allocating responsibilities for PV monitoring and cleaning the PV panels to a community member/group ensured occupants record of their energy generation through the read of PV meters in all PC projects and monitoring loggers (C, D), cleaning all the PV panels (C) and observing all the PV inverters (B). By contrast, this stopped the other occupants in project B from individually monitoring and understanding their own PV system performance. Allocating individual responsibility for occupants to maintain their house disabled three occupants in project D from cleaning their dirty PV panels because they could not afford to.
- *Location.* The hidden location of the inverters in projects A and B, and the invisibility of the PV energy generation monitor in project C significantly discouraged the occupants from observing these hidden appliances in order to match their energy load. The problem was worst in the NPC-project E, where three participants were not aware of their invertors: *"I don't know anything about it? What it does look like…I have never seen this thing in the house"* (video tour E1).
- *Skill.* Occupants interaction with the appliances that require some know-how to interact with them, such as the display screen of the inverter (A, B), and downloading the data from the monitoring loggers (C), worked because they had the skill in the first place. By contrast, occupants' limited understanding of using their energy monitoring device (E), led to ignoring it despite its load matching potential *"I don't interact with it because I don't know much about its application"* (Video Tour E1).
- *Collective graphs.* The collective PV and energy performance graphs, as a new intermediary, in the PC projects, enabled occupants to understand the relative performance by comparing their energy results with the results from neighbouring houses: *"So, individually we looked at the figures and compare the results…we have detected the problem of underperformance of our PV system and asked for suggestions"* (D1). Lack of publishing these graphs to all the community members (A) resulted in a surprisingly low rate of PV and energy performance awareness despite carbon reduction being a significant aim of the development.
- *Aesthetic values.* The occupants' aesthetic values overruled energy efficiency when they decided to hide their PV meter (A) and invertor (D), and reduce their interaction as a result: *"…lots of people have covered their meters with a blanket, put bookcases in front and around it... So, it is just ugly, not only for me"* (A4).
- *Cost*. The high cost of changing a PV meter or an inverter was the main intermediary obstacle for some occupants in projects A, C and D to not improve their capability to match their energy loads: *"…I did not make any change…I could buy a wireless smart meter or inverter, but the cost will be prohibitive for me"* (A3). Similarly, the cost stopped occupants in project D improving their systems by attaching micro-inverters to each panel, to avoid overshadowing the PV panels by trees.

- *Digital Forums*. Google and group email, as new intermediary, enabled occupants to discuss the possible methods to clean their inaccessible PV panels (D), to identify collective occupants' misunderstanding in relation to the FIT registration process and responsibilities (F), to argue how to achieve the optimum use of the total PV energy that was generating from the all community systems (A) and to identify a collective problem associated with the use of energy monitoring device (A).
- *Ethics*. Occupants' environmental ethics encouraged them in project C to regularly meet and discuss their PV and energy performance which had an impact on managing their energy loads and to suggest technical solutions to do so (C). This had also motivated some occupants to individually monitor their energy efficiency and to manage their energy loads (A, E). By contrast, not having this ethics for some occupants stopped all community members in project B from collectively discussing their energy performance as *"it generated a tension between people who really want to reduce their carbon footprint and people who do not give a very much consideration for that"* (B1).

Human intermediaries

Two existing human intermediaries from the provisioning stage (PO and architect) and three new ones for the occupancy stage (energy supplier, academic researchers, and experts) were identified in all projects.

- *Provisioning Occupant (PO)*. The PO acted as an intermediary in project A when he passed on advice to the other community members not to interact with their PV controls other than take meter readings, assuming that *"people in this project are already low consumers"* (A3) and supposing that all the measures to be a low carbon community was considered in the provisioning stage; as a result, the load matching potential was never examined and discussed.
- *An energy supplier, a researcher* and *an electric car charging point specialist* performed as significant intermediaries in project A in terms of passing on educational advice to the occupants about how to use their energy efficiently in their houses by matching their energy loads and reduce the imported energy from the main grid *"…if I used my things during the day, I actually then keep my bill low. (interviewer: Did the guidance tell you that?) No. Magda did"* (A4). In the same project, the academic researcher also passed on information to some occupants about how to improve their PV performance by keeping the invertor well ventilated. All these perceptions were supposed to be passed on by the PV installer as an intermediary before people moved into their homes.
- *Architect*. The architect of project F, as a continuing intermediary, led a large research program (SENSIBLE) funded by EU to install individual batteries in some houses and a big community battery. On the individual level, the small batteries enabled occupants to individually manage their energy loads, while on the community level, the community battery will support the community energy self-reliant by provide them access to affordable energy in the community by sharing excess electricity generated in their properties with other community members (Rodrigues et al., 2016).

Conclusion

This paper has investigated the emergence and function of various *intermediaries* as an innovative approach to shifting governance and low carbon transition, by linking an ANT-theoretical perspective with Practice theory in relation to PV provision and use, in two different types of housing provision in the UK. PV systems have not been examined in previous studies concerned with the implementation gap of domestic low carbon technologies, particularly in relation to the provision team governance of the system design and integration in homes. ANT shifts the focus away from fixed interest of actors to an explanation of actor networks by which PV design and use are specified and governed. ANT further demonstrates that non-human actors 'make a difference' to the outcomes. Practice theory has helped to address new and continuing intermediaries and the impact of the social and physical context of PV on the co-construction between occupants and PV systems. The innovative combination of these two theories and their distinct methods of data collection and analysis revealed new findings which the individual theories cannot do - the key methodological contribution of this paper. The potential neutral participatory role of POs in terms of improving the system design and reducing the implementation gap in the PC projects was significantly undermined by: 1) the assumptions made by PV professionals in relation to occupants interacting with the system, and 2) the POs having an individual agenda for PV system during the construction process.

The role of POs needs to be redefined in terms of them understanding the meaning of PV technology as a system that has potential to impact on occupant energy use instead of perceiving it as technology that provides green and free electricity. Load matching potentials, therefore, need to be clearly discussed and considered in the PV design stage and to be adequately translated to occupation by the PO during occupation. However, these roles were entirely absent in the NPC projects where the client and main contractor governed the occupants' use through their design. This resulted in occupants remaining ignorant about their PV affordance, competence and maintenance. Uniquely, the study has identified the different intermediaries and mediators that influence the occupants' use of the PV system during occupation, which has not been covered in previous studies.

FIT polices, location and aesthetic values were the key non-human intermediaries in the both provision and use stages. FIT need to be designed to encourage users to match their energy loads rather than simply installing PV systems for financial profit. All PV appliances should be located in visible places for occupants and consideration of aesthetics is an emotional necessity to achieve potential interaction. Collective graphs and digital forums, offered by community housing context, are very powerful intermediaries, which enable occupants to understand and compare their PV and energy performances and identify underperformance problems. These intermediaries are probably missing in NPC projects generally which is a major concern, as they make up the majority of housing in the UK. In general, the human intermediaries helped occupants to match their energy loads, while the non-human intermediaries encouraged occupants to interact with their PV appliances, to identify underperformance problems, and to increase their PV and energy perceptions.

Significantly, none of occupant in all projects referred to Home User Guide (HUG) as an intermediary that has an impact on their system use due to their limited PV information, and provision by the installers. Other new intermediaries need to be introduced by the policymaker in particular for the effective utilisation of new domestic technologies, through practices and processes, and in terms of educating PV occupants how to match their energy loads. Further study is needed to investigate the detailed role of other intermediaries, such as media, public forums and governmental campaigns in improving the PV system use.

SIPRIUS+: A sustainability monitoring tool specifically designed for urban brownfields regeneration projects

Martine Laprise[1], Sophie Lufkin[1] and Emmanuel Rey[1]

[1] Laboratory of Architecture and Sustainable Technologies (LAST), Institute of Architecture (IA), School of Architecture, Civil and Environmental Engineering (ENAC), Ecole Polytechnique Fédérale de Lausanne (EPFL), Switzerland, martine.laprise@epfl.ch

Abstract: One of the relevant strategies to limit the sprawl of post-industrial European cities is the regeneration of urban brownfields. This type of projects concentrates new development within already urbanized areas and contributes to their revitalization. Despite this, projects developed on urban brownfields are not automatically sustainable. It is explained by their inherent complex nature, due to the specificities of the site, the project process and the sustainability concept itself. Focusing on these challenges, SIPRIUS+ is an operational monitoring tool using an interdisciplinary approach. It supports a search for global quality, tailored to urban brownfields regeneration projects and integrated into the project dynamics. This new generation tool is a hybrid between a sustainability indicator system adapted to issues raised by brownfield regeneration and a user-friendly, web-based monitoring software. SIPRIUS+ assists practitioners in their decision-making: it facilitates the integration, assessment, and follow-up of sustainability indicators during the transformation of urban brownfields into new environmentally friendly and socially inclusive neighborhoods, respectful of future generations. This paper gives a description of the different steps of the tool's design and an overview of its functionalities. Then, the main features of SIPRIUS+ are presented through a test application on a case study located in Yverdon-les-Bains (Switzerland).

Keywords: Urban Brownfield, Regeneration Projects, Sustainability, Monitoring tool, Decision-making

Introduction

As the negative effects of urban sprawl are now widely recognized, post-industrial European cities must turn to strategic densification (EEA, 2006). In this context, Urban Brownfields Regeneration Projects (UBRP) offer great opportunities to densify and revitalize existing built areas. This type of operation matches the compact and polycentric city model, identified as a relevant vision to make the sustainable city (Rogers and Gumuchdjian, 1998; Williams, 2010). Hence, across Europe, land use policies strongly foster UBRP as a sustainable land take solution (European Comission, 2013). However, "any argument that all brownfields redevelopment is inherently sustainable is unjustified" (Eisen, 1999). Quite often, URBP refers only partially or superficially to the holistic concept of sustainability (Andres and Bochet, 2010; Rey, 2012). In fact, dealing with sustainability objectives asks for the consideration of a multitude of parameters going far beyond the limits of intuition. This adds to the complex nature of UBRP generated by the specificities of the site (neighborhood scale, possible contamination, social stigma, etc.) and the specificities of the project process (multitude of stakeholders, long duration, etc.).

To handle the overall complexity of UBRP, it is essential to act on the basis of sound information and to put a system in place to collect it as appropriate (Pediaditi et al., 2010). Because the integration of sustainability is not automatic, it appears essential to assess regularly, equally and concurrently environmental, social and economic criteria. To be accurate, the assessment must take into account the specificities of UBRP and the national/regional context (Sharifi and Murayama, 2013). Moreover, to pursue sustainability objectives throughout the operation, frequent assessments must be part of the project dynamics (Berardi, 2011). The assessment results should provide elements to support decisions in a way that allows iterative setting of sustainability objectives. To do so, a balance between exhaustive and clear information is needed, provided by an interdisciplinary approach (Bartke and Schwarze, 2015). In short, an operational monitoring tool is required. This tool must satisfy the following three general requirements: (1) a search for global quality; (2) an adequacy with the specificities of UBRP; (3) an integration into the project dynamics (Rey, 2012).

A recent state of the art has reported few evaluation systems adapted to brownfield regeneration, but dissociated from the overall project dynamics; they fail at monitoring sustainability in an operational way (Laprise et al., 2015a). To fill this gap, a research project entitled SIPRIUS+ is currently underway at Ecole Polytechnique Fédérale de Lausanne (EPFL) to propose a new sustainability monitoring tool tailored to UBRP. This innovative research project is based on a hybridization strategy, combining two existing tools from different fields: the built environment and the business management. Following the above theoretical considerations, this paper presents briefly the method behind the creation of the monitoring tool. Then, it describes the main functionalities of SIPRIUS+. Finally, a test application on a case study reveals how SIPRIUS+ can facilitate decision-making during the transformation of urban brownfields into new environmentally friendly and socially inclusive neighborhoods.

Method: hybridization strategy

Even if they do not answer the 3 general requirements, we know that a multitude of multicriteria evaluation tools in the built environment are already available (Sharifi and Murayama, 2013). At the same time, efficient digital monitoring software are used in many diverse fields where the management of sustainability issues is needed (Laprise et al., 2015b). While indicators may differ, the methods used to monitor sustainability in businesses or project development have considerable similarities. In reaction to that, we adopt an approach based on the potential of existing knowledge and expertise. This hybridization strategy is to select an existing monitoring software and combine it with the adequate indicator system.

An extensive analysis led us to the complementary selection of an IT solution, the web-based monitoring software OKpilot, and SIPRIUS, an indicator system specifically designed to integrate sustainability into the dynamics of UBRP (Laprise et al., 2015b). Together, they have the potential to fulfill the 3 general requirements previously described. Here we make a short description of the two tools and we identify the adaptations required before performing the hybridization.

The indicator system SIPRIUS

SIPRIUS measures several quantitative and qualitative sustainability indicators and follows their evolution through the UBRP process (Rey, 2012). The indicators covering environmental, socio-cultural and economic aspects reflect the Swiss context. They are grouped into two categories: Context indicators and Project indicators. To measure and compare each indicator, SIPRIUS attributes four reference values: Limit Value (VL), Average Value (VA), Target Value (VT), and Best Practice Value (VB). Each indicator has its own datasheet containing all the relevant information to perform the assessment (description, evaluation method, measurement unit, reference values, and references). SIPRIUS has proven to be a relevant method to evaluate sustainability. However, SIPRIUS is not operational yet; because it is not integrated into a digital tool, its use on a regular basis depends too much on stakeholder's motivation. Developed in 2006, SIPRIUS needs some adaptations to comply with current practice (Table 1).

The monitoring software OKpilot

OKpilot is a web-based solution designed to help businesses and organizations to comply with different checklists of indicators and to increase their performance (GLOBALITE Management, 2014). The collaborative monitoring software has features that allow an optimal control of projects and activities. In this sense, three main interrelated sections compose OKpilot: Evaluation, Outcomes, and Management. Initially, OKpilot is not adapted to monitor sustainability in the built environment. However, the main advantage of OKpilot is its adaptability; thanks to a clear dissociation between its monitoring functionalities and the assessment database, OKpilot has the potential, providing some adaptations, to answer the needs for an operational monitoring tool adapted to UBRP (Table 1). Most of OKpilot's adaptations involve minor adjustments (1 to 4). Adaptation 5 and 6 require more extensive computer programming. All these adaptations affect the Assessment and Outcome sections; the Management section has useful monitoring features (risk alerts, objective setting, deadlines, internal mail, user configuration, etc.) that are highly functional and already compatible with SIPRIUS. This latter section does not need adaptations.

Table 1. List of the required adaptations for SIPRIUS and OKpilot.

SIPRIUS: required adaptations	**OKpilot: required adaptations**
1. Update of the existing indicators	1. Integration of documents and data sources
	2. Possibility to unselect irrelevant indicators
2. Inclusion of missing indicators	3. Harmonization of terminologies
	4. Organization of OKpilot's tree diagram
3. Creation of a list of Governance indicators	5. Conversion of the reference values
	6. Enhancement of the graphical displays

The making of SIPRIUS+: hybridization process

Regarding SIPRIUS, we have updated 7 indicators to reflect current concerns of the practice, norms and standards evolutions. In all cases, the reference values (VL, VA, VT, and VB) are more restrictive than the ones suggested by the original version of SIPRIUS. For example, indicators C2.2 Global warming potential (GWP) and P2.1 Non-renewable primary energy for construction, renovation and demolition of buildings had no reference values in the first version of SIPRIUS because, at the time, no sufficient comparative calculations or recognized targets were available. Since then, the Swiss recommendation SIA 2040 has been released which encloses objectives for those two indicators (SIA, 2011). For Adaptation 2, we included 4 new indicators following the comparison of SIPRIUS with other indicator systems specifically developed for brownfield regeneration projects and sustainability certifications at the neighborhood scale. *C4.1 Degree of prevention of light emission* is an example of a new indicator completing SIPRIUS. Finally, we created a list of 11 indicators in relation to the governance of UBRP, which aim at evaluating the management and the process of the project. Half of these indicators have a concrete dimension in relation to the realization of the project such as remediation, temporary uses, construction site and commissioning. They are limited in time, to a specific project phase. This does not exclude a regular assessment, starting from the beginning, in order to set objectives. The other half of these indicators relate to all aspects involving the implementation and smooth execution of the UBRP and its sustainability objectives. Participation, collaboration, information access and assessment are part of it. We elaborated this new list while analyzing the literature as well as other indicator and certification systems. In total, after completing these three types of adaptations, SIPRIUS offers 57 indicators.

Regarding OKpilot, we performed Adaptations 1 to 4 in collaboration with the IT team as mentioned in the method. For Adaptation 5, we changed the way indicators are measured from percentages to absolute values, corresponding to SIPRIUS' reference values (VL, VA, VT and VB). In the Evaluation section, a new slider allows assigning a value to each indicator. This section also includes all relevant information and documents to assist the evaluation. In addition, a standard color code has been associated with each reference value: orange corresponds to VL, yellow to VA, light green to VC and dark green to VB. As for red, it corresponds to an indicator whose performance does not reach the limit value (VL). Adaptation 5 implied coding work that had repercussions on the representation of the results (Outcome). Thus, this work was done concurrently with Adaptation 6. The Outcome "Chart", used to show an overview of the results at a given moment, has evolved in order to show all indicators simultaneously. In the previous version, the "Chart" results were showing only aggregated indicators under their corresponding criteria. Furthermore, we added options to customize the visualization according to a selection of indicators, sustainability aspects or value (Figure 3). The graphical display entitled "Evolution" is a completely new feature of OKpilot, essential to monitor UBRP. It shows the evolution of a given indicator from the objective or initial situation to the expected final situation, including the current situation (Figure 4). It has the same options as the "Chart", plus the option to show a summary of the repartition of several indicators, according to their performance (Figure 5).

Once the adaptations completed, the two tools are ready to merge as one new hybrid operational monitoring tool. Entitled SIPRIUS+, it brings together the evaluation data of more than 50 sustainability indicators and offers several ways to communicate their results. Moreover, SIPRIUS+ has useful functionalities in order to manage them in an interdisciplinary and collaborative way (allocation and follow-up of indicators, alerts or objectives setting, reporting, risk identification, etc.). In other words, it gives a shared vision of sustainability and an important decision-making support to the UBRP key stakeholders. To finalize the hybridization process, we designed for SIPRIUS+ a new customizable homepage including a simplified menu. Figure 1 shows this homepage as an introduction to the test application.

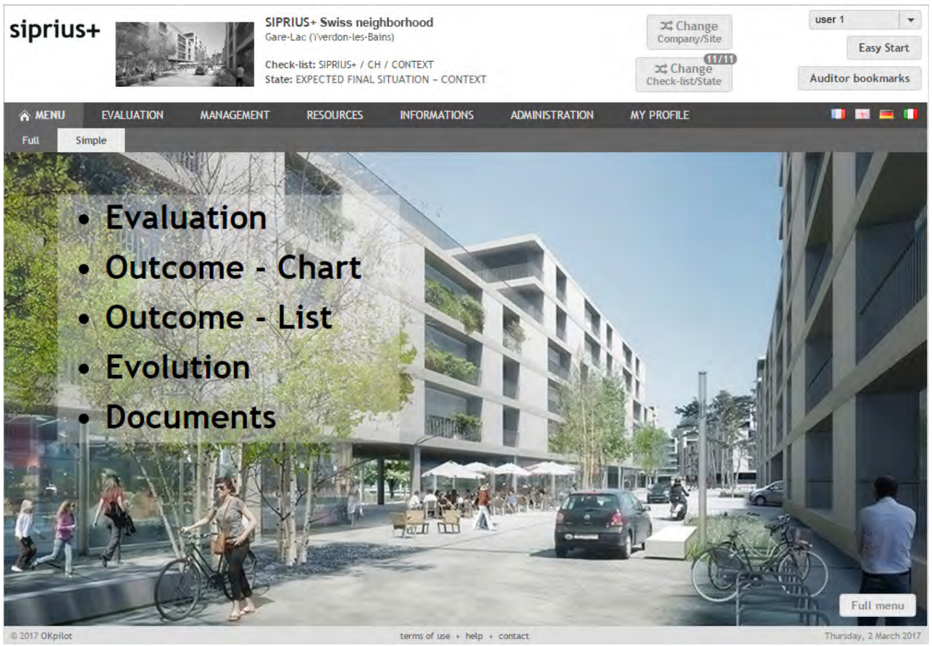

Figure 1. A screenshot of SIPRIUS+'s homepage customized for the Gare-Lac case study.

Test application

For the test application, we selected a case study representative of UBRP, with the strong intention of including sustainability in order to evaluate a maximum of indicators. Indeed, the underlying aim of the test application is to verify the usability of SIPRIUS+ and to make iterative settings on the tool. Known as the Gare-Lac neighborhood, the chosen case study is located on a 23 ha disused industrial area. It is close to the center of Yverdon-les-Bains (Switzerland) but remains disconnected by railways. The master plan (Figure 2), developed by a multidisciplinary team, was officially adopted in 2015 (URBAT et al., 2012). It consists of a new mixed-use neighborhood (3810 inhabitants + 1260 jobs) with open courtyard buildings, which put emphasis on an optimal density thanks to green and public spaces, soft mobility networks, eco-friendly construction and good access to services and public amenities. This new master plan will now be assessed with SIPRIUS+.

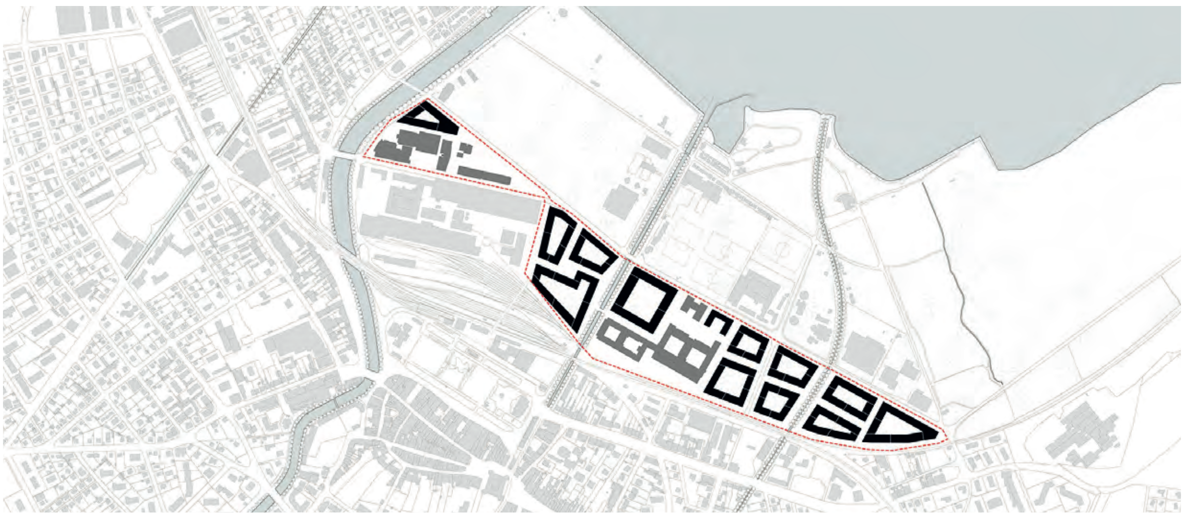

Figure 2. Master plan of the Gare-Lac neighborhood in Yverdon-les-Bains (Switzerland). In dark gray, existing buildings (to be retrofitted), in black future buildings.

Results

The test application has resulted in a detailed evaluation report. It includes a description of the process and case study, a description of each indicator results along with the "Evolution" graphical display, a global view of the results for each type of indicators (Context, Project and Governance) at different situations (initial, current ,and expected final situation), and a summary of the results for the Gare-Lac neighborhood. In addition, the report provides also the datasheets of all the indicators. We extracted all these data from SIPRIUS+. We show here a brief example of the Context indicators results.

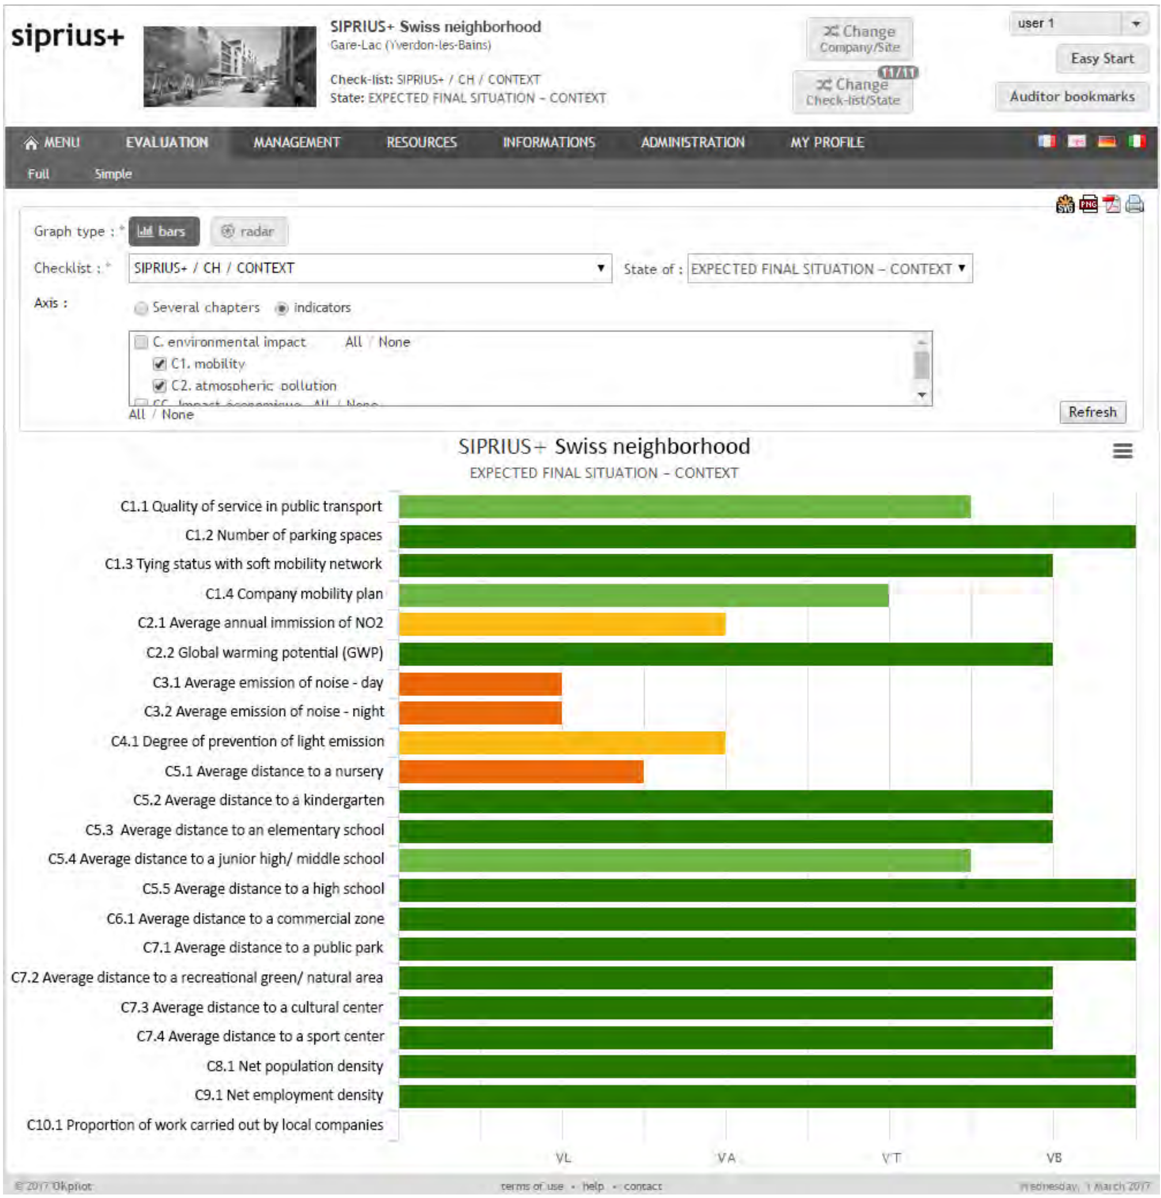

Figure 3. Outcome "Chart" extracted from SIPRIUS+ showing the results of the expected final situation for Context indicators

The "Chart" (Figure 3) gives an overview of the expected final situation of the Gare-Lac neighborhood, that is to say, the foreseeable values at the end of the UBRP. In general, we notice a high performance, reaching the Best Practice Value (VB) for most of the Context indicators. This is mainly explained by the fact that the evaluation is based on the master plan.

Because the integration of sustainability has more chances of success at the beginning of a project process, setting high objectives in the master plan is important. Nevertheless, this evaluation is not static; the results are likely to change over time, following the evolution of the project. This consideration is embedded in the monitoring concept. Otherwise, one can also notice by looking at the "Chart" that some indicators are at the Limit Value (VL) or Average Value (VA), i.e. orange and yellow. At this stage of the project, it highlights aspects that need particular attention in order to reach high performance in terms of sustainability. Going more into details with the graphical display "Evolution" (Figure 4), stakeholders can follow one by one the progression of different indicators, through all the UBRP process. Management features linked to each indicator, such as risk alerts and objective settings, can assist SIPRIUS+ users as the project changes. Finally, SIPRIUS+ offers a summary of the sustainability performance of the Gare-Lac neighborhood (Figure 5). This summary also gives insights on the global performances of Context, Project and Governance indicators.

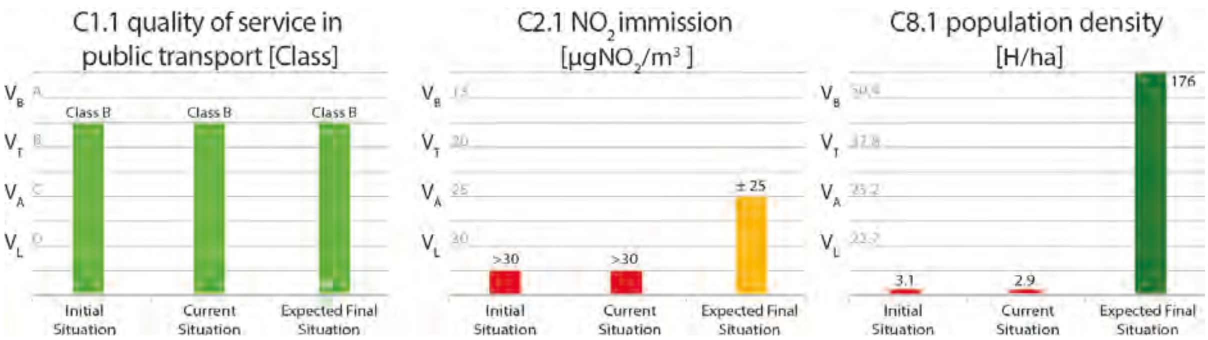

Figure 4. Evolution graphical displays extracted from SIPRIUS+ for three examples of Context indicators

This test application shows that SIPRIUS+ can provide an exhaustive picture of the sustainability status of an UBRP at a given moment, in this case, the Gare-Lac neighborhood. Altogether, SIPRIUS+' Outputs and Management features can contribute to following closely the evolution of sustainability objectives throughout the UBRP, which in turn helps to make informed decisions and to share a common vision of the future neighborhood with professional stakeholders as well as the concerned communities.

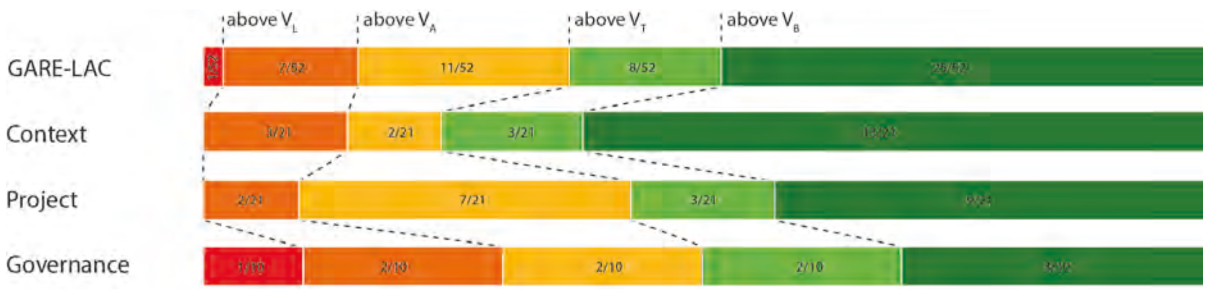

Figure 5. Repartition of sustainability indicators performance for the Gare-Lac neighborhood.

Conclusion

Urban Brownfields Regeneration Projects (UBRP) are not inherently sustainable. Consequently, this research project proposes an operational monitoring tool facilitating the transformation of urban brownfields into tomorrow's sustainable neighborhoods. Entitled SIPRIUS+, this new generation tool is a hybrid between SIPRIUS, a sustainability indicator

system adapted to brownfield regenerations and OKpilot, a user-friendly, web-based monitoring software. To combine SIPRIUS and OKpilot, some adaptations were first required. Then, we conducted a test application on a case study: the Gare-Lac neighborhood in Yverdon-les-Bains (Switzerland). It shows that SIPRIUS+ can offer a comprehensive picture of the sustainability performance of an UBRP. As a collaborative monitoring tool, SIPRIUS+ can facilitate decision-making regarding sustainability objective thanks to a long-term vision of multiple environmental, social, economic and governance indicators.
However, knowing that these operations sprawl over more a decade, it is not reasonably possible to verify how SIPRIUS+ can truly be integrated into a project dynamics. Thus, further experimentation implies interactive workshops with involved stakeholders of the case study to present SIPRIUS+ and the results. The intention will be to gather their opinion about the potential integration and added value of SIPRIUS+ in the long run within an UBRP team. These activities will be the subject of further publications.

Abstract: Thriving cities are characterised by vigorous growth and concepts of flourishing, healthy communities. However, these concepts are not immediately connected with the living conditions in squatter settlements in developing countries. With a rapidly increasing urban population, slum dwellers in developing countries continue to occupy a vulnerable position in urban areas with fear of eviction and displacement from their livelihood. Acknowledging a range of approaches to house slum dwellers, including problematic efforts to relocate inhabitants from a squatter settlement to a regular housing market in a single step, this paper examines the circumstances which have enabled squatter settlers to achieve legal tenure and to build homes, incrementally, that are eventually compliant with the building code. Based on detailed analysis of individual homes and interviews with householders, this paper presents the findings of a comprehensive study of slum settlements in Davao City, Philippines. The progressive development of urban settlements is analysed in the context of Filipino pro-people policies, which have prioritised the rights of the urban poor and empowered them to build low income housing, enabling them to develop sustainable, secure, thriving urban settlements which are the foundation for a better future.

Keywords: Housing policy, Philippines, progressive development, secure tenure, urban poor

Introduction

Thriving cities are characterised by success and prosperity as well as vigorous growth and concepts of flourishing, vibrant, healthy communities. However, these positive themes are not immediately connected with the urban living conditions of slum dwellers in developing countries. The world's population is becoming increasingly urban, and the rapid increase is found in cities of developing countries. In 2015, the United Nations declared that 54% of the world's population lives in urban areas. While it is estimated that the figure will reach 66% by 2050, nearly 90% of this increase will be in Asia and Africa (United Nations, 2015). In this context of unprecedented urbanisation coupled with widespread urban poverty, squatting is often the only means to access affordable shelter for the urban poor. Moreover, slum dwellers in developing countries continue to occupy a vulnerable position in urban areas with fear of eviction and displacement from their livelihood. Squatter settlements are often seen as indicators of disease in a healthy city because of their perceived negative impact on the urban and ecological environment (Appadurai, 2000), as McFarlane contends 'informal settlements…remain populations outside the sphere of citizenship and notions of the clean, ordered modern city' (2008, p. 1). On the other hand, the development of informal housing often provides an immediate solution to shelter needs of the urban poor who migrate to the city in search of a better livelihood. The recognition of self-help housing in informal environments has its roots in the 1960s evident in the work of Abrams (1964) acknowledging the role of squatters in the urbanizing world; and, in the seminal work of Turner (1968) derived from his involvement in the squatter settlements of Lima, Peru. Furthermore, in the 1970s, Ward (1976) explored squatter settlements in Mexico as a low-income housing solution. This process continues in the developing world, documented in the ongoing work of Mitlin and Satterthwaite (2004), Mukhija (2003), and others. Moreover, increasingly positive attitudes toward squatter settlements are expressed by UN-HABITAT (2008) in their case for a 'slum of hope' (in contrast to 'slums of despair' where formerly well-developed urban districts have deteriorated due to regressive economic and social activities).

Acknowledging that housing is a basic human right, governments are committed to provide shelter for the low-income sector of their respective countries. However, housing policy and programmes in developing countries, like the Philippines, are often based on models (applied with varying degrees of success) which originate in high-income countries. Defined by Lim (1987) as a 'one-step regularization model', this model is intended to relocate the urban poor from a squatter settlement to a regular housing market in a single step. Alternatively, it is also characterized as 'instant development' (Turner, 1967); or, a 'product approach' where a complete housing package is delivered through a sophisticated system in the housing market (Ferguson and Navarrete, 2003). In the Philippines, an example of this traditional approach was a major housing programme under the Marcos regime known as the *Bagong Lipunan* Improvement of Sites and Services (BLISS) conceived in the late 1970s. Intended as housing for the poor, many BLISS housing projects were completed in Metro Manila in 1983 as discussed by Abueg (1986). However, the buildings were similar to other condominiums catering to higher income earners that did not seem to match the affordability of the urban poor.

Decentralized housing and urban policies under the Marcos regime in the Philippines ended with the People Power Revolution in 1986. Consequently, the new 1987 Philippine Constitution served as a general framework for new governance which took an explicit stand on issues related to the alleviation of urban poverty. It established guiding principles on the conditions of eviction and the roles of the government, private and non-profit organizations in housing delivery and infrastructure development (Shatkin, 2007). The new Constitution became the basis for two major pieces of legislation pertinent to informal settlement, namely, the Local Government Code of 1991 and the Urban Development and Housing Act of 1992, which, according to Porio and Crisol (2004, p. 208), 'marked the departure from eviction and relocation to the adoption of a more decentralized approach towards housing and urban development'. Furthermore, these policies also integrated the participation of the urban poor in land use planning and redefined the roles of government agencies, urban poor communities and mediating groups such as NGOs. As such, they changed the performance and relationships of stakeholders in the housing sector (Porio and Crisol, 2004). Given these developments, there is a need to discuss the progressive form of urban development in relation to these recent housing and urban policies in the Philippines.

Background, aims and objectives of this paper

This paper maintains that the progressive development of urban settlements coincides with the legalisation of land tenure, and the incremental construction of housing units and improvements to sites and services. Preliminarily, this argument is informed by detailed observation of how an informal settlement in Davao City, Philippines, underwent a transformation from an informal settlement to a more formal one (Malaque III, 2013). In a subsequent comprehensive study of 74 households in 11 settlements, in the same city, the following housing phenomena were observed based on detailed interviews with residents and *in situ* building analysis. Firstly, it was deduced that urban households can be classified into five different types in a range of contiguous categories from formal (Type I) to informal (Type V) housing, and it was observed how householders moved from one type to another until they became owners of formal housing (defined as legal tenure with construction compliant with the building code). Characterised as a multi-step transition process, one way to achieve formal housing occurred when an informal housing unit in a progressive urban settlement was upgraded to become a formal housing unit in the same location (Malaque III et al, 2014). Secondly, further examination of the phenomenon revealed that the incremental construction of housing units in a progressive urban development was a direct result of the improvement of the householder's security of tenure. This was exemplified when an informal housing unit was upgraded with better building materials and standard methods of construction when the inhabitant's degree of legal and financial security improved. Over time, it was observed that the physical condition of the house could deteriorate over time while the inhabitants focused on payment for land. However, upon achievement of legal ownership of land, the house was further refurbished to become a formal structure (Malaque III et al, 2015). Thirdly, an evolution of housing is modelled by connecting the incremental constructions of housing cases representing the range of housing types from informal to formal. This illustrated the evolution of housing from a simple shack in a squatter settlement to become permanent formal architecture; these structures comprised one- and two-storey residential buildings during the course of their development (Malaque III et al, 2015).

Despite being the subject of comprehensive scholarship, this dynamic phenomenon of housing and urban development requires further understanding to inform more effective urban planning interventions which are both appropriate and sustainable in developing countries. Thus, to further understand this dynamic phenomenon in the case of a city in a developing country, the aim of this paper is to illustrate the progressive development of this type of urban settlement. This physical phenomenon is discussed in the context of pro-people housing and urban policies, empowering the poor and enabling them to develop sustainable, secure, thriving low-income urban settlements.

The study area

The comprehensive study was conducted in Davao City, Philippines, located a thousand kilometres south of Manila. This is the same study area presented in previous papers (Malaque III, 2013; Malaque III et al, 2014; 2015; 2016). Recently, the Philippine population based on the 2015 census was 100.98 million, reported by the Philippine Statistics Authority (PSA). In 2012, the population of Davao City was 1.45 million. It has increased significantly to 1.63 million based on the 2015 census (Philippine Statistics Authority, 2016). Davao City is the only city outside the National Capital Region, also known as Metro Manila, that has a population of more than one million. Housing provision in the low-income sector is one of the major issues in the context of local urban development in Davao City which is populated by impoverished rural immigrants who have settled in precarious informal settlements. While this pattern of mobility repeats trends throughout the developing world, the continued escalation of this pattern prompts the need for this continued scholarship in housing research.

Methodology

The data, identified in previous papers (Malaque III et al, 2014; 2015; 2016), was collected from February to April 2014, in accordance with fieldwork protocols approved by The University of Adelaide Human Research Ethics Committee (January 2014). This same data informs this paper. Access to a total of 74 households in 11 settlements, and the selection of settlements and representative household cases were discussed more thoroughly in a previous paper (Malaque III et al, 2014). In subsequent case analyses, previous papers explored the incremental housing construction (Malaque III et al, 2015), and the evolution of housing (Malaque III et al, 2016), of a representative sub-set of 16 of the 74 household cases. For this purpose of studying the phenomenon of progressive development of urban settlements, the analysis focused on 58 housing cases situated in seven progressive settlements. Contrary to planned settlements, progressive settlements are those which were inhabited by informal settlers who then became recipients of land tenure assistance from the government, or processed negotiation for purchase of their squatter land from the legal land owner, which are assumed to develop continuously over time. Contrary to observing the progressive development of a single urban settlement in a long span of time, from its informal formation towards attaining formal status, the cases presented in this study serve as snapshots of varying housing and settlement status taken at one time in 2014. The progressive development of urban settlements is analysed by counting on the number of housing cases respective to each housing type per settlement. This revealed the status of settlements and their position in the multi-step transition from informal to formal status. Hence, counting and mapping the housing cases respective to different housing types in each settlement, as shown in Figure 1, animates the dynamic progressive development of urban settlements. Finally, the result is discussed in the context of recent developments in housing and urban policies in the Philippines.

Result: the progressive development of urban settlements

The progressive development of urban settlements began with the formation of informal settlements. The settlement sites where 'informal' (Type V) housing is located, are characterised with undeveloped sites which lack basic services. In this study, it is evident in the Arroyo Compound and the Kobbler settlement sites. In the same informal settlements, the 'in-transition informal' (Type IV) housing types are located. With the same physical characteristics, the difference between the two housing types is that the householders of the latter are in the process of organising themselves to initiate improvement of land tenure, thus labelled as 'in-transition informal'.

The organisation of informal householders played an important role in the progressive development of their settlements. Among other requirements, the organisation must be legally accredited by an appropriate agency, such as the Presidential Commission for the Urban Poor, to be eligible for the government programme. In this study, there were two settlement cases which were identified as 'in-transition' (Type IV) housing. These included the Peace Avenue and Green Prairie Homes settlement sites which were beneficiaries of a Land Tenure Assistance Programme (LTAP) implemented by the National Housing Authority (NHA). The former is an example of 'on-site' project implementation while the latter is an example of 'off-site' LTAP project implementations. For the 'on-site' project in Peace Avenue, the progressive development of sites and services is starting to be noticed. The irregularity of the allotments reflects its initial formation as a squatter site. The inhabitants of these settlements recently subscribed to the government programme in 2000, which helped them to gain a small increase in their security. With a long way to pay for the land to own legal titles, at the moment, they are still holding some fear of eviction at any point in time if they fail to continuously pay for the land.

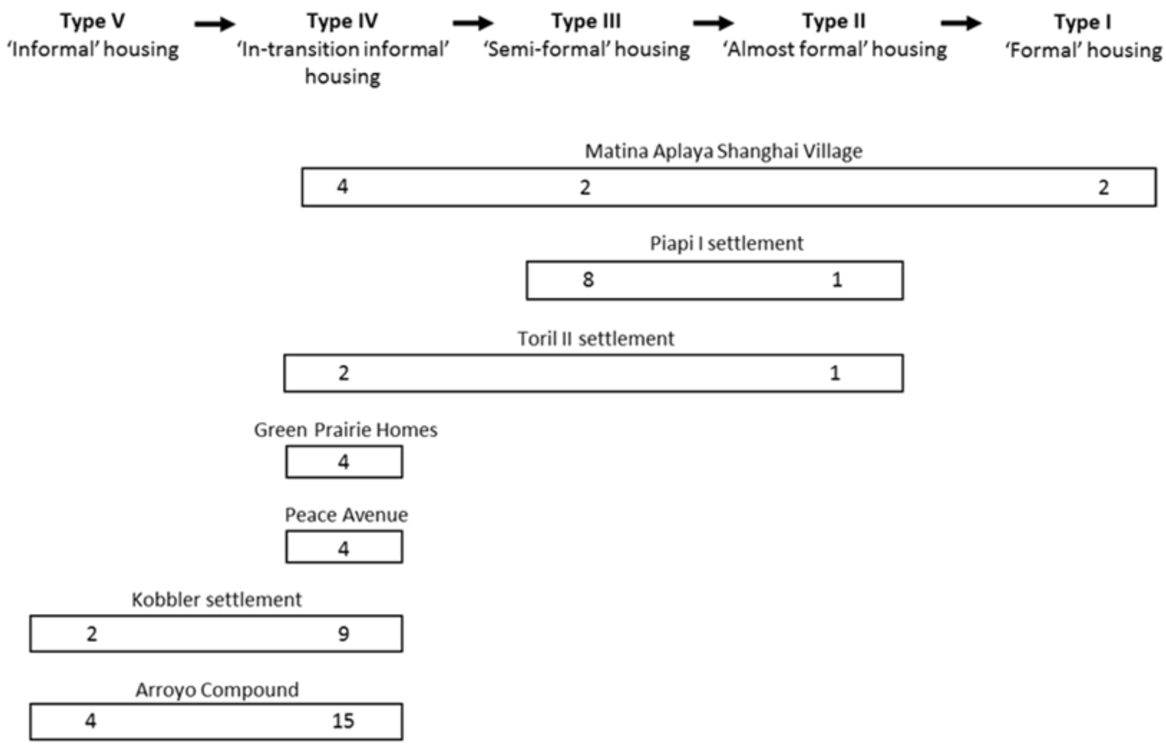

Figure 1. Progressive development of urban settlements.

The urban settlements covered by this study, with inhabitants who had been beneficiaries of government assistance for land tenure, had progressively developed towards a more formal status. For example, the inhabitants of Toril II settlement had been recipients of sites and services implemented by the NHA since 1988. As far as this study is concerned, two out three household cases are in 'in-transition' (Type IV) housing while the other one already progressed to an 'almost formal' (Type II) housing. On the other hand, the Matina Aplaya Shanghai Village, with inhabitants who had been recipients of the Community Mortgage Programme (CMP) since 1993, progressed further with varied housing types from 'in-transition informal' (Type IV) to 'formal' (Type I) as shown in Figure 1. Four out of eight household cases currently occupy 'in-transition informal' (Type IV) housing; two are in 'semi-formal' (Type III) housing; and, two are in 'formal' (Type I) housing. These settlement sites were former squatter areas which progressively developed in-situ, mainly because of government assistance for the formalisation of land tenure. In the case of these two settlements, the government programmes being implemented were the sites and services and the CMP, respectively.

The earlier the implementation of tenure assistance from the government, the greater the urban settlement progressed. For example, in the case of the Piapi I settlement, its inhabitants had been recipients of a slum upgrading programme implemented by the NHA after 1981. Currently, eight out of nine of its household cases examined in this study were classified as 'semi-formal' (Type III) housing as shown in Figure 1. The Piapi I settlement is more advanced compared to the Toril II and the Matina Aplaya Shanghai Village settlements, with beneficiaries of land tenure assistance by the government in the later dates. Most of the household cases in the Toril II and the Matina Aplaya Shanghai Village settlements were in 'in-transition' (Type IV) housing, which were behind in comparison with cases in the Piapi I settlement because their respective government programmes were implemented later, in 1988 and in 1993. With reference to the discussion on 'incremental construction' of urban poor housing (Malaque et al, 2015), the Piapi I settlement is mostly characterised by 'semi-formal' (Type III) housing, and physically appears as a slum with building structures that have become dilapidated over time. This is because the inhabitants are prioritising their investment in the improvement of land tenure rather than the incremental construction of their houses. It was noted that once the inhabitants gained better security, the formalisation of housing structures followed. The ultimate form of tenure security was ownership of the legal land title. However, in some cases, full security was also attained by continuous payments for the purchase of land through stable land tenure assistance programmes such as the CMP. This is the case of the Nacorda and the Rafales households in Matina Aplaya Shanghai Village. Despite the fact, that the beneficiaries were in the process of paying for the purchase of their land, their confidence to pay in full and to own legal titles in due course encouraged them to refurbish their houses in accordance with the national building code. Thus, these households were classified as 'formal' (Type I) housing which marks the end goal of progressive urban settlements characterised by formal status in terms of land tenure and housing construction

Discussion

The progressive development of an urban settlement, in the case of Davao City, Philippines, was first explored in a preliminary case study conducted in the Kobbler settlement (Malaque III, 2013). The case of the Kobbler settlement coincides with the observations by Burgess (1985) that are based on genetic principles, whereby an 'illegal' settlement will eventually transform to become a 'pirate' settlement when homeowners organise themselves to improve their tenure. This means an initial impetus to achieve legal settlement status in due course. Furthermore, the comprehensive study of 74 households in 11 settlements, which was informed by rigorous fieldwork, demonstrated a multi-step transition process in the provision of housing for the urban poor (Malaque et al, 2014). Focusing on housing cases in progressive settlements, subsequent case analyses have demonstrated an incremental construction process of housing units in relation to the degree of tenure security (Malaque et al, 2015); and, an evolution of housing whereby a simple shack eventually evolves to become formal architecture that complies with the building code when legal tenure is achieved (Malaque et al, 2016). This study, focusing on 58 housing cases in seven progressive settlements, demonstrated the complete pattern of progressive development of urban settlements from informal to formal status. These parallel observations are not actually new. For example, based on critique towards 'instant development', Turner (1967) alternatively viewed low-income housing provision in developing countries as 'progressive development'; and, in his critique of a 'one-step regularisation model', Lim (1987) alternatively posited the 'multi-step transition model'. What makes the findings of this study unique is that this current phenomenon, observed in this case of Davao City, emerges in relation to, and enhanced by, specific developments in housing policy in the Philippines, and with the urban poor's proactive response to government intervention.

In the context of a pro-poor urban development and housing policy championed in the Philippines, and the localised implementation of development programmes, the urban poor speculates to live in informal settlements, with the aspiration to own a house and a lot of their own, for which they can attain legal tenure in the course of progressive development. Although informal housing in squatter settlements has long been viewed in a negative sense within traditional paradigms of architecture and urban planning, this study shows it must be viewed, instead, as the most affordable and accessible type of shelter for the urban poor. Importantly, the comprehensive study reveals that informal housing is often the first step in a multi-step transition process which precedes incremental construction, the evolution of permanent housing, and the progressive development of settlements. Thus, this study supports the emerging view towards squatter settlement as 'slum of hope' that needs to be better understood such that more appropriate policies and interventions can be applied in the provision of, or support for, low-income housing.

Conclusion

It is noted that the Philippine government, in its recent housing policy approach, moved away from being a provider to focus on its responsibility as a regulatory body. This recent trend in policy making has widened to be more inclusive of the participation of all agencies in housing provision, most importantly the institutional role of NGOs in empowering communities at a grassroots level. Consequently, in the context of informal urbanisation, the urban poor as key stakeholders and beneficiaries, can be recognised as the main producer of the built environment. Accordingly, with the shift in the role of the government as a regulator, housing provision is now centred on the people who have the capacity to build and to provide their own shelter. These recent policy developments in the Philippines have prioritised the rights of the urban poor and empowered them to build low income housing, enabling them to develop sustainable, secure, thriving urban settlements which are the foundation for a better future. Thus, this explains and relates to the progressive form of urban development. In the twenty-first century when the world's population is becoming urban, Filipino pro-poor policies which place more value on the role of the people in housing provision and the formation of the built environment are much needed, most especially in developing countries which are rich in human resources.

Design to Thrive

A Decade Analysis of Transitioning Residential LEED Communities in the United States

Tarek Rakha[1], Dongmin Shin[1] and Todd W. Moss[2]

[1] School of Architecture, Syracuse University, Syracuse NY, USA

[2] Whitman School of Management, Syracuse University, Syracuse NY, USA

Abstract: Third-party verification and certification processes for low energy built environments have played a critical role in influencing transitioning communities to reduce their emissions footprint in both residential and commercial buildings. One prominent example is the Leadership in Energy and Environmental Design (LEED) certification program, which was conceived by the United States Green Building Council (USGBC). Its residential platform, LEED for Homes, started as a pilot in 2004 and was fully implemented in 2008. This paper attempts to answer the question: what are the characteristics of growing communities for United States LEED residential buildings? The paper examines residential LEED market adoption trends in the United States by analysing a decade-worth of data from 2004 to 2015 (71438 certified units). The study implemented data visualization techniques and statistical analyses to explore predictors of residential LEED community adoption trends. The investigation concluded that market share was associated with educational attainment and number of applied policies, but was not associated with median household income or political orientation (democrat vs. republican). The findings suggest further research is warranted, specifically as related to local practice support from LEED Accredited Professionals as mechanisms of growing transitioning low carbon communities, as well as local level green market incentivization policies.

Keywords: Certification, LEED for Homes, Market Adoption, Policy, Low Carbon Communities

Introduction – LEED for Homes

Minimum standards of construction practice are typically governed through building codes and regulations. However, third-party green building rating systems have played a critical role in influencing communities to transition to lower carbon buildings and neighbourhoods, through possible incentivized recognition (Prum et al, 2009). An example of such rating systems is the Leadership in Energy and Environmental Design (LEED) certification program. LEED was created by the United States Green Building Council (USGBC). The USGBC was founded in 1993, but the LEED program did not start until the early 2000s. Since then, there have been many changes to the certification process, and different categories of certification have been created. The nine main ones are LEED for New Construction, Core & Shell, Schools, Retail, Healthcare, Commercial Interiors, Existing Buildings, Neighbourhood Development, and Homes, the focus of this paper. LEED for Homes started as a pilot in 2004, and was fully implemented in 2008 (Reposa, 2009).

Multiple residential LEED studies were investigated in the literature focusing on case studies (Thomson, 2010), performative aspects (Xiong et al, 2015) and financial analysis (Glossner et al, 2015). However, a gap in the literature exists when investigating comprehensive long-term trends specific to transitioning residential LEED communities.

This paper examines residential LEED market adoption trends in the United States by analysing a decade-worth of data from 2005 to 2014 (71,438 certified units). The study implemented data visualization techniques and statistical analyses to explore the predictors of residential LEED community adoption trends. The paper details the research methodology and analysis procedures, presents findings focused on examined population demographics, implemented green building policies as well as political background, and discusses the findings in the context of potentials, limitations and further research to be pursued. The paper concludes by noting the characteristics of residential LEED communities, and outlines recommendations for relevant transitioning of community practices.

Methodology – Database and Analysis Procedures

In order to examine decade-long trends, a comprehensive database was constructed and analysed using data visualisation techniques and statistical evaluation (Figure 1).

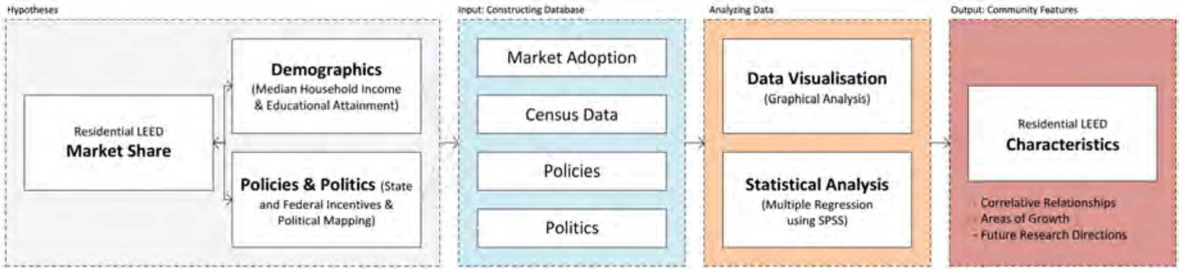

Figure 1. Research Methodology.

Hypotheses

This paper attempts to answer the question: what are the characteristics of growing communities for United States LEED residential buildings? The study was initiated by investigating two hypotheses: we expect to observe a relationship between residential LEED market adoption trends and 1) community demographics, pertaining to household income and levels of education and 2) community policies and politics, focusing on the number of policies that incentivize energy efficiency and adoption of renewable energy, as well as the political orientation of the state. The experiment, therefore, applied the forthcoming analysis techniques to a developed database, with the aim of investigating hypothesized relationships.

Database building

We constructed a database that encompasses the following:

LEED residential market adoption characteristics (2005-2014)
Publically available data for all LEED projects was exported from the USGBC website for all 50 states and Washington D.C. This included project IDs, location, owner, area, registration and certification details. Data was filtered to include only residential building types certified between 2005 and 2014. However, the LEED for Homes certification program started in the year 2008, and residential LEED projects continued under that designation or under a general LEED residential label. Therefore, the database comprised both LEED for Homes and residential LEED projects in that time period (U.S. Green Building Council, 2016).

US census data
The American Fact Finder from the United States Census Bureau website was used to collect all census data for the same time period (US Census Bureau, 2016)., except for the year 2014, where the American Community Survey (ACS) 1-year estimates were used (US Census Bureau,

2014). The database included median household income, population, number of housing units and households, as well as “educational attainment” tabulated for 18 years old and over, where “respondents are classified according to the highest degree or the highest level of school completed. The question included instructions for persons currently enrolled in school to report the level of the previous grade attended or the highest degree received.”

State incentives for renewable and efficiency
The dataset on sustainable technology incentive programs was collected from the Database of State Incentives for Renewables & Efficiency (DSIRE). The website enumerates policies and incentives on both the federal and state level for each state. The sum of policies and incentives was calculated accordingly, and attributed to each state individually (DSIRE, 2016).

Political orientation mapping
A political map was recorded for each state and DC based on the Presidential Election Map from the years 2004, 2008, and 2012. In order to fill the gaps between election years, we assumed that years where no election occurred followed the previous, most recent election map (e.g. 2005 to 2007 followed 2004). The mapping was binary, represented in red states and blue states form, following Republican dominant and Democrat dominant, respectively (Federal Election Commission, 2016).

Analysis techniques

To test the hypotheses using the database, two primary analysis methods were applied:

Data visualisation
A tabulation of the database on Google Sheets enabled in-depth analysis using “Motion” Bubble Charts (Mulrow, 2002). This is an interactive graphical tool that enables five-dimensional investigation charts using the x-axis, y-axis, size and colour of data points, as well as a timeline that animates data for every year, with possible trend trails for each data point across the years. In cases where further examination is needed, we constructed visual representations of data as graphical means of analysis.

Statistical analysis
Multiple regression analysis was applied to the database, where the dependent variable was LEED residential market share in each state. This is calculated as the number of certified LEED residential units divided by number of total residential units. Predictor variables were median household income, educational attainment, total number of policies and political orientation. Regressions reported beta coefficients and significance using the Statistical Package for the Social Science (SPSS) software.

Results – Demographical and Political Trends

The outcomes are predictors that are focused on two topics: community characteristics, as well as their energy efficiency incentivization and political orientation.

Median household income and educational attainment

Multiple regression analysis showed that educational attainment was a significant predictor of LEED residential market share (□= 0.415, $p < 0.001$). Median household income showed a significant but comparably weaker relationship with LEED residential market share (□= □0.085, $p < 0.003$). The motion bubble chart was used to visualise the finding (Figure 2).

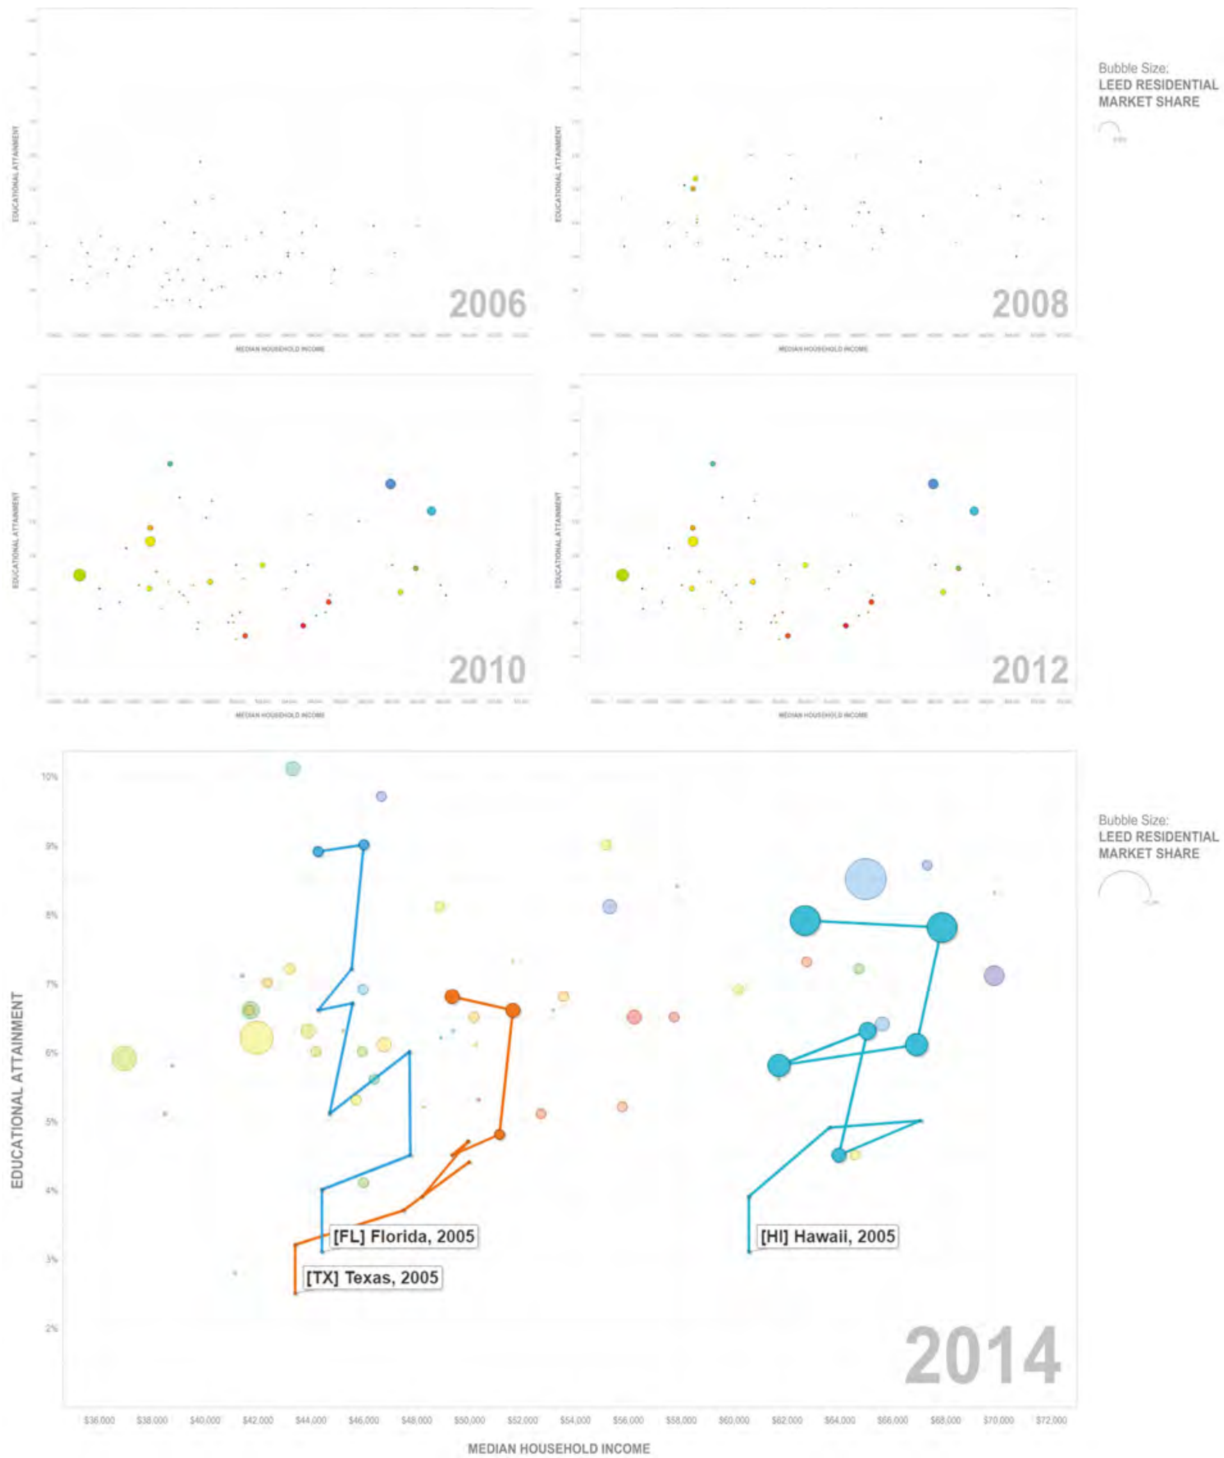

Figure 2. Decade-long motion bubble chart for median household income and educational attainment and LEED residential market share. We observe that data point size increases when moving upwards in time (educational attainment increases). When it moves horizontally (median household income increases), there is little size change. FL, TX, and HI were chosen to demonstrate the trends that correlate with this observation.

Incentivization policies and political orientation

In a multiple regression model including LEED residential market share as the dependent variable, no significant relationships were found when number of incentivization policies (□= -0.112, p< 0.075) and political orientation (□= 0.043, p< 0.015) were the predictor variables. We used graphical analysis as a means of identifying outliers in the data, and we identified cases where number of supporting policies were exaggerated, or cases where the market share was inflated (Figure 3). The bar graph format visualises trends, where gradation becomes significantly darker when number of policies or density of market share is unusually high. When outliers were removed, a test of correlation showed that the number of applied policies were highly correlated, and weaker support was found with political orientation (democrat vs. republican) (Figure 4 and Table 1).

Figure 3. Data visualization of policies/incentives and political map for LEED residential market share.

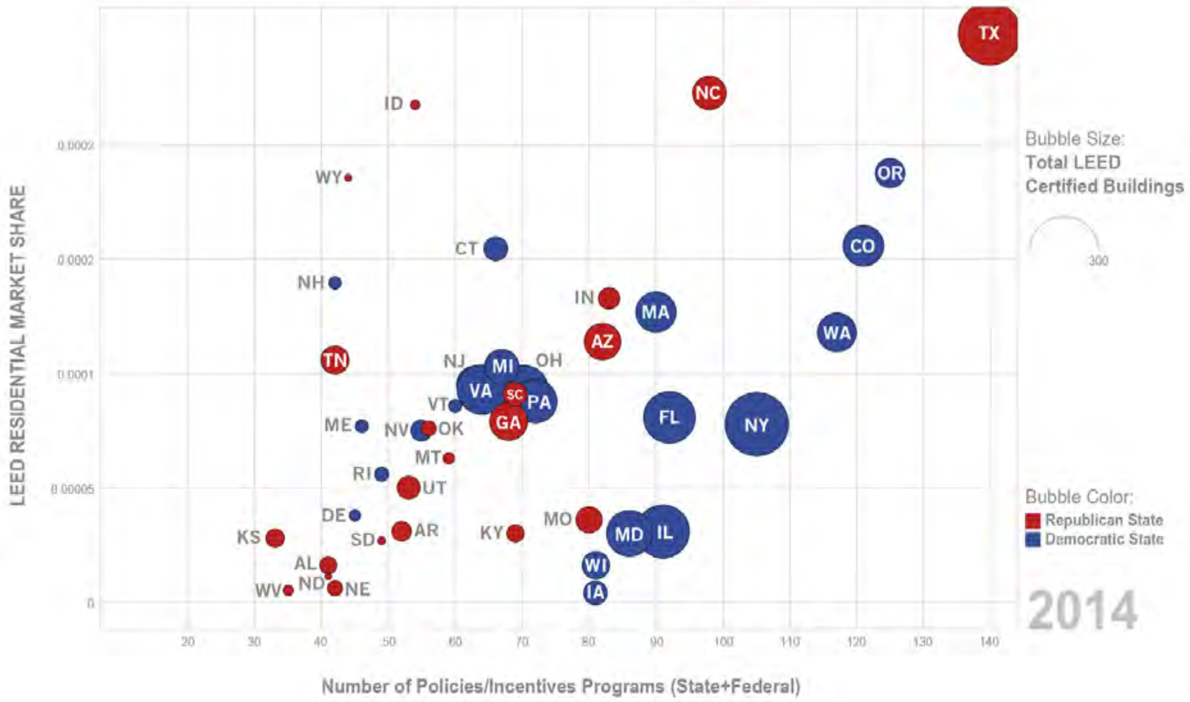

Figure 4. Policies/incentives and political map chart for LEED residential market share without outliers.

Table 1. Multiple regression analysis on policies/incentives and political mapping.

LEED Residential Market Share	Policies and Incentives Programs All States	Policies and Incentives Programs Without 8 Outliers	Political Orientation All States	Political Orientation Without 8 Outliers
□	-0.112	0.353	0.043	-0.076
p	0.074	0.000	0.014	0.022

Discussion – Potentials and Limitations

Third party certification for built environment praxis have the potential of being “carrots” in a world where policies and regulations may be perceived as “sticks” when reducing man-made environmental impacts. It is therefore necessary to understand relationships that aid communities in transitioning using such a positive reinforcement medium. LEED was developed in the United States and continues to grow in that market, and while it has been criticized for energy performance issues and certification level correlations with credits earned (Newsham et al, 2009), it is evident from this decade-worth of data analysis that the market continues to grow. We therefore discuss the potentials and limitations of such growth within the findings from a demographic and policy characteristics perspective.

Demographics

The results of this investigation indicate that median household income had a weaker influence on the adoption of LEED residential buildings in the United States over the past decade. However, level of education was a significant predictor of LEED residential market share, which suggests that number of LEED licenced residences in a community and level of education in that community are highly related. It is possible that lower educational attainment can imply lower income levels, but that is not necessarily a causal relationship (Blanden et al, 2004). Therefore, criticisms of LEED as “being only for the rich” (Cidel, 2009) are not necessarily valid in the case of examining a decade-worth of data. Nevertheless, other economic indicators could be further explored to confirm such inferences. For example, real GDP per Capita can be used as predictors for each state as an additional indicator of standard of living.

Policies and politics

Findings denote a moderately significant relationship between number of policies / incentives on both the federal and state levels with LEED residential market share. Such a directly proportional association suggests that the number of policies that administer green buildings aid transitioning LEED residential communities to proliferate and have their impacts supported through governance. Interestingly, research outcomes propose that being a republican or democratic presidential voting state has a much weaker influence on residential LEED market adoption. This suggests that previous research that specifies that "… political party has a significant effect on LEED concentration …" (Choi et al, 2011) may not be applicable in the case of LEED residential markets specifically. However, we used the presidential elections as the political mapping tool, and other political mapping approaches, such as political orientation of governors, may be used to confirm our findings.

Future research

The study suggests multiple directions for future research using the developed database, or through developing similar workflows. Further elaboration of demographic characteristics linked to LEED residential communities is needed, including multiple economic indicators. Policies investigated were at the federal and state level incentives, so future research can investigate enumerations of local policies as well, to study micro-level administration. Furthermore, special LEED practices that support transitioning communities, such as access to LEED Accredited Professionals (AP), should be incorporated and investigated as a potential defining characteristic of societies evolving towards low carbon practices, verified through third-party certification programs.

Conclusion

The comprehensive examination of LEED residential market adoption trends over time gives insight to the features of such communities in transit. We conclude in this paper that LEED residential market share growth has a stronger associative relationship with educational attainment over median household income, and with the number of federal and state policies over politics or the dominant political orientation of a state. The USGBC and similar third party certification entities which are interested in transitioning residential markets should be targeting states where number of policies supporting green building practices are growing, and where there is evidence of increasing educational attainment. Access to both these characteristics indicates inclination, not certainty, for transitioning through energy efficient and environmentally-aware practices based on historical data analysis. Future research should address limitations in the research method in terms of employing other robust data examination techniques such as clustering and computational complexity analysis, investigating other economic and policy indicators, as well as special features of such communities, such as the ratio of LEED AP per capita.

Financial and Ecological Interest of Cohousing: Impacts of Autopromotion and Mutualization of Spaces and/or Systems

Dorothée Stiernon[1] and Catherine Massart[1]

[1] Architecture et Climat, LOCI, Université Catholique de Louvain, Louvain-la-Neuve, Belgium, dorothee.stiernon@uclouvain.be

Abstract: Rising prices in real estate and demographic evolution make access to the individual property an important issue for many families. This leads to a clear demand for low-cost constructions. In this perspective, the research Opticost - Technical-Economic Optimization of the Construction Costs - led by “Belgian Building Research Institute” aims to suggest alternative solutions. As project partners, “Architecture et Climat” worked on conceptual optimization in order to limit construction costs. This paper focuses on cohousing as an economical and sustainable alternative solution. Cohousing is commonly defined as "a place where several entities live and where self-managed privative and collective spaces are organized" (Definition from “habitat et participation”, a non-profit organization). Cohousing, this very complete model deals with the three pillars of the sustainable development. The research is based on interviews with architects, and an online survey sent to inhabitants of cohousing. Cohousing in general and four case studies in particular are detailed. Research is structured on the following key elements: a) Definitions of cohousing; b) Characteristics of cohousing: collective facilities and spaces; c) Objectives pursued in cohousing projects; d) Pros and Cons encountered in cohousing

Keywords: cohousing, construction costs, sustainable architecture, ecological solution, collective spaces

Introduction

Rising prices in real estate and demographic evolution (in particular: increasing number of family units) make access to the individual property an important issue for many families. This leads to a clear demand for low-cost constructions.

In this perspective, the research Opticost - Technical-Economic Optimization of the Construction Costs - led by “Belgian Building Research Institute” *(www.bbri.be)* aims to suggest alternative solutions according three different perspectives: technical, organizational and conceptual optimizations.

As project partners, “Architecture et Climat” worked on conceptual optimization in order to limit construction costs. We studied:

- Design of the whole project:
    - Multiple constructions: Economies of scale;
    - Contiguity: Economies on the number of facades;
    - Cohousing.
- Sustainable architectural design:
    - Bioclimatic: Compaction - Orientation – Glass surface;
    - Simplicity : Rationalization of the spaces - Similar and repetitive plans;
    - Size: Decrease of private surfaces thanks to the enjoyment of the common spaces.
- Temporal dimension:

- Energy savings;
- Adaptability and flexibility;
- Ease of maintenance.

Cohousing could be a strategy to reduce construction costs. This hypothesis has been the starting point of a research on cohousing.

Research is structured on the following key elements:

- Definitions of cohousing
- Characteristics of cohousing: collective facilities and spaces
- Objectives pursued in cohousing projects
- Pros and Cons encountered in cohousing

Methodology

To answer this issue, four Belgian cohousing projects were studied in detail:

- Biplan, in Brussels: 6 passive apartments
- Bois del Terre, in Ottignies: 6 energy-efficient houses and 1 shared home
- Brutopia, in Brussels: 27 passive apartments and 2 apartments very low energy
- Pic au Vent, in Tournai: 20 passive patio houses, 14 garden-houses with positive energy and 8 balcony-houses with positive energy

They were chosen according to:

- the availability of information: website, documentations, contact with architects
- their situation: 2 in a rural and 2 in an urban context;
- type of promotion: 2 projects in self-promotion with local input since the beginning; of the process and 2 projects where the architects are sponsors and look for buyers when the construction is ended.

Data have been collected from interviews with the architects of these projects, and from an online survey sent to the inhabitants of cohousing dating less than 10 years. The questionnaire of fifteen questions was realized via the site “SurveyMonkey”. Unfortunately, although the sending was relatively wide (public listing of cohousing, knowledge and addresses available on cohousing blogs), we only had only 18 answers.

After that these case studies are detailed in particular, an attempt is made to highlight possibilities and specificities related to cohousing.

Results

It is difficult to give a good definition of cohousing because its characteristics are multiple and often personal. Here are a few examples from interviews:

- “A life plan - A human adventure - A single place for several dreams - The support for an ecological and collective project;
- A tool to live better - The creation of a village in the city - A lifestyle together in the city, harmoniously and close to the other;
- A catalyst for a more intense and more just social life - A vector of self-fulfillment - A privileged place where the life of each is respected, maintaining a high degree of intimacy;
- A sharing of time, tasks, bad adventures and success - Meetings, intergenerational relations and common values;
- A laboratory, a compost of experiments - A beautiful experience of life where we learn every day - Another way to live - The future. "

Some people consider that inhabitants live real cohousing experience only if their commitment to the project takes place from the very beginning. However, from case studies analyzed in the research, even in case of project realized by architects or real estate developers, from the time occupants live in the building, they quickly feel like being part of a real cohousing project.

The most used definition of cohousing in Belgium is "a place where several entities live and where self-managed privative and collective spaces are organized" (Definition from “habitat et participation”, a non-profit organization - www.habitat-participation.be).
Indeed, many collective facilities and spaces might be integrated in a cohousing (Figure1).

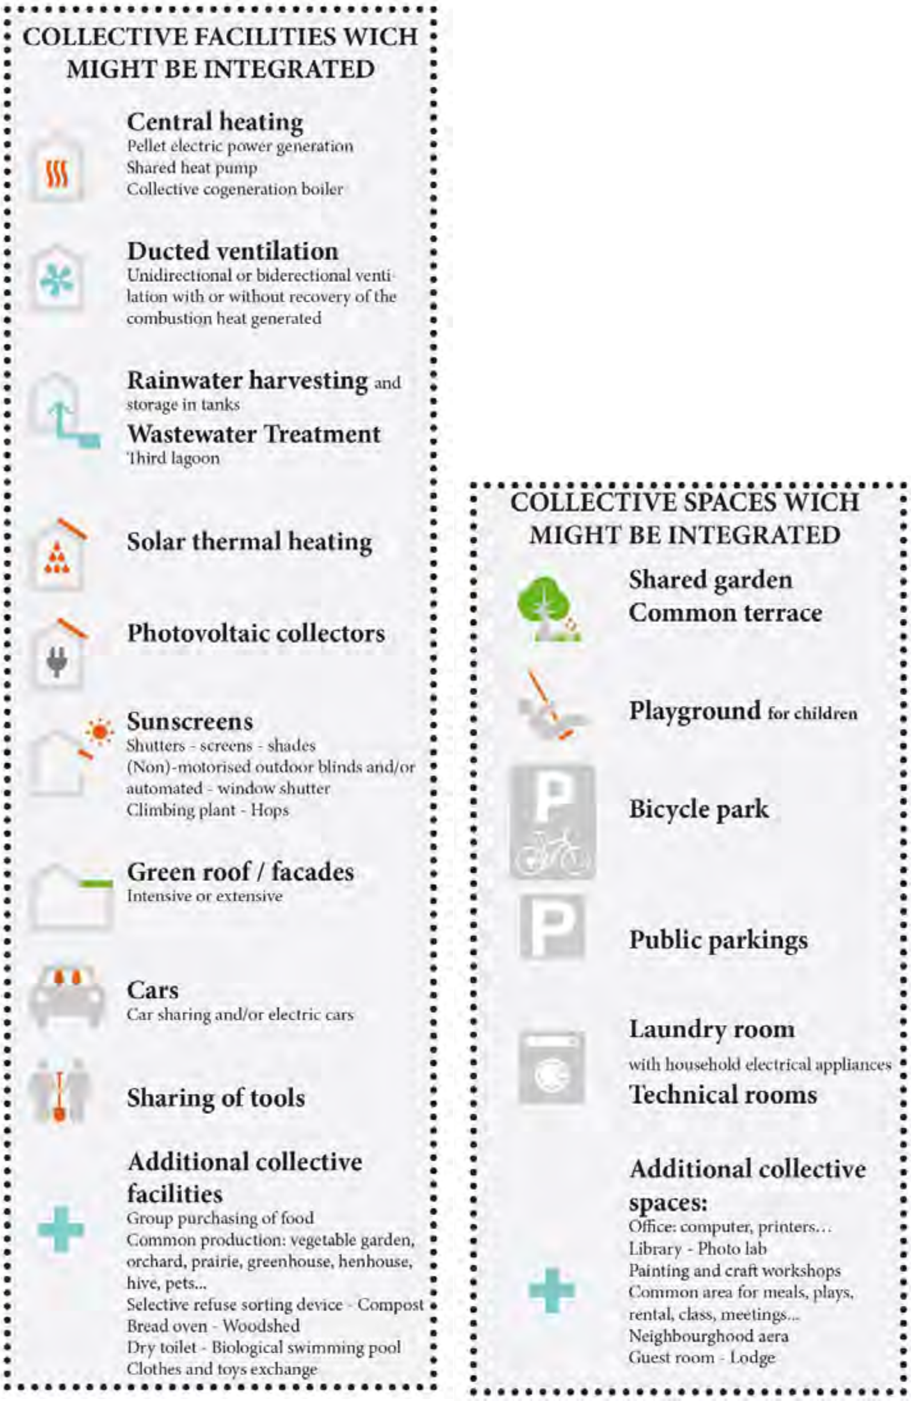

Figure 1. Examples of collective facilities and spaces, which might be integrated into a cohousing

Cohousing is more than a place to live. Cohousing is a way to develop a construction project but also a living mode. Analyze of case studies showed that many objectives were achieved, answering multiple challenges of sustainable development.

- Environmental objectives: reduction of environmental impacts of housing
    - Achieve high energy performance (reduce consumption and produce renewable energy);
    - Reduce greenhouse gas emissions;
    - Enhance biodiversity;
    - Reduce impacts on the water cycle.
- Social objectives
    - Create a community, sometimes to answer specific situation (support of single parents, intergenerational housing as a solution for old people…);
    - Collective commitment for a social or cultural project (support of precarious people, artistic project, religious community, vegetable gardening…).
- Economic objectives:
    - Answer to the housing crisis: way to reduce costs and access other categories of field / buildings to buy;
    - Cohousing ease action to fight against individualism and short term profit dictatorship.

According to case studies, interviews, definitions and context, cohousing cannot be considered only for its economical features. Those very complete models deal with the three pillars of the sustainable development: environmental, social and economic.

The following tables (Figures 3-5-7-9) show Pros and Cons encountered in cohousing for economic, social, architectural and environmental aspects. Extracts from interviews and literature have been added to illustrate the topics with numbers or facts from the field.

Pros - Economic	**Cons - Economic**
Organization and management: - Participation in a common project; - Self-promotion	Organization and management: - Time and energy consuming project for the inhabitants.
« Generally, you can save 20% on overall costs with self-promotion. » (DELLESKE A., architect, Freiburg - Germany, 2011)	
Design of the whole project: - A single team of architects and/or only one planning permission for the whole housing project; - Multiple constructions - Contiguity	Setting a longer timescale: - Slowness on administrative processes; - Very long set up the process. Problem for new constructions: - Important common investment before each entity has its own part.
Sustainable architectural design: - Bioclimatic - Simplicity - Size	Sustainable architecture: - Costs of the construction higher than for a traditional project.
« Apartments can be smaller thanks to the common spaces and to a rationalization of	*« (…) The diversity of housing pulls a largest number of architectural specificities (…). The*

<table>
<tr><td>the plans, for an economy from 10 to 20 %, according to the experience feedback. » (PARASOTE, 2011)</td><td>additional costs for this freedom of design can be estimated at 5 % of the total cost. » (PARASOTE, 2011)</td></tr>
<tr><td colspan="2">« A factor of economy is in the rationalization of space by an intelligent spatial design to limit corridors and by limitation of private space by mutualizing the common spaces. For example, a washing machine occupies approximately 0,80 m² on the ground, that is (for an average price of EUR 2.000 including taxes) EUR 1.400 including taxes of construction costs! The mutualization in a laundry allows to save space and money. It is the same for the guest room (…). We consider approximately 10% space savings. » (PARASOTE, 2011)</td></tr>
<tr><td>Renewable energy: Investment divided among the inhabitants – Power saving.</td><td rowspan="3">

Stekke + Fraas Office</td></tr>
<tr><td>«A house has a dry toilet which offers 35 % water savings and composting."» (COUPEZ J., architect, about cohousing “Bois del Terre”, 2016)</td></tr>
<tr><td>Construction :
- Only one contractor for the whole project;
- Possibility for self-construction;
- Multiple constructions: Economy of scale;
- Same and local materials: Savings due to bulk and local purchase;
Fixed costs shared between all inhabitants in proportion to surfaces.</td></tr>
<tr><td rowspan="2">Collective facilities and spaces:
- Improving homeownership affordability;
- Bigger surface area in collective buying than in private;
- 100% enjoyment of facilities and additional surfaces but only a part of the costs;
- Decrease of the private surfaces, the main characteristic of cohousing.
Fixed costs shared between all inhabitants in proportion to surfaces.</td><td>Collective facilities and spaces:
- Initial investment not to be neglected.</td></tr>
<tr><td>« Common spaces have a price which you should not neglect, but in my case I pay only 50 thousandth and I benefit from 1000 thousandth of use. » (A resident of cohousing “L’Echappée”, 2016)</td></tr>
<tr><td>Exchange of services:
- Daily group purchases;
- Common Production: kitchen gardens - Orchards – Henhouses;</td><td></td></tr>
</table>

- Household chores and works; Children’s care - Assistance to older people.	

Figure 3. Economic Pros and Cons

Pros - Social	**Cons - Social**
Sharing: - Participation to the common project - Investment according to our interests and skills; - Mixing of rooms and buildings functions; - Collective facilities and spaces which are places of meetings and intergenerational exchanges; - Household chores and works; - Children’s care - Assistance to older people.	Organization and management: - Time and energy consuming project for the inhabitants: too long process for some families who have to give up the project for financial or organizational reasons - Loss of energy and enthusiasm for some inhabitants because of the slowness of the steps; - Difficulty in making discover this concept to professionals: Entrepreneurs - Solicitors - Bankers; - Big management of information, meetings and decision-making; - Definition of the Internal Rules to make it easier to live together, to protect the intimacy and to organize the use and the maintenance of collective facilities and spaces.

Figure 4. Guest rooms of cohousing “Pic au Vent” 36°8 Office

Relationship: - Social mix and age diversity - Meetings - Extension of the social networks; - Human and intergenerational relationship - Participation of all the generations in the process -	Relationship: - Social mix limited by a relatively homogeneous level of income bound to the intrinsic cost of the project;

Decrease of the individualism and the solitude; - Equality - Solidarity - Consensus - Feeling of membership; - Confidence - Collective dynamics - Effect of mass.	- Difficulty of integration and living together while protecting its values and his personal projects; - Required to accept the differences and the complementarities; - Difficulty to find consensus, to satisfy everybody and to adapt itself to the evolution of needs and objectives of everyone.

Figure 5. Social Pros and Cons

Pros - Architectural	**Cons - Architectural**
Individual, collective and transition spaces: - Collective spaces which allow to enjoy additional surfaces; - Joints of private and common spaces to favor the meetings and to protect the intimacy; - Evolutionary and flexible private spaces to everyone can appropriate the personal space and to adapt it to the evolution of the family unit.	Architectural options: - Non-priority aesthetic; - Need of soundproofing between housing.  Figure 6. Square of cohousing « Bois del Terre » Coupez Office
Conceptual optimizations: Cohousing offers an ideal context for the conceptual optimizations (multiple constructions; common ownership; bioclimatic architecture; simplicity of volumes; adjusted surfaces).	

Figure 7. Architectural Pros and Cons

Pros - Environmental	
Cohousing are often a perfect opportunity to build more durably : - Sustainable energies (reduction of the energy impact; decrease of CO_2 emissions) - Local materials.	
Optimization of the housing stock: - Reduction of grey energy thanks to the density of built;	

- Collective facilities and spaces - Pressure strategies to improve public transport of the sector: bike paths - shared bikes - shared cars.	 Figure 8. Orangery of cohousing « Biplan » BxlECO Office

Figure 9. Environmental Pros and Cons

Conclusions

Economical approach was the starting point of the research project. Cohousing case studies quickly appeared to be difficult to compare with individual housing from many aspects linked to the process and related life mode.

Anyway, it seems also clear that none of the case studies analyzed could strictly be considered as a low cost solution. Costs are not low but there are lower than costs of a traditional individual housing with similar performance, equipment and available space.

Cohousing characteristics always depend on choices of developers and occupants and reducing the costs is only one of many objectives pursued in the projects that have been studied.

As a conclusion, cohousing can be considered as a way of developing housing projects and living mode that permits to achieve a high quality of life and to answer challenges of sustainable development with relatively low extra-costs.

Many cohousing projects are currently being developed in Belgium and work could be done to ease the process and give support to developers to encourage this type of housing solution for its social economic and environmental advantages.

Factors motivating bicycling in Sydney: Analysing crowd-sourced data

Parisa Izadpanahi[1], Simone Z. Leao[2], Scott N. Lieske[3] and Chris J. Pettit[2]

Abstract: Devising smarter strategic plans for more efficient modes of transport is fast becoming a priority for city planners and transport agencies. Having Sydney, Australia as case study, we analysed 6,932 GPS tracked cycling routes acquired from the RiderLog smart phone application to better understand interactions between bicyclists and the urban environment that encourage bicycling behaviour. Our approach used regression methods to identify a set of variables that can best predict the distance that cyclists ride. Gender, distance of the cycling track along parks and coastal areas, distance of the cycling track along commercial areas, percentage of the slope of the cycling track, and percentage of the type of cycling infrastructure (separate, shared, mixed, and no cycling lane) were considered as the potential predictor variables. Results indicate that although most of these variables could significantly predict the distance that cyclists ride, the distance of the cycling paths along parks and coastal areas and along commercial areas had the greatest contribution to the total R square. The findings of this paper provide important metrics which can inform city planners on how to improve attributes of the urban environment associated with bicycle tracks to motivate cyclists to ride longer distances.

Keywords: Bicycling behaviour, environmental attributes, crowd-sourced data, infrastructure, and facilities

Introduction & Background

There is a developing consensus around the effectiveness of bicycling to address the ills of the early twenty-first century cities. Public health crises, such as chronic disease associated with physical inactivity) (Pratt et al. 2014), environmental concerns (transition to less carbon intensive cities) (Haines and Wilkinson 2014) and costly infrastructure expansion are leading to a global shift toward more sustainable transportation, including bicycling (Bertolini et al., 2008, Hood et al., 2011).

Bicycling offers both personal health benefits as well as broader environmental benefits. Benefits to health result from decreased air pollution and increased physical activity. Research has shown the built environment can be significantly correlated with the physical activity behaviours of city residents (Saelens et al., 2003, Giles-Corti et al., 2011). Environmental benefits results from mitigation of the negative externalities of traditional fossil fuel heavy transportation systems including decreases in air pollution, greenhouse gas emissions as well as reductions in traffic accidents, congestion and noise (Bertolini et al., 2008, Sener et al., 2009, de Hartog et al., 2010).

At the same time as this developing interest in bicycle transportation, there is an increasing interest from city planners and policy makers in evidenced based research in active transportation (Pettit et al., 2016). Understanding the flows of people moving through the built environment is a vital source of information for the planners and policy makers who shape our cities (Pettit et al., 2016). However, information about bicyclist preferences, infrastructure and policies that may encourage bicycling and the effectiveness of bicycling infrastructure investment are limited (Pucher et al., 2010, Hood et al., 2011, Broach et al. 2012). Agencies seeking to improve bicycling infrastructure, safety, and mode share may be done through collection of data on bicycling routes, route attributes, and rider demographic information (Hudson et al., 2012).

There is an emerging body of literature presenting the results of investigations of bicycling infrastructure on bicycling levels and cyclist route choice. Dill et al. (2009) observe that bicyclists are "probably" (p. S104) going out of their way to take advantage of bicycling infrastructure. Hood et al. (2011) found preferences for bike lanes, especially for inexperienced riders. Broach et al. (2012) found cyclists value off-street paths and side streets with traffic calming but bike commuters are more sensitive to distance and less sensitive to infrastructure. Similarly, Aultman-Hall (1997) found high quality off road paths are used infrequently by bike commuters. However, Krenn et al. (2014) found cyclists prefer bicycle lanes and bike paths over the shortest possible routes. They also found bicyclists select routes with green infrastructure (including sporting fields) as well as water and aquatic areas. Wendel-Vos et al. (2004). also reported that the time spent on bicycling was associated with green and recreational space such as sport grounds and arks Sener et al. (2009) found traffic signals, stop signs, street crossings, speed limits, on street parking and continuity of bicycle lanes to be important in route choice.

The literature puts forward a number of a factors beyond bicycling infrastructure that influence bicycling activity. Bicyclists seek to minimize route distance (Dill 2009, Hood et al., 2011) Broach et al. 2012). Dill et al. (2009) found cyclists avoid high traffic streets. Krenn et al. (2014) found residential density and commercial areas to be higher along the shortest possible cycling routes suggesting bicyclists are avoiding these areas on longer rides. In contrast, Winters et al. (2010) report a positive correlation between the presence of more commercial land use and increased bicycling behaviour. Proximity to commercial areas may indicate the desirability of passing through such areas, potential positive or negative impacts of vehicular parking on bicycling in these areas (for example, hazards associated with bicycling past parallel parked vehicle) and/ or the influence of the often-reduced speed limits in these areas.

Sener et al. (2009) found travel time (for bicycle commuters) and motorized traffic volume are the most important elements of route choice. However, Hood et al. (2011) found traffic (both volume and speed) not to impact bicyclist preferences. Bicyclists are consistently found to avoid steep slopes (Aultman-Hall et al., 1997, Sener et al., 2009, Menghini et al., 2010, Krenn et al., 2014) Broach et al. 2012, , especially female cyclists and for commuting (Hood et al., 2011). Specific to Sydney, Ellison and Greaves (2011) note the relevance of slope including the possibility that the hilly terrain of Sydney may contribute to the low cycling mode share. As reported in Krenn et al. (2014), Titze et al. (2010) found high quality neighbourhoods with numerous trees positively influence cycling.

Sener et al. (2009) and Broach et al. (2012) highlight the potential importance of individual characteristics on route choice and infrastructure preferences. Sener et al. (2009) include age, gender, employment, cycling experience, and reason for trip in their analysis.

Broach et al. (2012) found studies indicating experienced cyclists prefer lanes to separate paths or simply hold no preference for bike lanes. They also found evidence women and less-experience cyclists prefer separate infrastructure, less traffic and lower speeds.

Dill (2009) and Pucher et al. (2010) specify data and methods limitations in cycling research that may impact our understanding of links between cycling levels and infrastructure. These include the inherent limitations of stated preference studies, small sample sizes in revealed preference studies, as well as lack of route and infrastructure information in large sample studies. Taking advantage of new technology to confront these methodological issues, there is an emerging bodies of studies noting the opportunities provided by smartphones for the collection of bicycling travel data (Hood et al., 2011, Hudson et al., 2012). When combined in a crowd scale, mobile phone data may have the capacity to reveal macro behavioural patterns (Pettit et al., 2016) including infrastructure preferences. Some mobile phone applications currently available for bicycling include BikeNet, Biketastic, SocialCycle, MapMyRide, iBike, Cycle Meter, Strava, and RiderLog.

Methodology

This study investigates contextual factors that contribute to cycling by encouraging people to ride longer distances, considering that longer cycling journeys promote physical activity to an intensity that according to the World Health Organisation lead to significant health improvement (WHO 2002). This understanding can be used to plan and implement healthier urban design solutions. RiderLog provides information on the cyclists and their journeys, but not about the context or environment where these journeys occur. Therefore, we integrate contextual information including: (i) slope, (ii) cycling infrastructure, (iii) proximity to parks and coast and (iv) proximity of commercial centres to the cycling routes. When integrated into a matrix, this information can be analysed through statistical methods to investigate their interdependencies.

Study Area Description

This section provides visualisations and brief descriptions of the characteristics of the study area in relation to the input data. Figure 1a shows the itineraries performed by voluntary bicyclists and recorded by the RiderLog mobile app from 2010 to 2014. It indicates a wide geographic distribution with a concentration of trips in the central area of Sydney. A dynamic visualisation of the cycling movement in a typical day in Greater Sydney based on RiderLog data used in this study can be found at https://cityfutures.be.unsw.edu.au/cityviz/cycling-sydney/. The overall distribution has an average of 9Km/journey, with 1/3 of the journeys between 7 to 9 km, and 2/3 of the journeys below or above that mark, roughly equally divided. This wide distribution provides a good case study to examine differences affecting cycling trips with varied distances. Figures 1b and 1c present the spatial distribution of urban characteristics analysed in this study as contextual factors affecting bicycling. It is hypothesised that these factors have an influence on how people cycle across the city in terms of their route selection and overall riding distance.

Figure 1b shows parks and commercial centres overlaid to the topography. Sydney has a varied topography and the high slope in some areas may affect cycling. In general, slopes up to 2% are considered the best for cyclists of any age or fitness level; slopes between 2-5% are still considered appropriate; slopes between 5 to 10% may not be appropriate for children, elderly, or people with limited fitness; slopes above 10% should be avoided, but they can be cycled for very short distances. Overall, the RiderLog routes are performed in areas with gentle slopes appropriate for cycling (63% are below or equal to 5%); however, the topography of the city seem to impose some proportion of cycling at higher slopes. Sydney also has a good distribution of parks. 32% of the distances ridden in all journeys were along parks; indeed only 1% of the journeys did not crossed any park, and 92% of the journeys had at least 10% of the ridden distance along a park. An analogous situation was found for commercial areas; 22% of the distances ridden in all journeys were along commercial centres; only 3% of the journeys did not crossed any commercial area, and 77% of the journeys had at least 10% of the ridden distance along a commercial area. Figure 1c shows cycling infrastructure overlaid on the road network. It is possible to see the concentration of infrastructure in the central area of Sydney and along few major roads, and also some lack of connectivity in the existing infrastructure. A visual comparison between Figure 1a and 1c seems to indicate that cyclists prefer routes with cycling infrastructure. Indeed, the proportional share of the distance of all RiderLog routes indicate that 64% of the distance ridden is along some sort of separated or shared lanes; and 36% mixed with traffic.

Figure 1. Cycling and contextual factors data in Greater Sydney from 2010 to 2014

Data Integration

A series of spatial analyses in ArcGIS were performed to integrate cycling patterns and geographic characteristics into a database suitable for statistical investigations of influence and interdependencies. Table 1 describes the spatial analyses derived from related data inputs.

The result of the spatial analysis applied to the geographic input layers is a large table integrating all the required data for statistical analysis. Each row of the table describes one cycling route (route id), while each column qualifies the route in terms of varied characteristics of the cyclists (rider id, gender, age), of the cycling journey (distance, and duration), and of the context/environment (slope, proximity to parks, proximity to commercial centres, cycling infrastructure).

Table 1. Spatial analysis for data integration

Goal	Spatial analysis	Output (New Table Fields)
Slope on cycling routes	Production of a slope map in % based on contours (raster, 50m); Classification of slope into 4 classes related to difficulty to cycle: 0-2%, 2-5%, 5-10%, >10%; Convert slope class raster map into vector; Intersect cycling routes to vector slope class map; Calculate distance and % of the route into 4 slope classes.	Route distance 0-2%; Route distance 2-5%; Route distance 5-10%; Route distance >10%; % route 0-2%; % route 2-5%; % route 5-10%; % route >10%
Proximity to parks on cycling routes*	Create a buffer of 10 meters around parks; Intersect cycling routes to park buffer map; Calculate distance and % of the route along parks.	Route distance close to parks; % route close to parks
Proximity to commercial centres on cycling routes*	Create a buffer of 10 meters around commercial centres; Intersect cycling routes to commercial centres buffer map; Calculate distance and % of the route along commercial centres.	Route distance close to commercial centres; % route close to commercial centres
Type of cycling infrastructure on cycling routes*	Classify cycling infrastructure into 4 classes according to safety for cycling: 1; Create a buffer of 25 meters around cycling infrastructure; Intersect cycling routes to cycling infrastructure buffer map; Calculate distance and % of the route along cycling infrastructures.	Route distance Infra 1; Route distance Infra 2; Route distance Infra 3; Route distance Infra 4; % route Infra 1; % route Infra 2; % route Infra 3; % route Infra 4

**RiderLog is subject to GPS imprecision, such as less or lost signal in urban canyons or GPS drift when rider is stationary. These imprecisions cause cycling routes to be 'around' roads, instead of perfectly aligned with them. Therefore, buffers around target areas (commercial centres and parks), were used in order to capture the majority or all the cycling routes in close proximity. For the same reason, topography was characterised as an average % slope within a cell with 50 metres spatial resolution.*

Regression Analysis

Multiple regression analysis was conducted using the SPSS Statistical; software package to identify a set of variables that can predict the distance cyclists ride. This analysis also indicated the relative contribution of each identified variable in predicting the total distance ridden. Multiple regression indicated how much of the variance in distance ridden is explained by gender, the distance in meters of the track along parks and coastal areas, the distance in meters of the track along commercial areas, percentage of the slope of the cycling track, and percentage of the type of cycling lane (separate, shared, mixed, and no lane).

Identifying outliers:

The initial attempt at assessing the normality of the distribution of data for both independent and dependent variables showed the data were not normally distributed. Therefore, outliers were identified through calculating z-scores (standardised residual) for all the variables. Through this process, 259 samples were deleted, because they had z-scores above the cut-off value of 3.29. The outliers were scrutinised for better understanding of the attributes they carry. It was identified that a large part of the outliers were related to highly-fit cyclists performing very long distance rides. Although they represent a genuine part of the data, they are a minority that skew the distribution. It was a decision of the authors to delete these records from the overall data of analysis. This decision was justified on two grounds: first, the study will at this stage focus on the majority of ordinary cyclists; and second, by turning the distribution into normal, more robust statistical analysis is possible. After this deletion, a histogram of the data was checked and the outcome corroborated that the distribution became normal.

Multiple regression was run to predict the total distance of the track ridden by the cyclists as recorded by RiderLog (Route_Distance). Gender and some environmental attributes such as the distance of the track along parks and coastal areas (DistParks), distance of the track along commercial areas (DistComm), percentage of the slope of the track (slope <=2%, slope >2 and <= 5%, and slope > 10%), and percentage of the type of cycling lane were considered as the potential predictors of the distance ridden. Preliminary analysis were conducted to ensure no violation of the assumptions of normality, linearity, multicollinearity, and homoscedasticity.

Results indicated that 69% of the variance in Route_Distance is explained by the model, F (9, 6663) = 1657.697, p<.0005, adj. R2=.69. All the variables except percentage of the overall track with shared cycling lane added statistically significantly to the prediction, p < .05. Regression coefficients and standard errors can be found in Table 2. DistParks made the strongest unique contribution when the variance explained by all other variables in the model was controlled for (β =.525). The second strongest independent variable in terms of the power of prediction was DistComm (β = .343), the third was percentage of the overall track with slope > 10% (β =.076), and the forth was percentage of the overall track with mixed traffic lanes (β =.227). The rest of the predictors, although significant, had a minor power in predicting the distance ridden.

Semi-partial correlation coefficients (Part-correlation) indicated that DistParks, DistComm, percentage of the overall track with slope > 10%, and percentage of the overall track with mixed traffic lanes respectively contributed 22%, 10%, 4.7% and 2.8% to the total R2. Regression coefficients and standard errors can be found in the following table.

Table 2. Summary of multiple regression analysis – Dependent variable: Route_Distance

Predictor Variable	**B**	**SE_B**	β	**Part-Correlation**
Intercept	245.896	243.338		
Gender	298.284	74.855	.028	.027
Distance to commercial areas (DistComm)	1.040	.022	.343	.318
Distance to Parks and coastal areas (DistParks)	1.253	.018	.525	.470
% of the overall track with slope <= 2%	3551.991	200.030	.150	.121
% of the overall track with slope >2 and <= 5%	-669.270	333.528	-.021	-.014
% of the overall track with slope > 10%	12469.117	504.025	.258	.219
% of the overall track with mixed traffic lanes	5822.758	180.877	.227	.168
% of the overall track with no cycling infrastructure	-1129.253	225.874	-.035	-.034

*Note: * p < .05; B= unstandardized regression coefficient; SE_B= standard error of the coefficient; β =standardized coefficient*

Discussion and Conclusion

This research considers several features as part of the built environment. Results suggest that to encourage cyclists to ride longer distances, some strategies work better than others. The findings of this paper suggest that proximity of cycling tracks to parks and coastal areas, and proximity of cycling tracks to commercial areas are the two most powerful predictors of the distance bicyclists ride based on the contextual factors examined. This finding is also supported by many studies conducted in different geographical contexts. In one such study conducted in Odense, Denmark, a positive correlation between the presence of cycling routs, and bike racks in urban green spaces and the increased level of physical activities was found (Schipperijn et al., 2012). This outcome is particularly important in planning of the new cycling tracks in cities, such as Sydney that has considerable area of coastal lands and parks.

Distance of the track along the commercial areas was the second most powerful variable in predicting the distances that bicyclists ride. Rider preference for commercial areas may be due to favourable infrastructure (e.g. dedicated cycle infrastructure), lower driving speeds in commercial areas as well as the desirability of commercial areas as destinations or stops along bicycling journeys. Moreover, safety of the cycle tracks is one of the determinants of bicycling behaviour which is strengthened where the tracks are along commercial areas, shops, retails, and small businesses.

Slope, or what has been reported as hilliness, has been shown as one of the determinants in cycling behaviour in literature (Parkin et al., 2008). Since Sydney has a hilly terrain, slope has been considered as one of the potential predictors of the distance ridden. This study result indicated that slope of the track can significantly predict the distance that bicyclists ride. Percentage of the tracks with more than 10% slope were the most powerful determinants and the tracks with less slope had considerably less predictive power, although statistically significant. As such, this study suggests that to encourage people to cycle longer distances, it is important to design cycling tracks with less than 10% slope.

The presence of bicycle paths and lanes is frequently associated with increased bicycle commuting (Reynolds et al., 2009). As such, the type of cycling lane was also taken into consideration in this study. Three variables of Percentage of the Overall Track with Shared Cycling Lane, Percentage of the Overall Track with Mixed Traffic Lane, and Percentage of the Overall Track with No Cycling Infrastructure were entered into the multiple regression model to evaluate their predictive power. The result of the analysis suggested that all types of lanes except the Shared Cycling Lane could significantly predict the length of the ride. According to this outcome, as long as cyclists have a path, whether it is designed only for bicycles or it is a shared path (Shared with pedestrians), the type of the path does not have a significant power in predicting the length of their ride. However, having a track with no cycling infrastructure, or with mixed traffic lane (mixed with cars) will significantly and negatively correlate with the length of the ride. Higher percentages of the track with mixed or no traffic lanes will discourage people for riding longer distances.

The analysis presented here suggests there is substantial evidence that environmental variables are consistently associated with bicycling behaviour. The authors would also like to highlight opportunities for further investigation and methodological improvements. This study has combined GIS recorded data with the Riderlog recorded data. Therefore, some of the trips could be slightly different from the ones that actually took place. Acknowledging this limitation and other limitations mentioned earlier in the paper, it is worth to mention that the simulated bicycle routes in this study are the most possible accurate representation of the journeys taken place, and is much more fine grained than traditional methods which rely on set point traffic counts or participant surveys. Further research needs to be conducted to confirm the cross-contextual validity and reliability of the result. Furthermore, there are several nuanced measures, such as weather condition which has not been included in this study and needs to be addressed in future. Despite certain limitations, this research has implications for city planning to facilitate a more active life style for citizens, and identifies promising directions for future studies.

Abstract: Given their reliance on emissions-heavy air transport and shipping transport, package delivery companies are challenged to reduce their carbon footprints. UPS-type hydraulic hybrid ground fleets can be greener by optimizing energy use in these low-emission vehicles, since stopping, and starting is key to saving fuel in these types of vehicles. With a residence time of only 78 days in the troposphere after combustion, more economical ethane (C_2H_6) can be a greener bridge in the transportation sector. Ethane can act as an alternative fuel stock to expand this vehicle truck option, provide an oil saving solution, and reduce global warming emissions without drivers changing their driving habits. This is the best use of ethane adding the highest value using the simplest technology. In 2015, an ethane bi-fuel field trial was conducted in Jewett, Texas, USA using a modified fuel injection system in a Ford F150 4.6L Triton pickup truck. Emissions results returned 2 ppm particulate matter, 0.00% Carbon Monoxide (CO), 0.01% Carbon Dioxide (CO_2), and 20.79% Oxygen. Performance results returned torque slightly better than gasoline, and fuel injection time slightly slower than gasoline, providing better combustion. A higher, 9% increase in miles/GGE (gasoline gallon equivalent) efficiency versus gasoline was produced, resulting in 30% less CO_2/mile on the same vehicle compared to gasoline. We are proposing a follow-up test. This test will show the ethane truck functions well in colder conditions, heavy traffic, that it meets or exceeds California's air pollution laws, and that the test is repeatable. This paper will provide some background on ethane production and usage, and assert that it constitutes a better fuel system for the entire United States.

Keywords: ethane, transportation, alternative, fuel, low-emission

Introduction

Municipalities around the world are working collaboratively to be the cleanest, most environmentally sustainable cities on the planet. Clearly there are issues from the latent CO_2 produced from fossil fuels, but also Liquified Petroleum Gas (LPG). These municipalities' ultimate and cumulative end goal is to reduce worldwide carbon emissions utilizing cleaner burning fuels for their vehicles. This is a noble effort. However, there are other ways to reduce carbon emissions that can achieve the same carbon reduction objective by utilizing readily available, alternative fuel stocks such as ethane. Use of ethane can result in significant decreases in energy costs, yielding positive results in these municipalities. Ethane as a green(er) clean(er) transportation fuel can be a significant opportunity for the urban and rural environment as it decomposes much faster than LPG and fossil fuels.

Given their reliance on emissions-heavy air transport, package delivery companies, and mass transit fleets are challenged to reduce their carbon footprints. A way to green their ground fleets is to optimize energy use in low-emission vehicles. Hydraulic hybrid propulsion systems deployed in the newer UPS-type delivery trucks use energy efficiently, producing less pollution than conventional delivery trucks. (USEPA 2007) UPS-type trucks are rarely used on the highway; stopping and starting is key to saving fuel with a hydraulic hybrid. Bus fleets are using Liquified Natural Gas (LNG) to lower their carbon footprint, but LNG is not an optimal fuel source. Ethane is a scalable solution down to a mid-size car, so taxis could be a part of the solution.

Ethane use can expand these vehicle options, providing an oil savings solution by reducing global warming emissions without drivers changing their driving habits. This is the best use of ethane adding the highest value using the simplest technology. There are two main areas of focus in current market trends for messenger and delivery companies with urban located large truck fleets:

- 'burn less' using hybrid vehicles; aero dynamic optimized vehicles, maximum speed reduction, or electronic modified engine control.
- 'burn clean(er)' by electric vehicles deployment and use of alternative fuels.

United Parcel Service (UPS) operates about 7,200 low-emission vehicles running on alternative fuels and technologies. (editors 2014) FedEx has one of the largest, in-service worldwide hybrid-electric fleets in the industry; almost 2,000 alternative energy vehicles. Deutsche Post DHL has 3000+ vehicles. (Connor 2013), (drrnm5 2011), (Simanaitis 2007)

If a more economical fuel source providing better carbon emissions, and is scalable down to automobiles is required, then ethane should be considered.

Project Scope

Back in 2014, UPS started using propane (C_3H_8) fuel in a test. (Lopez 2014) Ethane (C_2H_6) is far less expensive than C_3H_8, yet has similar range and is less carbon intensive. The market is for this fuel can be utilized throughout the United States, as can be used in existing gasoline engines and access existing fuel stations. The performance compared to the standard gasoline engine or LNG vehicle is improved—same driving range, less cost, less carbon emissions. Comparatively, Compressed Natural Gas (CNG) has range limitations; compressed ethane does not. Ethane has more hydrogen content per BTU than gasoline $(CH_2)_n$, hence less CO_2/mile. (Leveen 2014) This favorable result was proved in a field trial in the spring of 2015 with a dual-fuel (gasoline-ethane) Ford F-150 Triton Pickup Truck; Nucor Steel Corporation in Jewett, TX, USA sponsored this field trial. There is a real savings, financially and environmentally, by choosing ethane as a transportation fuel.

Aims of the Project

Our aim is to recover ethane in the oil refinery process or natural gas capturing process. Instead of using ethane as fuel input to boilers at refineries, or in the manufacture of plastics, we propose it be re-purposed as a transportation fuel for the use in railroad locomotives, package delivery trucks, or for similar delivery applications in other, appropriate industries. This proposition uses ethane as a transportation fuel by optimizing the storage pressure rating for the ethane on the vehicle in the onboard storage tank and via existing fuel control systems for gasoline engines. As long as the ethane is compressed to its critical pressure, and is below its critical temperature, it will be a liquid in the gas cylinder/tank. (Leveen 2014)

The forecast is that there is a glut of ethane way into the future. Hence, the arbitrage continues unless added uses, like the one we propose, will make this fuel useable throughout the USA. Industry partners like Nucor Steel Corporation have expressed interest in this opportunity. Many are looking to convert ethane to ethylene and petrochemicals, or to ship it to Europe for conversion to petrochemicals. However, the largest value add with the least capital intensity is to simply compress ethane and have a fuel that is more than twice the energy capacity as CNG, and almost as energy dense as gasoline.

Background

What is ethane?

Ethane (C_2H_6) is a liquid petroleum gas (LPG). Liquified natural gas (LNG) is primarily, 98+ % methane (CH_4), which is cooled to cryogenic temperatures to maintain a liquid state. Methane will always be a gas unless cooled below -82.6 °C (-116.68 °F). Unlike methane, due to it's very low critical temperature, ethane liquefies under compression, and does not require cooling or cryogenics.

Table 1. Critical Temperatures of Hydrocarbon Fuels

Hydrocarbon Molecule	Chemical Formula	Critical Temperature (°C)
Methane	CH_4	-82.3
Ethane	C_2H_6	+32.2
Propane	C_3H_8	+96.0
Butane	C_4H_{10}	+152.0

Source: The Engineering Toolbox (Editors 2015)

In a cylinder, if the temperature of ethane exceeds +32.17 °C, then it will become a gas. This is why the cylinder is only filled to 35% of its water volume with the liquid ethane when filled at a temperature below 32.17 °C. Cylinders holding ethane are designed for 1800 psi (pounds per square inch) or greater, yet ethane will only have a working pressure of about 600 psi.

This the most important point about ethane—its half-life in the troposphere is exponentially less than any other hydrocarbon fuels without sacrificing BTU's. (Hewitt 2003)

An expert reference point: Lindsay Leveen

Mr. Lindsay Leveen, a thermodynamics expert, chemical engineer, and award-winning journalist. He was awarded the Professional Development Award for his lifetime of achievement in chemical engineering by the American Institute of Chemical Engineering (AIChe). Mr. Leveen has consulted to major corporations in areas of energy deregulation, fuel cells, telecommunication, alternate fuels, thin film deposition, power generation, transmission and distribution, as well as a variety of other process-based technologies. At one time, he worked at L'Air Liquide where he was responsible for developing large onsite supply systems for industrial gas plants.

Mr. Leveen has visceral knowledge and a concrete understanding of ethane, and ethane's merits for application in the transportation sector. He recommends keeping ethane in the USA instead of offshoring it for use as the precursor feedstock in the manufacturing of plastics.

In late 2013, Mr. Leveen asserted compressing ethane and using it as a transportation fuel, hypothesizing compressing ethane would be more valuable than cracking it to make ethylene, the precursor feedstock for manufacturing plastics.

In 2015, Mr. Leveen predicted there would be a glut of ethane due to all the hydraulic fracturing activity in the Marcellus Shale Formation and Bakken Shale Formation. (See

Figure 1) In the fall of 2015, Mr. Leveen revealed in a report to the California Air Resources Board (CARB) there would be a glut past the year 2020.

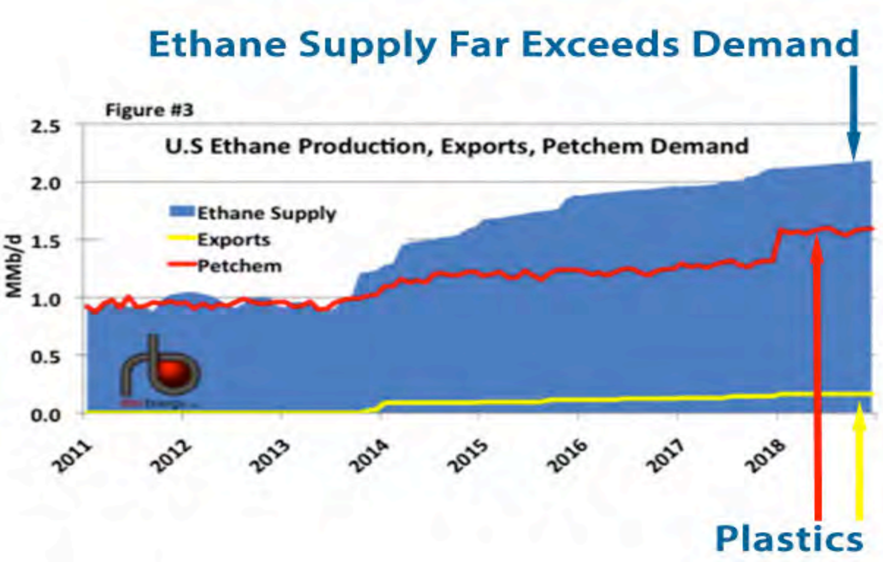

Figure 1. USA Production Exports Petrochemical Demand [Annotated] (Brazeil 2013)

In February 2017, business and financial services company, Moody's Corporation issued an affirming report on the strong LNG demand from Asia, "…will not be enough to absorb the fresh supply capacity coming online…the market will not rebalance until the early years of the next decade when global demand and LNG import infrastructure catches up with supply." (OGJ 2017)

Financial benefits

Compared to an ethane cracker, which takes upwards of four years to bring online, an ethane compression station requires two months to commence operations. (Leveen 2014)

A guesti-mate of the available feedstock of surplus ethane is about 200,000 barrels/day from the USA refining process alone. (Brazeil 2013) If one considers the shale gas in Pennsylvania and Colorado, without including Texas, there are probably about 400,000 barrels/day in surplus.

Figure 2-A shows ethane prices versus other liquid fuels in $/MMBtu. Ethane is 29 cents/gallon. A gallon of ethane has 66,000 BTU LHV (lower heating value), hence it is about half a gallon equivalent of diesel, and 0.6 gallon equivalent of gasoline. This means ethane can be bought from the LPG (Liquified Petroleum Gas) fractionator at about 50 cents/gallon on a gasoline equivalent. The NYMEX price of gasoline is over $3/gallon. And so, the big arbitrage is to place the bulk ethane in tube trailers and then smaller amounts into welding tanks aboard vehicles.

The forecast is that there is a glut of ethane way into the future. Hence, the arbitrage continues unless added uses, like the one we propose, which will be used in vehicles in the USA. As an example, industry partners like Nucor Steel Corporation have expressed interest in this opportunity, because they were investigating using ethane as a fuel for their service vehicles fleet from their natural gas wells.

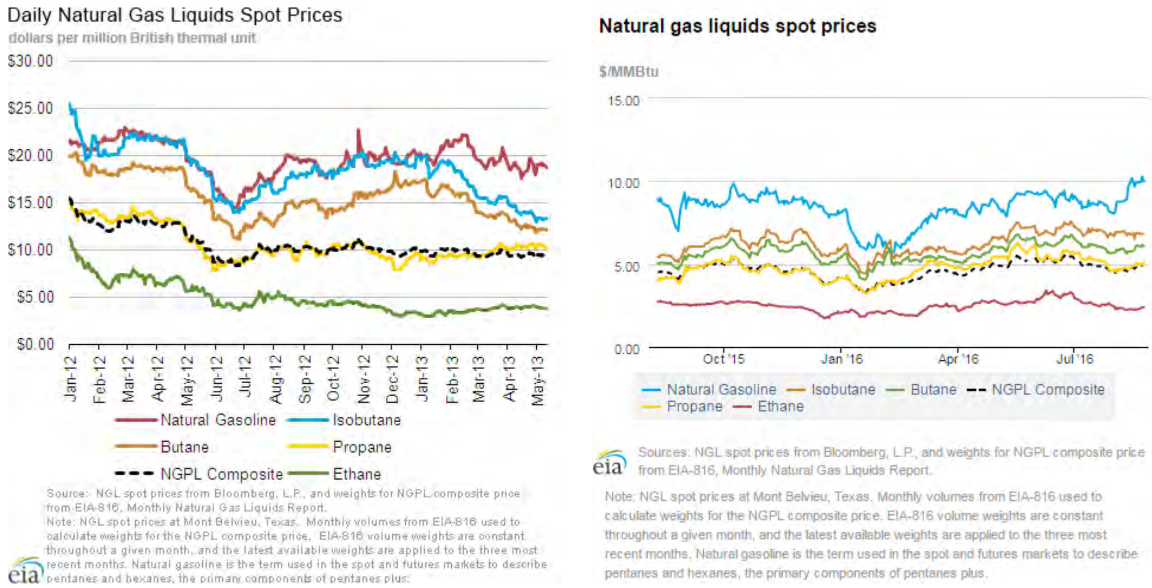

Figure 2-A&B. Natural gas liquid spot prices [January 2012 - May 2013 & October 2015 – July 2016] (USEIA, Natural gas liquids prices trend down since the start of 2012 2013), (USEIA 2016)

Environmental benefits

Compared to methane (CH_4) with a residence time in the troposphere (the lowest region of the atmosphere) of about 10 years, and carbon dioxide (CO_2) with a residence time of about 100 years, ethane's residence time is only 78 days in the troposphere. (Hewitt 2003)

The 100-year indirect global warming potential (GWP) is 5.5 for ethane, much lower than the 25 GWP of methane. (Yang 2015) This is due the highly reactive, short-lived, ubiquitous hydroxyl radical [OH], which oxidizes/destroys ethane as part of the photochemical process. (Hewitt 2003) By comparison, the rate of methane (CH_4) oxidation by OH is very slow, between 100 times and 1000 times slower than other organic compounds. (Crutzen 2006)

Sources of ethane come from oceans, vegetation, fossil fuel (conventional natural gas, shale gas, coal), modern microbial (wetlands, rice paddies, ruminants, termites, and landfills/waste) and biomass burning sources. (Sherwood 2017)

The Ethane Truck

For the first time in the world, a Ford F 150 4.6 Triton committed by Nucor Steel USA was converted to successfully use ethane fuel in a bi-fuel (gasoline or ethane) injection system. (See Figures 3-10) A prototype system was installed on the base of the IMEGA GAME LPG/CNG System, and re-designed with a 3-stage regulator. (See Figure 6) New ethane-dedicated software to optimize the system and record emissions was deployed. Compressed ethane fuel was transferred from a welding tank to the onboard fuel tank strapped into the truck bed. (See Figures 5)

The field trial was conducted in the town of Jewett located two hours travel by automobile northwest of Houston, Texas, USA. Field trial dates occurred on 10 August 2015 through 9 September 2015. Temperatures ranged from 71° F to 106° F at the start of each drive, and weather varied between sunny, overcast, and clear.

Ethane emissions testing results

- Low NOx, low HCs (hydrocarbons)
- Zero Carbon Monoxide (CO) emissions
- 30% lower than gasoline in CO_2/mile
- Complete combustion of HCs—No methane slip like CNG or LNG
- 86 mg/mile of non-methane HC (hydrocarbon) plus NOx
- Ethane and other HCs react out in the catalytic converter
- Lowest emissions of all transportation fuels
    - Exception: Hydrogen made from PV energy or wind energy

This Ford F150 Pickup Truck model was featured in a recent policy brief produced by The Baker Institute for Public Policy. This brief revealed "thirstier vehicles offer the highest return on fuel efficiency investment." (Collins 2017)

Conclusions

Ethane when compressed and cooled with cooling tower water is a liquid under pressure; it is non-cryogenic. Companies like L'Air LIquide sell ethane in welding cylinders that are almost full of liquid ethane. An L'Air Liquide 44 litre cylinder (also known by some companies as an 1A cylinder size) with ethane has 32 pounds of ethane. This has a lower heating value of about 650,000 BTU or about 5.7 gals of gasoline. (Leveen 2014) The same cylinder if filled with methane, compressed natural gas (CNG), would hold about 290 scf (standard cubic foot) of methane at 2,400 psi (pounds per square inch), and only have 267,000 BTU. (Leveen 2014) Ethane has about 2.5 times as much energy for the same volume and mass of storage. Vehicle range depends on the BTUs stored—hence rather than CNG, compressed, liquid ethane for vehicles is proposed. This schema should be workable for a(n) (extremely) large truck fleet operator in collaboration with a company like L'Air Liquide to perform the compression and logistics.

Compressed ethane will be as good as Liquified Natural Gas (LNG), and sans the additional energy input to cool to super low temperatures. Ethane will not require additional expense for cryogenic vessels/tanks required in the cryogenic process. Compressed Natural Gas (CNG) has a limited driving range and is challenging to store. Whereas, the process proposed in this paper will yield a lower carbon fuel for a lower price than diesel or gasoline, and driving range will not be sacrificed much.

Our group seeks funding to execute a field trial in the State of California to prove the viability of the ethane vehicle requirements. Funding would also include infrastructure needs to fuel vehicles. The final report will not only show that ethane meets and exceeds the California air pollution requirements, but also reveal the costs required to convert fuel stations and vehicles to ethane usage. We believe we can also produce data to prove this fuel could be used throughout the USA as a game changer in atmospheric pollution and green gas emissions.

Many are looking to convert ethane to ethylene and petrochemicals, or to ship it to Europe for conversion to petrochemicals. **However, the largest value add with the least capital intensity is to simply compress ethane and have a fuel that is more than twice as effective as CNG, and almost as energy dense as gasoline.**

Industrial carbon producers in the steel and iron, petroleum refining, manufacturing and transportation sectors realize they must take measures to further limit climate change. These sectors must act, especially since government policy is increasing the issuance of climate instability (change) measures requiring them to pay more damages—which in turn, could affect their profits. Looking at relative responsibility based on relative profits in the supply chain activities on carbon emissions and the climate, ethane should be a worthwhile investigation.

Acknowledgements

The authors gratefully acknowledge the help of those who provided extensive feedback and resources to conduct a pilot, proof-of-concept field trial in the spring of 2015 in Jewett, TX, USA—demonstrating ethane can be a cleaner, greener transportation fuel.

Notably, Brad True at Nucor Steel Corporation provided unwavering support for this endeavour, by offering frank feedback, scintillating suggestions, and constructive critiques, but by generously providing funding and resources to conduct the field trial project. The Jewett, TX staff, Bryan Linton and Matt Way, also deserve recognition for their contributions, support, and knowledge-base transfer.

The remarkable vanguard Danilo Gardi at Imega International USA Alternative Fuel Systems was instrumental and critical at steering the injection system design and direction of this pilot project proof-of-concept research—ultimately proving ethane can be game changer as a future transportation fuel stock.

Joe Marcenillo at Imega International USA Alternative Fuel Systems who constantly girded us on with his unwavering and unconditional support.

Finally, Dr. Chi-Jen Yang generously provided antecedent research in his 2015 American Chemical Society (ACS) paper "Ethane as a Cleaner Transportation Fuel."

A Design Framework for Sustainable Mobility Hub Networks in Mid-sized Cities

Christian Martinez and Tarek Rakha

School of Architecture, Syracuse University, Syracuse NY, USA

Abstract: Contemporary society is dependent on mobility and transportation in urban and regional settings for work, services and leisure activities. Recent changes of perception have shifted the outlook of car-centric plans toward more sustainable and shared modes which are regarded as more efficient for air quality, health, and other environmental factors. When considering mid-sized cities we see that their performance issues may be partly due to population density declination, climate, available infrastructure, etc. This paper develops a framework for the design of a mobility hub network in mid-sized cities that challenges the established method of infrastructure planning. Through the analysis of three urban conditions (urban sprawl, downtown core, and institution node) this paper presents a method for an integrated urban architectural system that fosters sustainable urban mobility. These include design guidelines for mobility hubs, development of scenarios for arranging integration of programming and infrastructure, and strategies for mobility network optimization. The research method combined qualitative analysis for existing conditions, categorization of infrastructure and services available and finally mapping and projections for future scenario development of sustainable urban transportation. The investigation is concluded with a representation of design strategies for a site in Syracuse, NY USA as a test bed for the study.

Keywords: Mobility hub, Network, Mid-sized City, Sustainability, Transportation

Introduction

The dependence on single-occupancy vehicles in cities for mobility is the lead contributor to the 26-39 percent in transportation energy consumption nationwide (NY Power Authority, 2015). In recent years, American cities have been working toward reducing transportation energy consumption through planning efforts that emphasize human-powered mobility and public transportation modes (Litman, 2015). The consideration and development of mobility hubs in these efforts have been underlined as a key component to transportation planning and as positive contributors to the successful management of movement in a city using multiple-modes of travel (Metrolinx, 2008).

The Mid-sized City

In the context of this study, we characterize the mid-sized city as one with a city population under 500,000.

A mobility hub network for a mid-sized city under these assumptions will be understood to be different from that of a larger city. Mobility hub operations in larger cities tend to focus on the opportunities for overlap of various robust transit modes and networks as well as the use and activities set within the hub itself. This is possible because of opportunities derived from conditions of congestion, which mid-sized cities lack as a resource (Chakrabarti, 2013). The developed framework in this paper differs in application due to conditions of smaller density, available infrastructure and distances between destinations. The analysis aims to expose a phenomenon of activity hubs and opportune moments of transit mode transfers. The mobility hub for a mid-sized city is thus a destination-based model that capitalizes on an available infrastructure with much reliance on the private sector and community based efforts to generate links to zone of high activity.

Framework

This paper presents a framework to generate a mobility hub network in mid-sized cities. The method is developed for urban and architectural design, where the outputs are guidelines for the design of a mobility hub and design of its urban network. The paper includes: a methodology that details analysis procedures for precedents and city characteristics, followed by the results of research focused on implementation at three urban conditions that differ in scale (urban sprawl, downtown core, and institution node), and concludes by presenting a framework that suggests future implementation in other mid-sized cities. The city of Syracuse, NY USA was analysed and tested through the presented framework for a mobility hub network, focused on sustainable transportation.

Methods

Figure 1 demonstrates the developed framework. A targeted collection of information pertaining to characteristics of the city specific to urban mobility and destination institutions and activities is analysed to determine travel behaviour and patterns in the city, key areas to capitalize on existing infrastructure and what types of mobility hubs could be implemented. A set of mobility hub design guidelines is also generated for application at the hub locations.

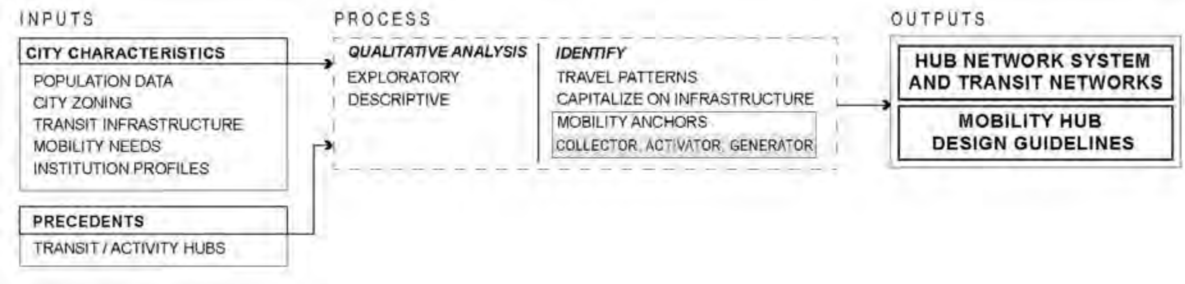

Figure 1. Presented framework.

Inputs

Information about the mid-sized city that detail demographics, current physical conditions and infrastructure, available transit services, mobility needs and major institutions is collected for analysis. This information aids in assessing transit modes for consideration, population and demographic travel information to accommodate and address any proposed programmatic needs for additional transit modes.

City Characteristics

Characteristics information relevant to mobility consists of a compilation of census travel data and local/municipal travel studies. Information on new mobility options and needs as determined by the city through travel action plans is to be collected to anticipate the accommodation of future infrastructure and services, especially those that influence sustainable modes of travel.

City characteristics should also include information related to major institutions and destinations/activities. This should focus on setting up profiles for institutions and areas that are accessed and support mobility patterns in the city. Based on areas and zones with significant travel and density, these profiles can be analysed for consideration as a mobility anchor point.

Precedents
Precedent survey includes a collection of information on projects that focus on the relationship between the overlap of transit infrastructure and opportunities for support programs. These precedents provide examples of mobility hubs to catalogue design strategies for the possible configurations of transit and destination junctures (Figure 2). Precedent search is not limited to scale, as a qualitative analysis is conducted to determine application at an appropriate urban condition of the same scale.

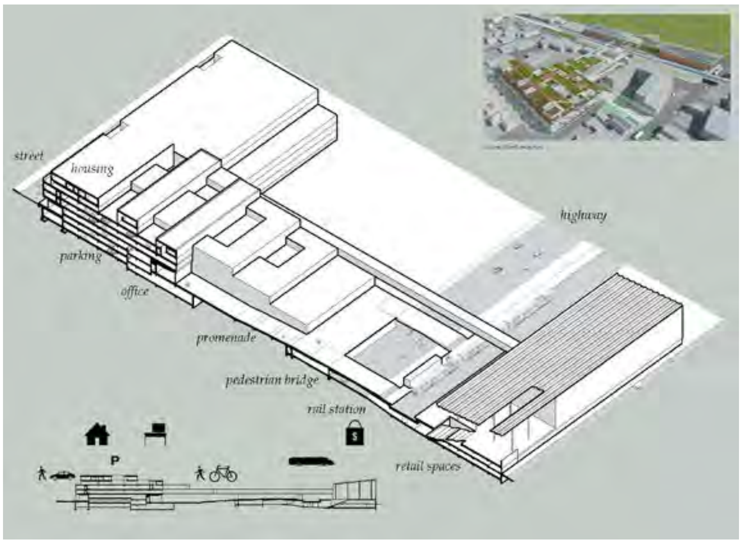

Figure 2. Parking Plus precedent by LTL Architects. Image produced by authors.

Process

Existing Conditions Opportunities
A qualitative analysis approach is used to understand travel patterns of the city from the characteristic inputs. From these patterns we can generate information that locates major travel corridors, available infrastructure, mobility services and frequented key institutions. In addition to capitalizing on overlapping infrastructures an emphasis on areas or pockets of density is a factor in determining hub locations. Infrastructure that fosters human-powered mobility (walking and biking) and public transit are primary considerations in this process. Links to car infrastructure are considered for partial trip use with a hub or nearby location offering the opportunity to drop-off or dock a vehicle and complete the trip by an alternative mode.

Anchoring programmatic needs to the existing networks and infrastructure is also considered to implement the success of new mobility modes. The proposed mobility modes will include new systems of infrastructure for additional mobility support and integration with the existing conditions. Additional travel modes create a range of travel opportunities and a flexible comprehensive network.

With the key institutions identified there are opportunities for inclusion of supplementary activity programs to further increase activity levels. These could include housing, office, grocery, retail, recreation, day-care, etc. if not already available. Supporting programs should be identified to balance the travel schedule to the area allocating more programs that offset that of the key institution. For example, in the study, the downtown urban district and core has a business district with many of the city’s major employers. This area primarily operates during weekday business hours. Additional programming may be added for activities past work hours or on weekends to generate constant flow.

Mobility Hub Anchors

Identifying mobility hub locations in the mid-sized city relies on the ability of an area to perform as an anchor point to sustain activity. All mobility hubs in the network of a mid-sized city are mapped with the intent of them operating as a city wide system. Some criteria to consider are maintaining a quarter-mile radius of activity zone or destination area from each mobility hub and also keeping a two mile distance between hubs. This would accommodate pedestrian trips from the hub location to the destination and bike or public transit trips between hubs. Each hub location would differ in operation, size and type (Engel-Yan and Leonard, 2012). Figure 3 represents hub location types that are categorized based on existing conditions and prospects to link with destination activities. Collector hubs are larger hubs that are located in proximity to active areas with good supporting infrastructure and would be primary hubs in the network, meanwhile activator hubs make an effort either to introduce new activities or new modes of transit. Generator hubs attempt to service areas that lack infrastructure or activities for any sustainable mobility.

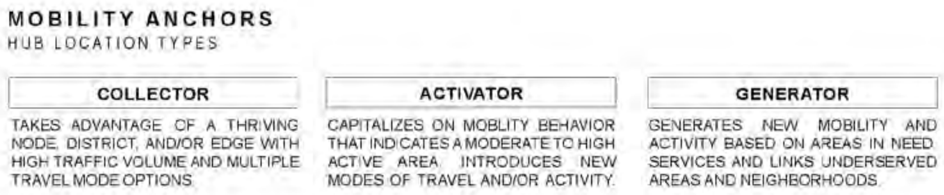

Figure 3. Mobility hub types based on activity and infrastructure parameters.

Output – Network and Hub Design Guidelines

Two outputs are determined from processes outlined above. A scheme for a network of mobility hubs is derived with mobility hub locations and impact areas. The second output is a set of guidelines for mobility hub design.

Results

The method was applied to Syracuse, NY as a test-bed for a mid-sized city. The mobility hub network for Syracuse operates as a destination-based hub system. Each mobility hub weighs equally in the system to each other despite different characteristics and locations. Programs vary based on the available infrastructure and characteristics of density and scale. From the three urban conditions derived from the analysis of Syracuse, (urban sprawl, downtown core, and institution node) each are ascribed a hub as a link in the system.

Syracuse Profile Inputs

The survey conducted on city characteristics of Syracuse resulted in finding population demographics and major transit infrastructures. Areas with higher rates of access, the major corridors and thoroughfares that connect them and the institutions at play were found for analysis (Figure 4).

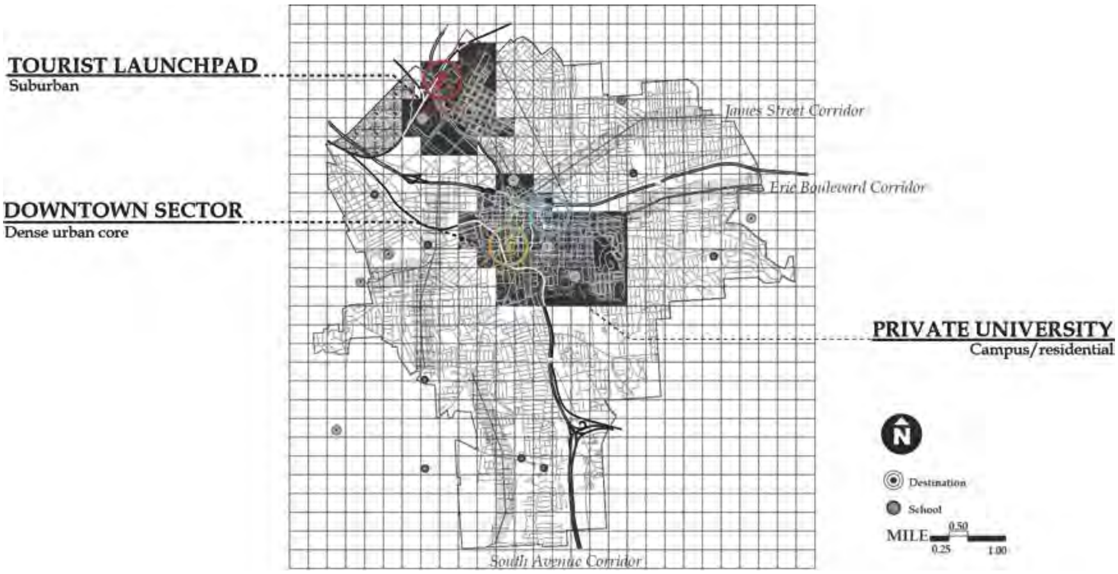

Figure 4. Syracuse general profile. Major thoroughfares and institution locations. Image produced by authors.

Exploratory Analysis

Qualitative analysis of the city characteristics was done to identify opportunities for hub locations. Three key areas were identified as potential collector hubs because of the infrastructure resources and institution profiles.

Sprawl-City Edge

As noted earlier, Syracuse has been experiencing a consistent decrease in the residential population of the city while the residential population in the neighbouring suburban towns has increased and continues to grow. With consideration of a large population of travellers to the city coming from outside the city limits by car the scope of the mobility hub is altered to address users from greater distances. The focus here is on utilizing the strong network of car infrastructure and regional transit to draw in commuters within a 10 – 20 minute commute area of the regional zone at the edge city. At the site of the Destiny Mall in Syracuse and Regional Transit Centre we find these two systems converge (Figure 5).

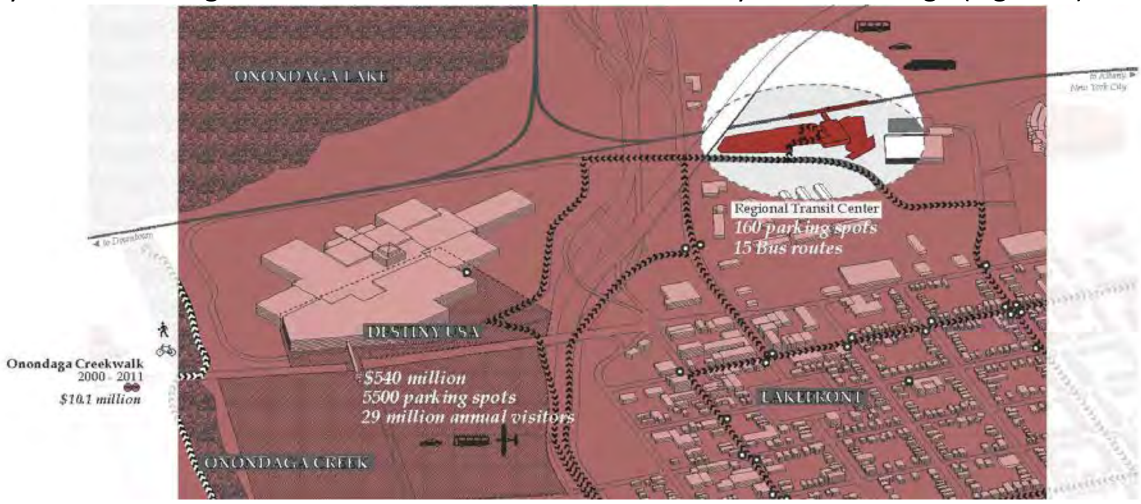

Figure 5. City Edge. Sprawl characteristics and transit catalysts. Image produced by authors.

Downtown-Urban Core

The downtown zone consists of an array of destinations and an urban density and size that can capitalize on walking and biking, the mobility hub for this location is focused on linking the current mobility systems to seamlessly integrate all modes of transportation. A priority here is to manage parking for the business and convention districts from travellers of the region at a particular location and convert the rest of the trip to the downtown destination via human powered mobility or public transportation. One of the main issues to overcome is the convenience of the use of the automobile to and within this district.

Institution Node

From the survey we find there are two major institutions located within the same neighbourhood. These are Upstate Medical University and Syracuse University. These universities have the highest numbers of employees in the region among two institutions. In addition to the large numbers of trips made to these locations for work they offer additional destinations for education, recreation and entertainment. The existing transit infrastructure relies mostly on driving and parking. The trip is then completed by either walking or shuttle network provided by the institution. These institutions have established themselves as walkable communities within the primary zone of activities from the campus setup that promotes walking.

Syracuse Mobility Hub Network

The mobility hub network for Syracuse in the context of this study would be comprised of thirteen hubs. Each would operate across three scales based on level of activity, density and available and future infrastructure. The two-mile distances between hubs are intended to provide adequate coverage and accessibility for travel by public transit or service a fifteen minute bicycle ride (Figure 6).

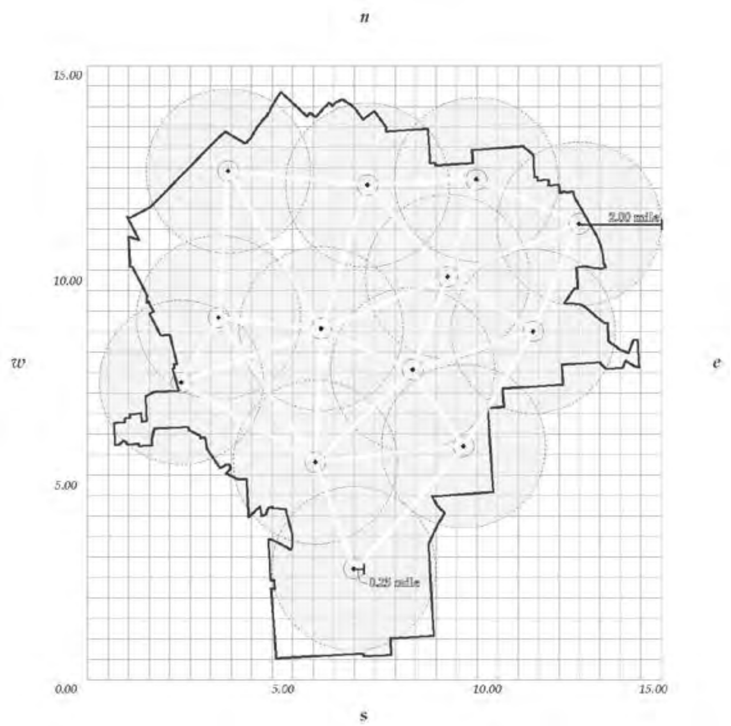

Figure 6. Syracuse mobility hub network. Image produced by authors.

Mobility Hub Design Guidelines

In addition to the hub design considerations stated in the methods, the guidelines for the design of hubs in Syracuse include some of the following strategies:

Site specific locations – Locations for infill to be considered at an opportunity where two transit mode infrastructures overlap. Placement at the edge or centre within proximity of destination is decided based on anticipated impacts.

Convergence of infrastructure – All accommodating infrastructures are to be housed within the hub. The moments of convergence can be stacked, flanked side by side, staggered or overlapped.

Integration of mixed use programming – Activity drivers to stimulate economy and attraction to the site as well as mobility services should be configured in the hub in collaboration with the design of the convergence of transit infrastructures.

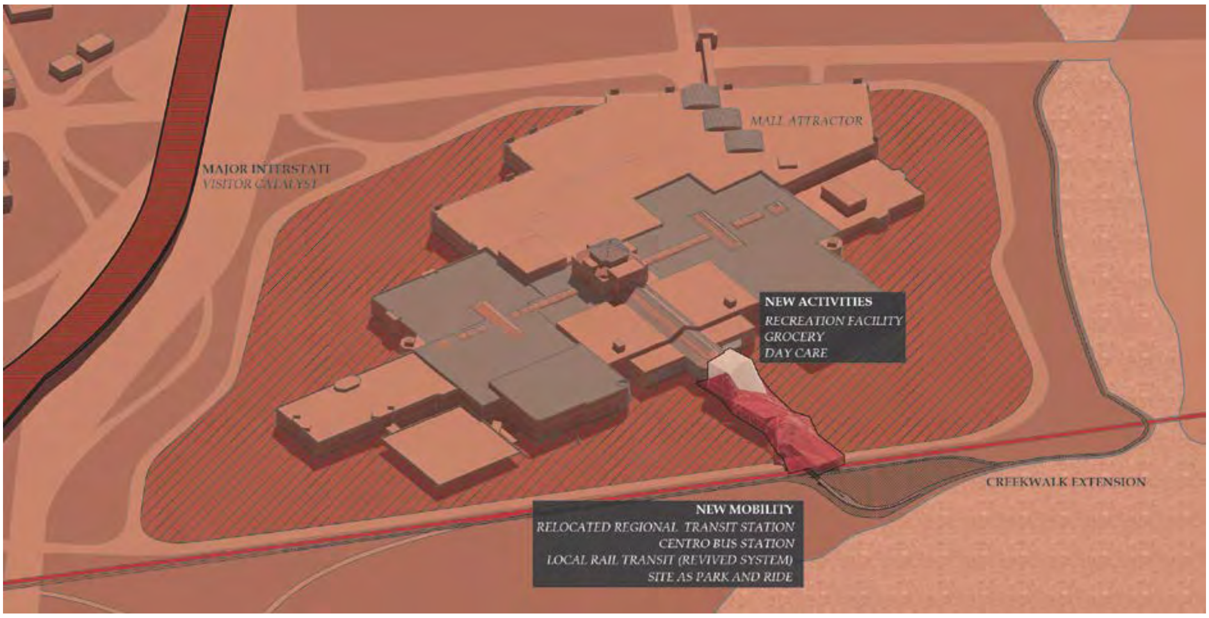

Figure 7. Sprawl-city edge transit hub. Image produced by authors.

Discussion

It is worth noting that the solution of a mobility hub network is not a one size fits all. This framework is intended for a working method in creating a network and guidelines for the design of a mobility hub. When applied to future case studies it is inevitable that design of the network and mobility hubs will be different despite following similar principles of accessibility, activity and sustainable mobility.

Supporting Institutions

In the case of mid-sized cities, a destination based model would rely on significant support from the private sector. The role that the destination plays in this model anticipates generous provisions from the affiliation with key institutions. Therefore, the institutions of a city are crucial resources for the feasibility of a hub network.

System Phasing and Prioritization

Recent literature suggests that in developing the network there is prioritization in the phasing of mobility hubs (Engel-Yan and Leonard, 2012). Planning for improving transit infrastructure is a major priority to perform as a catalyst for successful mobility and accessibility between hub destinations. Once an adequate transportation system is in place, collector hubs would be first in priority while other hubs would be phased shortly after their completion. The goal would be to make sure that there are initial drivers for established the network followed by activator and generator hubs that increase accessibility to and from areas that require more support.

Conclusion

The proposed scheme for a mobility hub network in Syracuse focuses on and anticipates new mobility for the city that is driven by travel to key destinations and sustainable travel mode choices. Based on the mobility hub design guidelines, a design approach can be followed for implementation at other suggested locations across the city. Although not a conventional element of urban design or urban planning, mobility hubs can play a vital role in motivating human-powered mobility, sharing economies and public transit in other mid-sized cities and because of the convenience of car use in these cities a network approach of mobility hubs as presented through this framework could provide an alternative. Further investigations into this matter should outline quantitative assessment and feedback mechanisms that can predict potential outcomes of the results.

Human-powered Mobility Programming Needs in Mid-sized US Cities: the Case of Syracuse NY

Tarek Rakha and Christian Martinez

School of Architecture, Syracuse University, Syracuse NY, USA

Abstract: Metropolitan regions in Upstate New York evolved over the past 50 years following a pattern of sprawl without growth in population, similar to many other post-industrial regions across the United States. This phenomenon increased the number of trips via Single Occupancy Vehicles (SOVs). This paper assesses the feasibility of developing and promoting human-powered mobility systems in mid-sized US cities in order to counter reliance on SOVs. The study focuses on Syracuse, NY, as a case study of a downtown core with a sprawling suburban growth, and examines complementary efforts in four other NY state cities as well as twelve motivated cities across the US that joined the National Association of City Transportation Officials (NACTO). Through the quantitative and qualitative examination of infrastructure projects and their effect on mode-share in the 17 examined cities, this paper presents comprehensive sustainable mobility programming needs for Syracuse, NY, as well as other mid-sized US cities. The investigation is concluded by presenting eight action categories in walkability/bikeability enhancement for sustainable mobility scenarios.

Keywords: Mobility, Walkability, Bikeability, Infrastructure, Syracuse

Introduction

The past century has seen a steady decline in human-powered transportation in urban areas. Throughout history, towns and cities were planned around accessibility to resources such as water and market places. Urban form followed the transportation technology available, and where a horse or donkey could take you was the limit for growth (Muller, 2004). However, each step forward in the field of transport technology development negatively affected the pedestrian environment. The degradation of the walkability and bikeability of cities was strongly related to the loss of intimate scales in streets as it became a separator between person and automobile. With the awareness of such auto-dependency, researchers, governmental agencies, and activists have begun to address these issues simultaneously. The concept of “walkable cities” as the foundation for a sustainable development was reborn. As populations switch to alternative modes of transportation (namely walking, biking and public transit), the benefits are demonstrated in different aspects and scales. Examples of these are reduction in congestion, lower carbon footprint, energy efficiency and lower noise and air pollution (Forsyth et al, 2008). Comprehensive sustainable transportation research has investigated issues such as automobile access (Nordfjærn et al, 2016), automobile dependence (Buehler et al, 2016) and the effect on sustainable mobility adoption as well as infrastructure investments and its effect on behaviour change (Ogilvie et al, 2004). Nonetheless, research investigating multiple cities to inform human-powered mobility planning is limited.

Similar to many other post-industrial cities, the Syracuse, NY, metropolitan area has evolved over the last 50 years following a pattern of sprawl without growth. Employment opportunities are concentrated within the city, and the majority of employees live in suburban and exurban communities. Mobility between home and work, and within the city during work hours, is highly dependent on personal automobiles. In 2010, vehicles travelled approximately 893.6 million miles in Syracuse, and the resulting GHG emissions totalled 551,850 metric tons. The city's recent Energy Master Plan envisions a 31% reduction in average municipal vehicle fuel consumption achieved via fuel efficiency measures; however, increased adoption of sustainable transportation alternatives—such as walking, biking and public transit will be necessary to achieve substantial citywide reduction in GHG emissions (NYPA, 2015).

This paper assesses the feasibility of developing and promoting human-power mobility systems in Syracuse, NY, as a case study of a downtown core with a sprawling suburban growth. The study contextualizes Syracuse through descriptive research and mapping analysis followed by examining 16 other complementary mid-sized US cities. This comprehensive approach is undertaken using exploratory statistical analysis followed by three descriptive case studies. The paper concludes by recommending action categories for walkability/bikeability enhancement for the city of Syracuse as well as similar mid-sized cities.

The Case of Syracuse NY

Syracuse has an historic opportunity to rapidly increase adoption of sustainable transportation alternatives by leveraging more than $80 million invested in multi-modal transportation infrastructure in four projects: the Connective Corridor (Knauss, 2015), the Onondaga Creekwalk (City of Syracuse, 2012), the Centro Transit Hub (Weaver, 2012), and a multi-modal transportation hub at the Syracuse Center of Excellence. Further, the City is implementing an ambitious comprehensive plan that envisions steady expansion of bicycling and pedestrian infrastructure over the next 25 years (City of Syracuse, 2012). The characterization of human-powered mobility in Syracuse is composed of an extensive pedestrian network and small, yet expanding, bicycling network. As part of the Syracuse Comprehensive Plan 2040, improved pedestrian and bicycle infrastructure each have a dedicated plan of study and implementation. At the time of writing this paper, the Bicycle Plan has been adopted while the Pedestrian Infrastructure Plan is not yet complete.

Since the beginning of the Connective Corridor project in 2005, a 2-mile long pedestrian friendly corridor was created from the University Hill neighbourhood to the downtown neighbourhood. The walking improvements consisted of new sidewalks, better street lighting, public seating for resting and enhanced storm water management to keep the sidewalks and intersections from flooding (Knauss, 2015). In addition, the Onondaga Creekwalk is the first multi-use recreational path from the urban centre to Onondaga Lake. A project idea that was conceived nearly fifty years ago and took 11 years to complete Phase I. Phase I finished in 2011 with a 2.6-mile and 13 ft. wide path along Onondaga Creek from Armory Square, a relatively vibrant public space in downtown, to Onondaga Lake. Plans to extend the path south 2 miles from Armory Square to Kirk Park are currently in progress (Creekwalk, 2009).

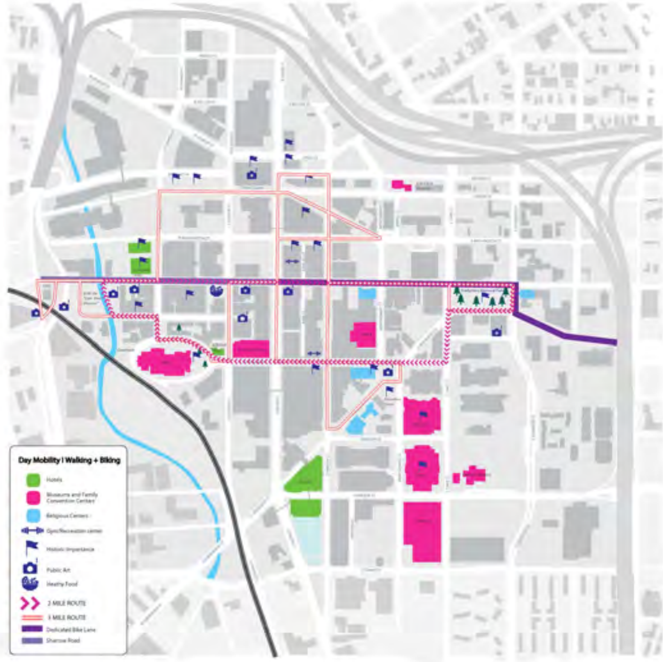

Figure 1. Day time mobility mapping in Downtown Syracuse highlighting human-powered mobility priority routes, as well as relevant activity categories.

Figure 2. Night time mobility mapping in Downtown Syracuse, highlighting night activity amenities and their operating hours. Public transit is highlighted with 5 and 10-minute walking radii from transit nodes.

Bicycling in Syracuse is limited due to the lack of bicycle specific infrastructure. The Syracuse Bicycle Plan proposes to add a total of 65 bike lanes throughout the city. Since 2004, 23% of the Bike Plan has been implemented with most of the improvements being completed in the past five years. The improved bicycle network is projected to increase bicycle mode share. However, this may not be a consistent increase throughout the year with consideration of the harsh winter weather that may alter travel decisions amongst bicyclists (City of Syracuse, 2012).

Figures 1 and 2 show mobility options in downtown Syracuse. Destinations in the day activity map were selected based on different interests during the daytime such as museums, public art, and historic landmarks. Night activities were selected to show destinations with late operating hours such as dining and entertainment locations. For both maps, mobility options were highlighted to show viable alternatives for each time condition and reveal any gaps in mobility modes. The information represented on these maps reflects scenarios with the currently available infrastructure.

Exploratory Research of Mid-sized US Cities

Table 1. Developed database for investigated cities characteristics. Mode share source: DATA USA, 2016. All infrastructure project counts (ped, bike and transit) were retrieved from public works websites for each city.

		Pop. Density (p/mi^2)	Ped. Infra. (No.)	Bike Infra. (No.)	Transit Infra. (No.)	Walk Share (%)	Bike Share (%)	Transit Share (%)	Walk-Score®	Bike-score®	Transit-score®

In order to inform Syracuse human-powered mobility design and planning praxis, we investigated efforts in four other cities in NY state, as well as twelve motivated cities across the US that joined the National Association of City Transportation Officials (NACTO). Table 1 shows data gathered to enumerate population density, number of pedestrians, bicycle and transit infrastructure projects, transportation mode share as well as the walkscore, bikescore, and transitscore of the 17 investigated cities. A Pearson correlation statistical test was computed to assess the relationship between all factors with no established hypotheses in an effort to explore correlation trends and statistical significance. The correlation measures the strength of the linear relationship between two factors. It is important to note that the sample size is limited, and due to paper scope limitations, we are only reporting significant and trending correlations for mode share and infrastructure project observations.

Mode Share

Transportation mode share is reported for all cities as the percentage of travellers adopting a certain mode of travel. Walk mode share was moderately correlated with transit infrastructure projects ($r = -0.436$, $p < 0.05$) and transit mode share ($r = 0.556$, $p < 0.02$). A stronger correlation was found with transitscore ($r = 0.686$, $p < 0.004$). We also found moderate correlations between bicycle mode share and total number of pedestrian infrastructure projects ($r = 0.45$, $p < 0.036$). Correlations with bicycle infrastructure projects ($r = 0.388$, $p < 0.062$) and public transit mode share were moderate and approaching statistical significance based on the standard cutoff p-value of .05 ($r = 0.386$, $p < 0.064$). A strong correlation between bicycle mode share and bikescore was also observed ($r = 0.707$, $p < 0.001$). Finally, public transit mode share was moderately correlated with walkscore ($r = 0.486$, $p < 0.025$) and strongly correlated with transitscore ($r = 0.711$, $p < 0.003$).

Infrastructure Projects and Initiatives

The number of all infrastructure projects and initiatives related to pedestrians, bicyclers, and transit users over the past decade was tabulated and represented in table 1. Concerning pedestrian infrastructure projects, we found moderate correlations with number of bicycle infrastructure projects ($r = 0.481$, $p < 0.026$) and bicycle mode share ($r = 0.45$, $p < 0.036$), correlations that were approaching statistical significance with bikescore ($r = 0.429$, $p < 0.063$), and strong correlations with transit infrastructure projects ($r = 0.6$, $p < 0.006$). As for bicycle infrastructure projects, moderate correlations were found with population density ($r = -0.415$, $p < 0.06$), and correlations with bicycle mode share were approaching significance ($r = 0.388$, $p < 0.063$).

Case Studies: Madison, Minneapolis, and Portland

Qualitative assessment of all investigated cities was undertaken to rationalize quantitative and exploratory research results. In order to adhere to the paper's scope, we chose three cities to discuss their approach to developing various aspects of human-powered mobility.

Madison, WI

We find the city of Madison comparable to Syracuse based on population counts, city size, the relatively colder climate, demographics and mode-share impacted by the population of a large university within the urban area. For Madison, the majority of pedestrian infrastructure improvements typically include sidewalk repairs, intersection improvements, and filling gaps in the pedestrian network. Two of the initiatives that are worth noting:

- *Pedestrian Flags Initiative: Orange flags are placed at intersections for pedestrians to use to get cars to yield for those crossing.*
- *Madison in Motion: Comprehensive strategic transportation plan that outlines missing gaps in pedestrian network and describes which to prioritize.*

Relatively higher bicycle mode share in Madison is likely attributed to the number of infrastructure projects that improve the network. A total of 58 projects were found, making it the city with the highest number of projects in this study including citywide bike racks, new bike lanes and new cycletracks. Two other to make particular note of are:

- *Citywide Bike Detector Stations: Detectors/sensors placed underground in streets and bikeways that measure bicycle count data.*
- *Acewood Bike Trail Lighting: Improve visibility for night cyclists (City of Madison, 2016).*

Minneapolis, MN

Human powered mobility in Minneapolis is relatively successful especially in terms of bicycling. When compared to Syracuse, Minneapolis is comparably a larger city. However, it was considered in order to investigate how biking in particular, is much more successful despite being a city with cold weather climate and winter precipitation. Some noteworthy pedestrian projects include:

- *Painted curb extensions – These are extensions of sidewalks at intersections to shorten crossing distances and provide refuge for pedestrian.*
- *First Ave. Walking Pilot Project – A temporary sidewalk expansion to evaluate the impacts of providing additional pedestrian space.*

There are several projects for improving bicycle infrastructure in Minneapolis through the means of adding shared lanes, bike lanes and cycle tracks. The Minneapolis Bicycle Master Plan (City of Minneapolis, 2011) outlines the goals for bicycling and how it plans to make it a more viable option through both infrastructure development and policy changes. These strategies are listed as:

- *Education: Giving people of all ages and abilities the skills and confidence to ride.*
- *Encouragement: Creating a strong bike culture that welcomes and celebrates bicycling.*
- *Enforcement: Ensuring safe roads for all users.*
- *Equity: Create an accessible network for all users of different demographics.*
- *Evaluation: Planning for bicycling as a safe and viable transportation option.*

Portland, OR

Although Portland is much larger than Syracuse both in area and population, we considered it for an investigation of how it managed to successfully establish sustainable transportation as a viable option. Since 1998, the Pedestrian Master Plan has been in action improving walking in the city. More recent efforts include Walk There! And Ten Toe Express which provide guided walks and resources to promote walking (City of Portland, 2016).

In terms of biking in the city, a significant number of infrastructure projects exist that are geared towards increasing the number of bicyclists, bicycle mode share, and biking safety. The Portland Bicycle Master Plan adopted in 2010 is a twenty-year plan that sets a vision and goal for bicycling to be a more viable option for traveling three miles, and 25% of all trips are projected to be made by bicycle. To achieve this six key areas were outlined:

- *Attract new riders: Plan and design for people who feel either unsafe or uncomfortable.*
- *Form a dense bike network: Provide an array of route choices.*
- *Increase bicycle parking: Satisfy demand for parking at travel destinations.*
- *Expand programs to support bicycling: Introduce more education programs.*
- *Increase funding for facilities.*
- *Strengthen bicycle policies.*

Discussion

The results we present in this research show interesting relationships that should inform future implementations relevant to human-powered mobility in mid-sized cities. These can be summarized as follows:

Every transit trip starts and ends with a pedestrian trip
Statistical analysis reveals a strong relationship between assessments of walk mode share and pedestrian initiatives with transit mode share and transit initiatives, as well as correlations between transit mode share with both walkscore and transitscore. However, bicycle mode share relates weakly to public transit on all fronts, and beyond that, correlates with pedestrian infrastructure projects only. This finding suggests that walking and bicycling as travel modes should be treated separately in terms of initiatives and assessments. Ped/bike initiatives typically happen at the same time, but their impacts differ. Whereas walking as a mode is strongly linked to transit and should be studied in that context.

If you build it, they will come
Results also suggest that pedestrian, bicycle, and transit infrastructure projects and initiatives are typically related to each other via a positive trend (when one increases, so does the other). This suggests that when a city is planning for human-powered mobility initiatives for all modes other than cars are affected. Interestingly, no correlation was found between pedestrian infrastructure projects and walk mode share, but bicycle infrastructure projects and initiatives relate moderately to bicycle mode share. This finding suggests that for bicycling as a mode share, infrastructure has an influence.

It is not just about the numbers
Although examined cities varied in their priorities, resources and approaches, they share common themes that can be categorized qualitatively. Based on the analysis, categories typically include 1) facilities and infrastructure, 2) educational resources, 3) policy, 4) marketing, 5) financing, and 6) operation and maintenance. It is worth noting that some quantitative assessments may fail to correlate with what they are intended to measure. For example, walkscore did not correlate with walk mode share but instead correlated with transit mode share. This suggests that walkscore may not be effective in assessing walkability due to a process of assessment that is linked to accessibility. However, bikescore and transitscore correlated more reliably with bike mode share and transit mode share, respectively.

Conclusion

Human powered mobility needs across all examined cities vary based on funding resources, climate, and population. Although the number or projects, plans, and programs sum up to a variety of different improvements and efforts, we can begin to categorize them into more broad needs to improve human powered mobility. We recommend that mid-sized US cities, like Syracuse, NY, can address human-powered mobility programming needs through:

1. *Facility upgrades: Design and infrastructure improvements to repair, beautify. and improve safety for pedestrians and bicyclists as separate modes.*
2. *New facilities: Addition of facilities for pedestrians linked to transit, or bicycle network to focus on cyclists. This could be in the form of new lanes, paths, etc.*
3. *Education resources: Digital or physical resources for self-learning information on walking and biking based on successful case studies.*
4. *Education programs: Active programs provided and led by advocacy groups and organizations for communities to help promote human-powered mobility.*
5. *Policy changes: Improve policies to benefit pedestrians and bicyclists making them a priority as well as making travel to destinations more fun, safe, and convenient.*

6. *<u>Outreach Marketing</u>: Increase awareness of walking and biking improvements around the city together with the benefits of utilizing the network.*
7. *<u>Funding Resources</u>: Seek funding from a variety of sources as well as redistribute funding toward human-powered mobility services.*
8. *<u>Action Planning</u>: Develop plans for maintaining the active transportation networks as viable options year-round.*

Future research should address the limitations of this paper and pursue quantitative assessment of education and policy initiatives in different cities and scenarios. Furthermore, other case studies should be investigated to inform success in sustainable mobility adoption.

Design to Thrive

Upgrading urban highways: issues and negative impacts based on a case study of Sadr's Elevated highway

Ehsan Ranjbar[1] and Seyed Navid Mashhadi Moghadam[1]

[1] Faculty of Art and Architecture, University of Tarbiat Modares, Tehran, Iran.
Correspondence email navid.m.moghadam@hotmail.com;

Abstract: Transportation as the vessel of the world has always a significant role in urban functions. This important part of urban big picture sometimes struggles with environmental aspects. By highlighting its goal of accessibility and economic features, may conclude to damage urban environment. In recent years, Tehran municipality decided to upgrade one its own highway to an elevated highway called Sadr's Elevated Highway. This study aims to evaluate this urban phenomenon from the environmental prospect. For this purpose, firstly, this paper reviews a body literature around environmental impact assessment (EIA) then secondly argues about urban highways, expressways and elevated highways through an epistemology of why urban highways are important? And does the true time arrive to eliminate this subject from urban structure? After that, this study assesses environmental impacts of Sadr's Elevated Highway as an empirical study based on two distinguish models. The first model is an integrated model and its functionality based on weighting and matrixes and second one is a ranking model also known as Multi-criteria decision analysis called VIKOR. Results of this paper showed the elevated highway in case of Tehran is a mistake in types of urban transportation developments form prospect of urban environment sustainability.

Keywords: Elevated Highway, EIA, Urban, VIKOR.

Introduction

In 2013, Deputy of Technical & Development Affairs of Tehran Municipality constructed second level of a highway which makes the old one highway as a new elevated highway. This is a personal vehicle oriented action which generally encourage citizens to use their own car travel around the city. Is this a sustainable architecture in urban scale? To answer this question it is needed to apply an Environmental Impact Assessment. The first phenomenon influencing the thinking of Environmental Impact Assessment was the publication of Silent Spring by Rachel Carson in 1962, which brought the attention of American society on the living environment and created some concerns about neglecting environment vulnerability during the development projects in the late 60's (Overseas Environmental Cooperation Center, 2000). In 1969, According to the National Environmental Policy Act (NEPA), sustainable environmental impact assessment took legal position in North America (Ogola, 2007). Based on the NEPA 1969 act, all large-scale projects like constructing a dam or mine should have environmental impact assessment before initiation of a project (Partidario, 2007).

Through the 1960s, two key factors increased attention to the local effects of and public participation in urban highways and public transit construction. The first was operating the federal-state system of highways, which had significant effects on local resources and neighborhoods, and the second factor was raising awareness of issues such as protection of the environment and the marginalization of the poor / minority population in urban communities' thoughts (Weiner, 1992). The federal highways' law (1967) set an independent organization for monitoring the environmental impacts of construction of the highway were required, as well as citizens on the basis of this law could have their opinions in relation to social and environmental issues surrounding by the proposed highway projects. But the meeting between public officials and highway construction projects in the final stages of the development project was held. The biggest step through the process of construction of the highway is divided into two parts in late 1969 and early 1970, with the adoption and implementation of the national environmental policy act (NEPA). According to the national law that reflects the concerns of the previous decade, In the first phase of the project, there should be a report of assessing the possible effects (both macro and micro) of development projects on the environment, local communities and the economy and secondly after the adoption of the first phase by the public and local stakeholders, the project must be divided to multiple phases due to reducing its own negative impacts (Hughes, 1998). This process quickly spread around the world and played a significant role in reducing the environmental impact of highway development projects. Following table is a summary of five stages urban highways passed from 1911 until the contemporary century.

Table 1. History of urban highway developments approaches

Stages	Describe
First stage: Birth of highway	The first Highway constructed in 1911. Prior to influence of economic approach in the 1950s it can be considered the first course of highways' construction between 1911 and 1950. In this course as John Dewey in his the most important theory states "learning by doing" is the main approach that consciously or unconsciously applied by the authorities in highway construction (Ord, 2012; Plummer, 2005).
Second Stage: growth of highways	The second period placed between 1950 and 1962. What distinguishes this period from before and after is appearance of economic science and economic performance of cities. This economic approach tried to maximize speed and number of citizens and goods transportation. The root of such thinking as stated earlier in Chicago Transportation Studies (CATS) can be seen clearly (Plummer, 2005).
Third Stage: respond to public thoughts	In the period of 1962 to 1970 as well as with rising local communities' awareness of the negative effects of the highway, the economic approach founded by the study of the Chicago Transit faced with some. The changes were responses to the protests of local communities, with the aim of taking into account environmental issues in construction transportation projects of Metropolis. As a result of those changes some organizations founded to monitor large-scale projects (such as freeways and subways) in order to predict and prevent damage to the natural environment during the preparation of development plans and programs (DYBLE, 2007; Mohl, 2002).
Fourth Stage: Appearance of Environmental Impact Assessment	In 1970, with mandatory of environmental impact assessments for development projects, a new framework conducted for highway development projects, which authorities must prepare a report of environmental impacts of their projects and published for the public. In this report, impacts of social, economic and environmental of a

	development project on the target population should be mentioned in all phases of construction, including pre-construction, during construction and operation phase. Meanwhile, discount strategies and plans for mitigation of negative impacts should be included in it (Overseas Environmental Cooperation Center, 2000).
Fifth Stage: Death of urban highways	This stage refers to recent approach to urban highway developments but has lack of enough comprehension to be an inviolable theory. This theory argues about the removal of urban highways; however, in recent years a lot of researches done on this issue or are in progress. For example, one of the most important research into this field is the study of Bocarejo, LeCompte, and Zhou (2012) in their magnificent book titled "Life and Death of urban highways" in which they argue about the reasons for the removal of urban highways, viable alternatives to the removed highways and some cases of successful elimination of highways in the United States America and other countries such as South Korea and Colombia. Although an overview of existing studies on the removal of urban highways shown that highways' elimination happened in certain circumstances, but in most cases occurred with the wishes and demands from local communities. Although admission to this lack of cohesion just needed to more contemplate, however, it shows that local communities in most developed countries, and few developing countries reached to high level of awareness and understanding of environmental issues in their surrounding living area (Bocarejo et al., 2012).

In the late twentieth century, international institutions (including the World Bank and the Asian Development Bank), and different countries conducted different frameworks and guides for environmental impact assessment. According to different contexts of highway development projects, there are differences in dimensions and criteria, which should assess in the process of EIA. For example, the quality of urban design and attention to viability in the context of environmental impact assessment in the United States of America is important, and the cultural effects and avoiding interference in the city dynamic are one of the late criteria considered in EIA in Great Britain (Department for Communities and Local Government, 2006). Table 2 shows selected dimensions and criteria based upon the context of this paper case study.

Table 2. Dimensions and Criteria used in this study

Dimensions	Criteria
A. Social environment	*A1. Social justice*
	A2. Safety and Security
B. Physical environment	*B1. Relocation of houses*
	B2. Land acquisition
	B3. Traffic Management
	B4. Accessibility

C. Visual environment	*C1. Urban landscape and visual appearance*
	C2. City image and the sense of belonging
D. Economic environment	*D1. Land price*
E. Ecological environment	*E1.Air pollution*
	E2. Noise pollution
	E3. Energy
	E4. Environmental damage

Method

The first method using in this study introduced by Hao Cai (2011) which in this method, the whole road will be divided into several sections, and giving the different weight to each zone, and each zone with the first-class indexes and the second-class indexes, with Analytical Hierarchy Process (AHP) and Delphi software to calculate the weight of different indexes.

The Second Model to evaluate environmental impacts in this paper is the VIKOR model. The VIKOR method is a multi-criteria decision making (MCDM) or Multi-criteria decision analysis method. It was originally developed by Opricovic (1998) to solve decision problems with conflicting and non-commensurable (different units) criteria, assuming that compromise is acceptable for conflict resolution, the decision maker wants a solution that is the nearest to the ideal, and the alternatives are evaluated according to all established criteria. VIKOR ranks alternatives and determines the solution named compromise that is the closest to the ideal. The purpose of using VIKOR method for this study is the VIKOR method checks; whether the top-ranked alternative can be considered better enough than the others by testing acceptability advantage and acceptable stability conditions. If any of these two conditions is not satisfied, then VIKOR proposes a set of compromise solutions based on maximum group utility of majority and minimum individual regret of the opponent. Furthermore, another reason for employing the VIKOR method is because this technique is mainly based on the particular measure of closeness to the ideal solution, and it focuses on selecting the best choice from a set of feasible alternatives in presence of mutually conflicting criteria by determining a compromise solution (Shankar Chakrabortya & Chatterjee, 2013).

Case Study

Sadr's Elevated Highway (SEH) is a freeway in northern Tehran, Iran. This freeway runs west from the Modarres Expressway in Gholhak neighborhood east through Gheytarieh, Doulat, Darrous, Chizar, and Ekhtiariyeh, at which point it crosses Pasdaran Avenue and becomes Babayi Expressway. Sadr Expressway serves the dual purpose of connecting the northeastern suburbs of Tehran to the business center, as well as functioning as an arterial road between the capital and the north and northeast of Iran. This bridge consists of the main bridge with 22.7m width and 6 km length and over than three set rams with 5km length at all.

Figure 1. Sadr’s Elevated Highway

Results

The first method: based on Table 3, the Sadr’s Elevated Highway (SEH) has negative impacts in the ecological and visual dimensions but positive impacts in the economic, physical, and social dimensions. The overall physical impact of the SEH in all of its four sections is plus 1.61, which is its strongest point, while its impact in the ecological dimension is minus 2.39, which is its largest negative impact among the various dimensions and, therefore, is its most important shortcoming. Moreover, the visual dimension of the SEH has the negative impact of minus 1.31, which is its second most important negative impact. The social and economic dimensions with plus 0.42 and plus 0.21, respectively, are its second and third most important positive impacts. Therefore, the SEH has positive impacts in three dimensions and negative impacts in two dimensions.

Table 3. First Method final results

Dimensions	First Section of SEH	Second Section of SEH	Third Section of SEH	Fourth Section of SEH
Social environment	0.04	0.1	0.23	0.06
Physical environment	0.12	0.39	0.87	0.23
Visual environment	-0.1	-0.32	-0.71	-0.18
Economic environment	0.02	0.05	0.11	0.03
Ecological environment	-0.18	-0.58	-1.3	-0.33

The second method: Table 4 presents the distance between the actual performance and the best and worst case performance of the SEH with respect to the impacts of each criterion. In other words, the value of Si for each criterion represents the distance between the actual status of the SEH and that of a highway in the best case scenario. For example, as shown by the calculations in Table 4, the ideal Si value for the local integration criterion is zero, while its value for the SEH is 0.019; i.e., there is a distance of 0.019 units between the impact of the SEH and that of a highway in the best case scenario in relation to the local integration criterion. However, this distance by itself does not signify a low or high value. Therefore, the Si values for the worst and intermediate case scenarios must also be calculated so that the distance between the impacts of the SEH and those of a highway in the best case scenario can be tangible, and the status of the SEH can also be determined compared to those of the intermediate (average) and worst case scenarios, by considering the best, the intermediate and the worst case scenarios.

Table 4. Results of second method

Criteria	Ideal	SEH	Mediate	Worst	w	Ideal	SEH	Mediate	Worst	Ideal	SEH	Mediate	Worst
	dij	**dij**	**dij**	**dij**		**si**	**Si**	**Si**	**Si**	**Ri**	**Ri**	**Ri**	**Ri**
a1	0	0.493	0.500	1.000	0.038	0.000	0.019	0.019	0.038	0	0.126	0.089	0.178
a2	0	0.449	0.500	1.000	0.074	0.000	0.033	0.037	0.074	**Si**	**Si**	**Si**	**Si**
b1	0	0.551	0.500	1.000	0.052	0.000	0.029	0.026	0.052	0	0.532	0.5	1
b2	0	0.462	0.500	1.000	0.065	0.000	0.030	0.032	0.065	**S***	**S***	**S***	**S***
b3	0	0.300	0.500	1.000	0.053	0.000	0.016	0.026	0.053	0	0	0	0
b4	0	0.417	0.500	1.000	0.043	0.000	0.018	0.022	0.043	**S^**	**Su^**	**Su^**	**Su^**
c1	0	0.649	0.500	1.000	0.063	0.000	0.041	0.031	0.063	1	1	1	1
c2	0	0.537	0.500	1.000	0.043	0.000	0.023	0.021	0.043	**R***	**R***	**R***	**R***
d1	0	0.500	0.500	1.000	0.035	0.000	0.017	0.017	0.035	0.178	0.178	0.178	0.178
e1	0	0.709	0.500	1.000	0.178	0.000	0.126	0.089	0.178	**R^**	**R^**	**R^**	**R^**
e2	0	0.525	0.500	1.000	0.110	0.000	0.057	0.055	0.110	0	0	0	0
e3	0	0.553	0.500	1.000	0.133	0.000	0.074	0.067	0.133	**Q**	**Q**	**Q**	**Q**
e4	0	0.457	0.500	1.000	0.114	0.000	0.052	0.057	0.114	0	0.621	0.5	1

Thus, as shown in Table 4, the impact of the local integration criterion with the value of 0.019 is equal to that of the intermediate case scenario. Moreover, the security impact of the SEH with the value of 0.033 is slightly smaller than that of the intermediate case scenario; i.e. it is closer to that of the best case scenario. However, with respect to the criterion related to the destruction of the original local structure, the value for the SEH (0.029) is 0.03 units higher than that of the intermediate case scenario; i.e., it lies somewhere between the worst case and intermediate case scenarios. As for the impact of the traffic management criterion also, the SEH with the value of 0.03 and a distance of 0.002 units from that of the intermediate case scenario, is placed between the intermediate and best case scenarios. The SEH (with the value of 0.016) has a greater distance from the intermediate case scenario with respect to the criterion of the land seizure impact and is closer to the best case scenario. Furthermore, with respect to the criterion of impact on access, the SEH lies between the intermediate and best case scenarios. As for the two criteria of the impacts on “urban landscape and visual appearance” and “city image and the sense of belonging,” the performance of the SEH is placed between those of the intermediate and worst case scenarios. In the criterion of the impact on “land price,” the performance of the SEH is equal to that of the intermediate case scenario, and in the criteria of the impacts on “air pollution”, “noise pollution”, and “energy,” the performance of the SEH lies between those of the worst case and intermediate case scenarios.

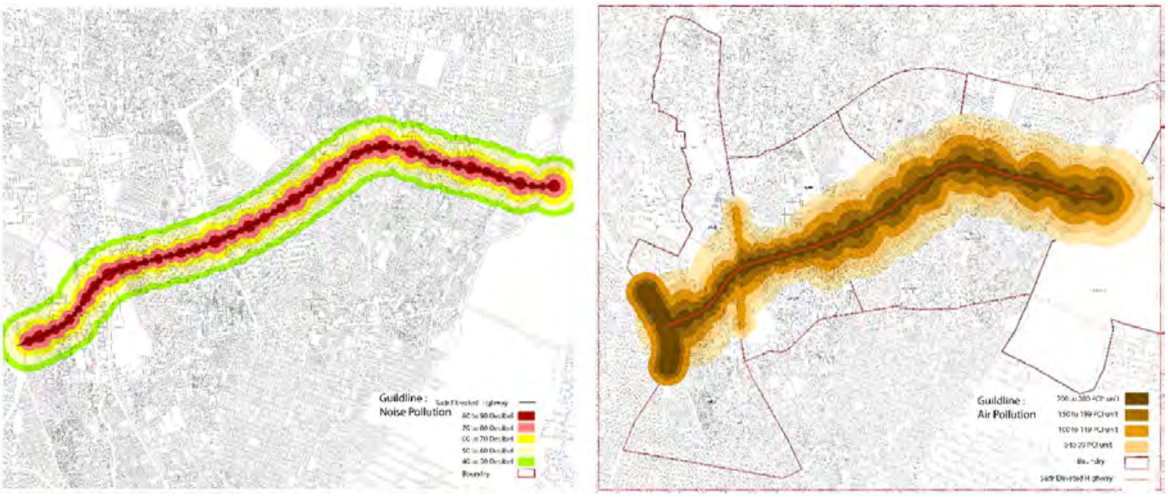

Figure 2. Noise and Air Pollution after construction of elevated highway.

Figure 1. Noise and Air pollution map for Sadr’s Elevated Highway 2016. PCI*: percutaneous coronary intervention.

Finally, the Q index, the values of which for the worst, the intermediate, and the best case scenarios are listed in Table 3, shows the distance between the performance of the SEH and that of the best case scenario. The value of the Q index (0.621) indicates that the SEH is placed between the worst and the intermediate case scenarios with respect to its environmental impacts. To better understand the final score of the SEH, the formula below is used to calculate the value of the Q index for the performance of the SEH in the interval from zero to 10, with zero being the Q value for the worst case scenario and 10 the Q value for the best case scenario:

$$Final\ Score\ of\ SEE = (1 - Q_{\mathrm{SEH}})\times 10 = (1 - 0.621)\times 10 = 3.8$$

Therefore, the score for the SEH is 3.8 out of the perfect score of 10.

Conclusion

The results from this study showed an elevated highway in this case Sadr’s Elevated Highway has significant negative impacts in ecological dimension, including air and noise pollution and energy-consuming parameters; this means regarding to creating sustainable structure for urban development, upgrading Sadr’s Highway to an elevated one is a failure action. Due to final score of VIKOR method in this paper, SEH is also a fail experiment; however, if any changes occur on the number of criteria, the result may have been different from this study result but 3.8 as a score between 0 and 10 is very low and completely beneath of middling scenario. Therefor this study is first step to consider this fact that elevated highways/expressways aren’t perfect alternative to respond to vehicle demands in urban transportation. There could be more investigations on this subject to find an answer is the truly time arrived for removing this structure from the urban face?

Towards an integrated urban design approach for a sustainable modal shift: Presenting insight from design practices

Maja Karoline Rosenkilde Rynning[1,]

[1] Laboratoire Matériaux et Durabilté des Constructions de Toulouse (LMDC), Institute des Sciences Appliquées de Toulouse (INSA Toulouse), University of Toulouse, Toulouse, France
maja.karoline.rynning@gmail.com

Abstract: Reducing greenhouse gas emissions from urban mobility are a major challenge for cities, in part because of its importance for everyday life. Promoting sustainable modes through neighbourhood design is an interesting strategy. However, uncertainties in the scientific evidence on neighbourhood-built environment and modal choices complicate its use in design practices. Disparities between research and practice further hinder knowledge-transfer. The experience-based knowledge of urban design professionals could be a source for new insights; preliminary investigations gave promising results. Further investigations included surveys and interviews in Norway and France. Survey-elements are presented here, compared in part to current scientific evidence. Results from these investigations, in combination with scientific literature, provide the basis for a framework for an integrated urban design approach. Linking modal choices to urban design qualities, it weaves together evidence-based and experience-based knowledge for a holistic approach; a step strengthening mitigating efforts upon urban mobility.

Keywords: Urban design, Modal choice, Experience-based knowledge, Urban mobility, Mitigation

Introduction

Urban mobility represents a multifaceted problem for cities. It is essential for a city to function (Ascher, 1995; UN Habitat, 2013), but produces greenhouse gas emissions (GHG-emissions) that leads to global warming and climate change (IPCC, 2014; New Climate Economy, 2014). Reducing mobility-related emissions (mitigation) calls for a variety of approaches, and for interdisciplinary collaborations. One strategy is to promote a sustainable modal shift towards zero- and low emission mobility modes[1] (New Climate Economy, 2014). An on-going doctoral thesis (Rynning, foreseen 2017) explores how to achieve such a modal shift through urban development at the neighbourhood scale (i.e. urban design), by combining experience-based knowledge (from practice) and evidence-based knowledge (from research).

There is a reciprocal relationship between the urban built environment and mobility behaviours (Næss, 2006). How a city is planned and designed influences how people move around in it, and vice versa. Consequently, integrated land-use and transport planning is an important mitigation strategy at the city scale (Tennøy, 2012). At the neighbourhood scale however, a similar approach appears less explored. One explanation is a significant knowledge-gap in literature regarding the neighbourhood-built environment and modal

[1] Per today these include primarily walking, cycling, and public transport (assuming it runs on low- or zero-emission fuels, and has a high level of occupancy) (New Climate Economy, 2014).

choices (Krizek et al., 2009; Næss, 2012); making it difficult to provide urban designers with concrete knowledge on how to promote sustainable mobility modes through urban development (Krizek et al., 2009). More insight is necessary, perhaps from exploring other sources. Furthermore, disparities between research and design-practice often complicate the use of scientific knowledge in development projects (Eliasson, 2000; Dubois, 2014). A reinforced dialogue between research and practice is needed in order to strengthen interdisciplinary co-operations and reciprocal knowledge-transfer (Rynning, 2016).

This paper explores the knowledge and experience of urban design practitioners for new insights into the reciprocal relationship between neighbourhood-built environment and modal choices. Preliminary investigations through a series of workshops implied that mobility has a central role in a development project (Rynning, 2016); integral to assure good living contexts for urban dwellers (ibid). To further explore, surveys and interviews were conducted with urban practitioners in France and in Norway. This article focuses on survey-findings, compared to previous findings and to relevant scientific evidence. These enquiries also provide an improved understanding of the methods and practices of urban design professionals; insights which can enhance reciprocal knowledge exchange research-practice – key to reinforcing adaptation and mitigation efforts through urban development (Eliasson, 2000; Tennøy, 2012; Dubois, 2014).

Theoretical framework: The built environment and mobility behaviour

Mobility behaviours are influenced by contexts (physical, built environment, social, cultural, economical, etc.), and by personal preferences and capacities (Næss, 2006; Krizek et al., 2009). It tends to be highly different from one person to another, though common traits can be found for segments of a population, for instance age-groups (children, elderly, etc.) (Bull and Bauman, 2007). Krizek and Forsyth (2009a) found presence of pedestrian infrastructure to be critical for elderly's decision to walk, while able-bodied adults relied less upon this. Similar tendencies were found regarding experienced and inexperienced cyclists and the presence of cycling infrastructure (ibid). Neighbourhood-built environment is particularly important for walking and cycling (Saelens and Handy, 2008; Krizek et al., 2009). By correlation, it influences transit use as well, as people mostly walk or cycle to and from transit stops (Mees, 2010). Several built environment elements have been found to influence modal use at the neighbourhood scale, for instance sidewalk width, number of intersections, and view-lines. (Alfonzo, 2005; Ewing et al., 2016). However, which factors influence the most remains unclear (Krizek et al., 2009). In part, because people's experience and perception of a built environment depends on context, physical as well as social and personal (Cho and Rodriguez, 2015). Based on these findings, a holistic strategy might be more beneficial, directing the focus towards the kinds of urban environments or scapes a combination of factors and elements create. One example are streetscapes – the space between buildings (Gehl, 2010; Ewing et al., 2016). Different built environments can be perceived as more or less welcoming for walking and cycling, thereby encouraging or discouraging their use (Stefansdottir, 2014). Three built environment-components have been identified as particularly influential upon modal choices: *Destination* (location of a trip's objective), *Availability* (if a mode is compatible with a trip), and *Annoyance* (barriers for using a particular modal choice). They are interdependent, and the built environment's influence on a modal choice is the sum of all three. Together they form a holistic framework, linking modal choices to urban environments, scapes, and to qualities. Such a framework can render scientific evidence more relatable and useable for urban design practitioners.

Urban qualities such as human scale, legibility, and connectivity, are often expressed by urban practitioners as particularly important for creating good, urban living contexts (Gehl, 2010; Rynning, 2016). Through the holistic framework, they can be linked to a potential influence upon modal choices as well. This can strengthen urban design as a strategy to promote a sustainable modal shift in order to curb mobility-related GHG-emissions.

Method: Interview and survey design

Studies have shown that workshops, interviews, and surveys are particularly interesting for exploring the experience-based, often tacit, knowledge of design professionals (Schön, 1983; Lawson, 1993; Skogheim, 2008; Dubois, 2014; Kirkeby, 2015). In the context of the doctoral thesis all three have been employed; the focus here in on the survey results. The workshops, a simulated design situation, served as a case study of urban design practices, and provided initial insights (Rynning, 2016). Through the survey, workshop observations regarding mobility in a design process were pursued in a more quantitative manner. It also enquired how practitioners relate urban qualities to modal choices, based on findings from the literature (see above). The targeted respondents were primarily professionals with an education within Architecture, Landscape Architecture, Urban Planning or Design. The survey was held in Norway and France, from November 2016 to January 2017, using SurveyMonkey. Respondents were recruited via social media forums for professionals, and through personal invitations. The analysis comprised both qualitative and quantitative methods. The questions were all close-ended, asking respondents to rate the influence of an element, or to what extent they agreed to statements (four grades, no neutral). A rating average was calculated with coefficients, e.g. 2 = strongly agree, 1 = agree, -1 = agree to some extent, -2 = disagree. The results are presented in the tables below, total rating average for Norway and France combined.

Results

A total of 112 practitioners commenced the survey and 71 (63,4%) completed it, of which 67 (59,8%) provided information about their practice. The majority of Norwegian respondents had 10-20 years of experience (15 of 31), none more than 30 years. Most of the French respondents had 0-5 years of experience (15 of 36), the rest were quite evenly spread between 5 to 30 years of experience. The respondents were also asked about educational background, for which several choices were possible, as this tends to vary for urban practitioners. Architecture (39 of 67) was the most common education, followed by Urbanism (26 of 67), Planning (17 of 67), and finally Landscape Architecture (10 of 67). A few had other backgrounds, for instance Sociology (2 of 67), Geography (2 of 67), or Engineering (2 of 67). The most common combination was Architecture and Urbanism (17 of 67).

Mobility in an urban design process

This part primarily tested the workshop observations. The vast majority of the respondents (101 of 109) consider the daily mobility of inhabitants in a project. Some only in the site analysis, but most implement measures and solutions directed towards daily mobility (25 versus 72 of 97). The survey asked what considering daily mobility in the site analysis contributes to (Table 1), likewise for the implementation of mobility solutions and measures (Table 2). Exploring elements that influence the choice of mobility solutions and measures, respondents were asked to choose the three most influential from a list of suggestions (Table 3).

Considering mobility in the site analysis contributes to (87 responses)	Analysis (19 resp)	Analysis+Solution/Measure (66 responses)
1. Link the project to the urban context	1,63	1,52
2. Understand the inhabitants' use of the neighbourhood	1,47	1,69
3. Identify challenges and issues beyond project description	1,37	1,37
4. Establish an idea, a concept	0,79	0,90

Table 1 What mobility in the site analysis contributes to, ranked score (min. -2, max. +2)

Implementing mobility solutions/measures in a project contributes to	
1. Facilitate walking and cycling	1,66
2. Facilitate the use of public transport	1,52
3. Link the project to the urban context	1,44
4. Introduce measures to reduce the inhabitants' use of cars	1,39
5. Structure/shape the neighbourhood	1,38
6. Create an identity to reinforce the inhabitants' sense of belonging to the neighbourhood	0,86
7. Establish an idea, a concept	0,73

Table 2 What implementing solutions/measures contributes to, ranked score (min. -2, max. +2)

Elements that influence choice of mobility solutions/measures (%)	
1. Existing and potential access to area (street network, access to public transport, active mobility infrastructure, etc.)	81,0
2. Existing structure, urban fabric and form	55,6
3. The program (mixed use, dwelling density, parking solutions, public space, etc.)	50,8
4. The physical context (local climate, vegetation, topography, etc.)	39,7
5. The client's objectives for daily mobility (facilitate public transport, reduce n° parking spaces, space for various modes, etc.)	33,3
6. Society's targets of reducing traffic volume growth	28,6
7. The economical, social, and cultural context	14,3

Table 3 What implementing solutions/measures contributes to, ranked score (min. -2, max. +2)

The survey confirmed that mobility has a central and structuring role in an urban design process, as was seen during the workshops. According to the respondents, in a site analysis mobility contributes to link a project to its urban context. It provides an understanding of both context and site, and a broader comprehension of the project. Implementing solutions and measures is understandably done to act upon mobility, but also aids the practitioner in establishing a relation between a neighbourhood and its urban context. Examples of this were observed in the workshops, where participants used pedestrian infrastructures to interrupt existing barriers (e.g. a large road) between a project site and its surroundings. Survey respondents further reported that mobility solutions and measures contribute directly to the design of a neighbourhood, for example its shape and structure. Similarly, in the workshops prioritising pedestrians had important influence upon the street network. Elements that influence choice of solutions and measures appear in line with the role accorded to mobility in a design process. Context, in a broad sense, influence choice of solutions and measures the most, in particular immediate and surrounding context (1., 2., 4., Table 3). This is in line with findings from literature. The influence of built environment elements on modal choice depends on urban and physical context. This also shows the importance of existing context for urban practitioners' design actions, especially mobility structures and systems. The program and the client's objectives are also reported as having some influence (3., 5., Table 3), indicating the importance of such constraints for promoting or limiting mobility modes through urban design. Finally, mobility solutions and measures were said to contribute somewhat to creating an identity for a neighbourhood. This might be related to the design of public places. In the workshops, good public places with a clear usage were said to encourage pedestrian activity within a neighbourhood, important to establish social cohesion through encounters among inhabitants. Vice versa, prioritizing pedestrian and cycling activity was a means to ensure good public space, illustrating thus the reciprocal relationship mobility/built environment design.

Built environment and modal choices

Respondents were asked to rate the influence of the urban qualities in Table 4 on the use of mobility modes. These are urban qualities often related to the quality of living contexts (Carmona, 2010; Gehl, 2010).

URBAN QUALITIES AND MODAL CHOICE (68 responses)	**Walking**	**Cycling**	**Public transport**
1. Connectivity - Connections between streets, pedestrian networks, etc. within and/or between several neighbourhoods	1,79	1,62	0,49
2. Legibility - How easily one can recognize and understand a neighbourhood, for instance to orient one-self	1,76	1,22	-0,01
3. Human scale - Dimension of built environments relative to human dimensions (e.g. street width, block size)	1,63	0,54	-0,62
4. Enclosure - To what extent buildings and other elements define and shape spaces	1,53	0,44	-0,57
5. Transparence – The possibility to see what goes on at the end of a street and past it, e.g. human activity or particular buildings	1,26	0,50	-0,71
6. Complexity - How a rich variety of buildings and other elements create a diverse visual impression	0,85	0,21	-0,97
7. Coherence – To what extent the built environment creates an overall impression, e.g. through shapes or facades	0,72	0,12	-1,03

Table 4 Survey results regarding urban qualities and modal choices

Connectivity was reported as most influential for both walking and cycling, and for the use of public transport. This is likely related to the link between connectivity and distance. Studies have found that actual and perceived distance is important for modal choice, especially walking and cycling (Krizek et al., 2009). A high level of Connectivity can reduce the distance to cover by breaking up urban blocks. This can also increase the range of route choices for a trip, allowing a person to adapt a trip to their modal needs, for instance choosing a pedestrian-friendly route. Connectivity is to some extent related to *Human scale*, as a high level of Connectivity tends to produce smaller blocks divided by streets and paths. However, Human scale was reported as little influential upon transit use, so it is possible the respondents relate it more to the perception of a pedestrian-friendly environment. Connectivity is a result of the structure and shape of a neighbourhood. These are elements that according to the respondents, implementing mobility solutions and measures can contribute to. Moreover, Connectivity can assure connections between neighbourhoods, also related to the consideration of mobility in a design process. This illustrates the reciprocal relationship between mobility-related actions and objectives in a design process, and the multifaceted role of mobility in a design process. *Legibility* was also reported as influential for all three mobility modes, although most importantly for walking (-0,01 for transit use indicates an approx. 50/50 split on level of influence). It is particularly important for orienting one-self in an environment, for instance via sight lines that allows a person to easily see further ahead (Lynch, 1960). Legibility is related to Transparence and Connectivity. The level of the latter can influence sight lines and the possibility to see what goes on beyond a street (Transparence), which can contribute to reducing the experience of distance (Gehl, 2010). Transparence in itself was given less influence on modal choice then Connectivity and Legibility. This could indicate that for practitioners, actual distance (Connectivity) is more important then perceived, and that Legibility influences modal choice in ways that could be further pursued. Finally, *Complexity* and *Coherence* were said to be somewhat influential for walking, a bit less for cycling, and not much for transit use. These urban qualities are most likely more important for visual experiences and perceptions of a built environment, then for physical aspects such as distances. That they are given a lower level of influence is therefore understandable, although they are not entirely un-influential. The relationship between these qualities and other aspects of a neighbourhood, such as quality of public places, is an interesting aspect for future analyses.

Discussion

Mobility is integral to city life (Ascher, 1995; Gehl, 2010). It is therefore not surprising that it holds an important position in an urban design process. The surveys, combined with the previous workshops, provided further insight to this. Mobility has a multifaceted function in a design process; it influences and is influenced by design actions. Considering mobility in a design process was related to the overall, physical design of a neighbourhood, and to creating perceptual characteristics. It also contributes to identifying issues beyond a project description. Schön (1983) refers to this as a practitioner identifying what a problem "really is", and finding a way to properly "frame it", displaying an understanding of urban development projects as societal problems (Rittel and Webber, 1973). Through a city's many interdependencies, projects are influenced by and influence aspects beyond their limits. This was equally seen in the workshops, where a reported lack of social cohesion was an important issue. Interestingly, encouraging walking within the site was seen as a contributing remedy to this. Thus underlining the multiple functions of mobility for the quality of a neighbourhood as a living context. During the workshops mobility appeared to be seen as a function to resolve, and simultaneously as a means to achieve/resolve other objectives and issues. The results from the survey seem to confirm this observation, providing an interesting aspect for further developing the holistic framework (see above).

The survey results indicate a holistic approach to mobility in an urban design process, in line with findings from literature and observations from the workshops. According to planning literature, an improved living context for urban inhabitants is a common, 'global objective' (Madanipour, 2006; Carmona, 2010; Gehl, 2010). This was seen in the workshops, where participants displayed a holistic approach to the project at hand (Dubois et al., 2016). Every action or solution for a particular issue was evaluated iteratively in light of its potential effect on the totality of the project. Illustrating an understanding of the interdependencies and connections between elements of the built environment. Furthermore, win-win solutions were often employed, to resolve or to achieve several issues/objectives at once. For example when establishing urban qualities expressed as important for creating "a neighbourhood feeling", but also for promoting walking: *porosity, transparency, visibility,* and *openness* (Rynning, 2016). The survey responses similarly showed that mobility solutions and measures are implemented to act upon mobility, and to advance the design of a neighbourhood.

Combining responses on the role of mobility in a design process with urban qualities said to matter for modal choices, might indicate the kind of qualities or scapes practitioners aim for when implementing mobility solutions and measures. Integrated in to the holistic framework in progress, this could further the understanding of the relationship between the built environment and modal choices. The respondents related the suggested urban qualities more to walking and cycling then to transit use. However, as explained previously, walking is a part of most transit trips, and so by correlation these qualities should have a certain influence on transit use as well. In the suggested framework, Destination represents the influence of the built environment at the end of a trip. If that built environment does not support or invite to walking, it can contribute to a person choosing to drive rather then public transport, despite a sufficient transit offer (Mees, 2010). Promoting sustainable mobility behaviours therefore requires a holistic take on a trip, from beginning to end. As practitioners have a holistic approach to urban design projects, there are evident profits from integrating evidence-based and experience-based knowledge. As an example, combining the empirical findings with scientific evidence can contribute to render the connection neighbourhood urban qualities/transit use more apparent for practitioners, making them more aware of the potential influence of their design actions. Together, this could help address the 'last mile'-issue, an important barrier for transit use (UN Habitat, 2013).

Conclusions and future perspectives

Through the results from the empirical enquires so far, the experience-based knowledge of urban design practitioners has provided interesting insights in to the relationship between the built environment and mobility behaviours; insights complementary to that of research. The findings emphasize the importance of a holistic approach to urban development, and to the mitigation of mobility-related emissions. The experience-based knowledge contributes to situate mobility within the totality of an urban development project, linking it to the overall goal of an improved living context. Thereby contributing to identifying more efficient solutions and measures for promoting sustainable mobility modes, and to bridge current knowledge-gaps. The findings also show that urban design can be a strategy towards a sustainable modal shift. Mobility is integral in a city's functioning, and thus integral in people's way of urban life. A sustainable modal shift therefore requires important changes on several levels. The built environment can contribute by facilitating the use of sustainable modes, while limiting GHG-emitting ones; urban design practitioners display knowledge on how to do so. As mobility has a central and structuring role in a project, adding mitigation as an additional objective seem quite possible. To further this, a framework for an integrated urban design and mobility approach is currently being developed, based on evidence-based knowledge from research and experience-based knowledge from practitioners. Moreover, the framework can reinforce the dialogue between research and practice by translating scientific evidence to urban design practices and vice versa, thereby strengthening a much-needed reciprocal knowledge-transfer.

Design to Thrive

Wellington- the role of transport in creating "the coolest little low-carbon capital"

Rehan Shaikh[1], Robert Vale[1] and Wajid Shaikh[2]

[1] School of Architecture, Victoria University of Wellington, Wellington, New Zealand.
[2] Quaid-e-Awam University of Engineering, Science & Technology, Nawabshah, Pakistan.

Abstract: Transportation is a basic need, but currently it is powered by fossil fuels which add CO_2 to the atmosphere. It will be difficult to achieve reduced CO_2 emissions in cities which rely on transportation systems fuelled by oil. What is required is a mobility system capable of delivering the required capacity and performance while based on zero-carbon energy resources. Transport is a key component of the low-carbon future envisaged by the Paris Climate Agreement. In New Zealand buildings are serviced largely by renewable electricity, whereas road transport produces more than 40% of total CO_2 emissions. The EU says that emissions need to fall by 80% by 2050 to meet the Paris target. If transport is to play a part in this, it means that transport emissions must also be reduced by at least 80% by 2050. Many transport ideas seem to focus on new technologies such as electric vehicles or self-driving cars, but transport is also a result of built environment choices and behaviour changes. How much difference could these apparently "non-transport" options make in developing workable transport for a low-carbon city?

Keywords: Low-carbon, transport behaviour, choices

Introduction

The Lonely Planet travel guide described Wellington, New Zealand as "the coolest little capital in the world" (New Zealand Herald, 2010). This paper describes the initial findings of research at Victoria University of Wellington into how transport in Wellington could change, in the light of the Paris Climate Agreement, to make it "the coolest little low-carbon capital". If possible for one city, these changes could be possible in many cities as the world seeks ways to move towards a more sustainable path. There is little point in having a city made up of sustainable buildings if they are not connected by sustainable transport. At a local level, Wellington City Council has proposed a transformation of the city to a "Low Carbon Capital" (WCC, 2016) and a key part of this transformation will need to come from the transport sector as this is such a large component of total emissions. Many transport ideas seem to focus on new technologies such as electric vehicles or self-driving cars, but transport is also a result of people's choices and behaviour. How much difference could these make in developing a low-carbon city?

Transport and emissions?

Transportation is a basic need and the history of transportation is as old as humanity. From the simple movement of humans emerged the demand for different modes of transportation not only for people but also for their goods. Increases in economic growth have enhanced the purchasing power of individuals and hence have led to increasing private vehicle ownership especially in urban areas (WEC, 2011, 12-14). Thus, it is estimated that private vehicle usage will be doubled by the year 2040 (ExxonMobil, 2013, 17).

No one can deny that economic prosperity is reliant on human mobility and freight transportation but the adverse effects of mobility services need serious attention, particularly in the light of the climate agreement concluded in Paris. The CoP21, United Nations Framework Convention on Climate Change (UNFCC), 21st session of the Conference of Parties was held in December 2015 in Paris, France. After lengthy deliberations, 196 countries (New Zealand is one of the signatories) successfully negotiated the Paris Climate Agreement with the global goal of holding temperature increase to below 2^0 C above pre-industrial levels, with parties agreeing to make efforts to keep it below 1.5^0 C (Climate Action, 2015). The situation is urgent, by 2015 the UK Meteorological Office reported that global average temperature would that year for the first time be already 1 degree Celsius above the pre-industrial figure (Met Office, 2015).

Transport without emissions?

The industrial revolution, which brought with it significant changes in modes of transport, first by water, then rail and finally the private car, has been powered by fossil fuels and as a result concentrations of CO_2 in the atmosphere have risen, forming a blanket around the planet, trapping heat reflected from the earth's surface. Mobility is an important part of living standards; it underpins a country's economy and is a substantial contributor to its GDP. On the other hand it will be difficult to achieve reduced CO_2 emissions in cities which rely on the continued use of transportation systems largely based on private vehicles fuelled by oil.

What is required is a system of mobility capable of delivering the required capacity and performance while based on zero-carbon energy resources and at the same time compatible with the desired lifestyle as well as being clean and affordable. Transport is a key component of the low-carbon future envisaged by the Paris Agreement. This is particularly true in New Zealand where dwellings are serviced largely by electricity sourced to a considerable extent from renewable hydroelectricity, whereas transport relies on oil. Indeed, road transport, fuelled by oil, provides the largest share of New Zealand's CO_2 emissions, more than 40 % of the total (MfE, 2013, 55). New Zealand's aim is to reduce its climate-related emissions to 50% below 1990 levels by 2050 (MfE, 2013, 62) but the European Union says that emissions need to fall by 80 - 95% by 2050 compared to 1990 levels to meet the Paris target (EC, 2016). If transport is to play a part in this, it means that transport emissions must also be reduced by at least 80% by 2050.

Can we do it with technology?
